The distribution of performance losses is shown in Fig. 16c as the mean annual frequency (MAF) of exceedance for the system serviceability index (SSI). SSI provides a global scalar measure of the system performance. It is defined as the ratio of the sum of the real power delivered from load buses after an earthquake to that before the earthquake. For each bus inside the substations, voltage ratio (VR) is defined as the ratio of the voltage magnitude in the seismically damaged network to the reference value for non-seismic, normal conditions. Figure 16b displays a contour map of the expected values of VR, averaged on the whole simulation for each demand node. It can be seen that the reduction in voltage due to induced damage is less than the tolerated threshold of 10 %, allowing the power demand delivery everywhere in the island.

Water Network of Thessaloniki, Greece (City Level)

A connectivity analysis is performed for the main water system (WSS) of Thessaloniki in Greece considering the interaction of electric power network (EPN) with pumping stations (Pitilakis et al. 2014b). If a pump serving a source node is not fed by the reference EPN node due to damage in EPN substation, then the pump itself is considered out of service and the relative WSS node is removed from the system. A probabilistic evaluation of the performance of networks is carried out by means of Monte Carlo simulation by sampling seismic events for five seismic zones with $M_{\min} = 5.5$ and $M_{\max} = 7.5$. Pipeline damage is evaluated for each simulation considering both wave propagation and ground failure due to liquefaction. The network is analyzed for each sampled event and the results are aggregated all over the sampled events, in order to numerically obtain the marginal distribution of performance losses (Fig. 17). The interaction can be important; as an example the water connectivity loss is increased from 1 to 1.8 % for $\lambda = 0.001$ (corresponding to mean return period $T = 1,000$ years) when the connections of water pumping stations to EPN are included in the analysis.

Figure 18 shows the level of correlation between the water connectivity loss and damages in pipes as well as the nonfunctional EPN

Seismic Vulnerability Assessment: Lifelines, Fig. 18 Correlation of damaged pipes and nonfunctional EPN transmission stations to water network connectivity

Seismic Vulnerability Assessment: Lifelines,

Fig. 19 Mean annual frequency (λ) curve for road network connectivity loss with and without interaction with collapsed buildings

substations supplying the water pumping stations. The most correlated pipes are concentrated along the coastline where liquefaction susceptibility is high and therefore damages due to permanent ground displacement are expected. A higher level of correlation is obtained for the EPN transmission substations. The highest value of 80 % is attributed to a component in the south-east part of the city, where several pumping stations (connected to EPN) are located.

Road Network of Thessaloniki, Greece (City Level)
The main network of the urban area is considered in this case study, together with the ring road and the main exits of the city where the majority of bridges and overpasses are located. In particular, 594 nodes and 674 edges are included in the simulation. The nodes are subdivided into 15 external nodes, 127 traffic analysis zone (TAZ) centroids, and 452 simple intersections. Edges are assumed to be the only vulnerable components in the network. They are classified into road pavements and bridges, with fragility models expressed in terms of permanent ground deformation (PGD) due to liquefaction and peak ground acceleration (PGA) for ground shaking, respectively (Pitilakis et al. 2014b).

Road closures are estimated due to soil liquefaction and bridge damages. Moreover, the interaction with collapsed buildings that can induce road blockages is considered (Pitilakis et al. 2014b). A probabilistic evaluation of the network's performance is carried similarly to the one described in the previous example.

The interaction with building collapses can be important especially for return periods higher than 500 years ($\lambda = 0.002$). As an example the connectivity loss is increased from 20 % to 33 % for $\lambda = 0.001$ ($T = 1,000$ years) when the building collapses are included in the analysis (Fig. 19). Figures 20 and 21 show the level of correlation between the connectivity loss and the distribution of blockages due to building collapses and damage in bridges and road pavements, respectively. Relatively higher correlation factors are found for edges blocked by building collapse, demonstrating the importance of this failure mechanism in the analysis. A few road segments near the coastline which are subjected to ground failure due to liquefaction are also highly correlated to the network connectivity. The high risk of failure for bridges is attributed to their typology characteristics (old, simple span bridges) and the high values of PGA.

Seismic Vulnerability Assessment: Lifelines, Fig. 20 Correlation of edges blocked by buildings' collapse to road network connectivity

Port System of Thessaloniki, Greece (Infrastructure Level)

The port covers an area of 1,550,000 m² and trades approximately 16,000,000 t of cargo annually, having a capacity of 370,000 containers and six piers with 6,500 m length. In this case study, waterfront structures, cargo handling equipment, power supply system, roadway system, and buildings are examined. In particular, waterfront structures of a total 6.5 km length, 48 crane nodes, and two terminals (one container and one bulk cargo) are considered. The interactions accounted for in the analysis are the supply of EPN to cranes and the road closures due to building collapses. A probabilistic evaluation of the performance of networks is carried out by means of Monte Carlo simulation by sampling seismic events for five seismic zones affecting the city of Thessaloniki and the harbor with $M_{\min} = 5.5$ and

$M_{\max} = 7.5$. The performance of the port is described through the total cargo or containers handled in a predefined time frame per terminal and for the whole port system (Pitilakis et al. 2014b).

Figures 22 and 23 show the level of correlation between the total cargo handled per day (TCaH) and the distribution of damages in cranes and non-functionality of electric power distribution substations, respectively. In this way the most critical components can be defined in relation with their contribution to the performance loss of the system. All cranes have medium (40–70 %) to high (over 70 %) levels of correlation, indicating their great importance to the functionality of the overall port system. A higher level of correlation is estimated for the EPN distribution substations, with 40 % of the components having values greater than 70 %.

Summary

Lifelines are spatially distributed systems that provide essential services to any modern society. They play also an important role for emergency response and restoration in the aftermath of disastrous earthquakes; in general they are vital for the resilience of society. They are often grouped to transportation and utility systems and comprise multiple components, which are exposed to different ground shaking effects and geotechnical hazards. Research efforts and studies undertaken the last 20 years, and after numerous devastating earthquakes that caused extensive losses and disruptions to lifelines and infrastructures, contributed to important improvement of knowledge and expertise in the seismic vulnerability and risk assessment of lifelines. The main objective of these efforts has been the development of methodologies and tools for the estimation of probable direct and indirect losses (physical, performance, economic, social) due to future earthquakes in order to develop efficient emergency response and mitigation strategies. A general layout for the seismic risk assessment of lifelines is outlined in Fig. 24. Inventory and taxonomy/typology definitions of all elements at risk and systems are the necessary initial steps to describe the elements and networks exposed to seismic risk. The estimation of site-specific seismic ground motion and other geotechnical hazards and the selection–estimation of appropriate seismic intensity measures (IM) is the basis of the seismic hazard analysis. Vulnerability is the expected response of an element or a network to a given seismic intensity. It is commonly assessed based on fragility models, which estimate the probability of exceeding certain damage states for given seismic intensity. Fragility functions are adapted with respect to the typological characteristics of each element at risk. The expected damage and loss of the entire network are estimated through appropriate systemic analysis, which takes into account the physical damage and the relations and interactions between the different components and systems. The interdependencies among different systems may considerably increase the overall impact. The results, which are commonly

provided in terms of performance indicators that describe the network functional losses or the expected economic or socioeconomic losses, provide the means for an efficient mitigation or recovery planning. Obviously, several sources of uncertainties are inherent in the various definitions, models, tools, and methods for estimation of losses, which make the risk assessment of lifelines a complex and challenging topic.

Seismic Vulnerability Assessment: Masonry Structures

Dina D'Ayala and Viviana Novelli
Department of Civil, Environmental and
Geomatic Engineering, University College
London, London, UK

Introduction

The assessment of the vulnerability of the building stock of an urban center is an essential prerequisite to its seismic risk assessment. The other two ingredients are the expected hazard over given return periods and the distribution and values of the assets constituting the building stock. All three elements of the seismic risk assessment are affected by uncertainties of aleatory nature, related to the spatial variability of the parameters involved in the assessment, and epistemic nature, related to the limited capacity of the models used to capture all aspects of the seismic behavior of buildings and to describe them in simple terms, suitable for this type of analysis. Hence it should always be kept in mind that the computation of a risk level is highly probabilistic and that to accurately represent the risk, the expected values should always be accompanied by a measure of the associated dispersion. A very preliminary estimate of the seismic capacity of the local building stock can be obtained by consulting requirements included in seismic standards and code of practices in force at the time of construction of such buildings. This information together with a temporal and spatial record of the growth of the urban center can provide a definition of classes of buildings assumed to have different capacities. This information can be obtained by looking at past and present cadastral maps with ages of buildings and knowing the historical development and enforcement of codes at the site. In general however for a correct assessment of the seismic risk, a more detailed inventory and classification should be considered, the extent of which is a function of the economic and

technical resources available and of the dimensions and building density of the area under investigation, as well as the diversity within the building stock.

Seismic vulnerability analysis of masonry structures has traditionally been carried out using “empirical” (or statistical) methods. These can be divided in categorization methods, which classify buildings into typologies characterized by propensity to damage, or inspection and rating methods, wherein scores are attributed to each significant characteristic of the buildings thought to have a bearing on its overall vulnerability (UNDP/UNIDO 1985). Several of these methods have been developed in the past 30 years, and the more robust and commonly used are reviewed in section “[Empirical Methods](#).”

Recent dramatic increase in computational powers and consequent improvement and refinement in numerical modelling of relatively complex structures, using either static or dynamic approaches (e.g., Fajfar and Gašperšič 1996; Vamvatsikos and Cornell 2005), has facilitated greater exploitation of analytical approaches for vulnerability assessment purposes. Analytical methods need experimental validation of the various parameters used to define the vulnerability, and so far relatively little experimental work on the behavior of masonry structures has been undertaken by the international community, albeit a wide variety of existing unreinforced masonry typologies, both historic and modern, exists. The framework within which analytical methods can be applied and their limitation are presented in section “[Analytical Methods](#).”

An attempt to exploit positive aspects of the two classes of methods above is made with the so-called hybrid methods. These combine numerical input/output from analytical models with statistical and probabilistic data to define exposure and vulnerability distribution. This allows to reduce the analytical burden while grounding results in a geographical context. Applicability and reliability of such approaches are constrained by the ability to define certain mechanical and structural characteristics in numerical terms and by the need to define a common approach for treating the various sources of uncertainty

associated with vulnerability, exposure, and hazard. This is further discussed in section “[Hybrid Methods](#).”

The review and discussion of existing methods sets out the rationale for a combined method, called FaMIVE (Failure Mechanism Identification and Vulnerability Evaluation), and developed by the first author and her co-researchers, in the past decade. The hypotheses and analytical approach to derive capacity curves and fragility functions are presented in detail in section “[Development of Analytical Methods: FaMIVE](#).” Results obtained from the FaMIVE method are presented in section “[Damage Thresholds and Performance Indicators](#)” in terms of damage limit states and drift and compared with the recommendation of Eurocode 8 (EC8) (CEN 2005) and experimental evidence to discuss issues of validation and calibration.

Vulnerability Approaches

Empirical Methods

The damage probability matrix (DPM) method has been the most common vulnerability assessment method used since the 1970s. Based on field observations, it expresses in a discrete form the conditional probability of obtaining a damage level D_j , due to a ground motion of macro intensity I_i ,

$$P = \left[D = \frac{D_j}{I_i} \right].$$

The method relies on the wealth of observed damage data available from past earthquakes and the correlation of these, on the one hand, with assigned shaking macroseismic intensity at the site of observation and, on the other, with construction materials and methods in different geographical and seismic regions. First proposed by Whitman et al. (1973) after the San Fernando earthquake of 1971, specific applications of this method to masonry structures are numerous (Braga et al. 1982; Corsanego and Petrini 1990; Di Pasquale et al. 2005) and still widely used in developing countries and regions with extensive

historic seismicity records (Askan and Yucemen 2010; Zobin et al. 2010). Notwithstanding its popularity, the DPM has major limitations: discrete definition of damage levels/states and dependence on a specific seismic and architectural context. Hence, it may not be applicable to different geographic locations, in the absence of direct damage data.

Some of these limitations are overcome by the Vulnerability Index Method (VIM) (Benedetti et al. 1988), based on the vulnerability index I_v . The vulnerability index is a summation of weighted parameters, each associated with a constructional or structural feature of the typology, which affects its vulnerability. In this way the definition of vulnerability relates only to the mechanical characteristics of the building, while damage data from past earthquakes are used to calibrate the vulnerability functions, by relating I_v to observed global damage levels for buildings of the same typology and hence extending applicability in regions having experienced the same level of macroseismic intensity or peak ground acceleration (PGA).

The most substantial improvement of the VIM over the DPM is that the former provides a continuous vulnerability function, while the latter uses discrete vulnerability classes expressed in terms of expected damage. This means that possible interventions to shift the vulnerability level of a structural typology are readily quantifiable with I_v , while they are only recorded in the DPM if the intervention results in a shift of damage class. Moreover, the correlation of VIM with an instrumental measure of seismic action allows for application to and comparison between different seismic zones, even though in the last decade the reliability of correlating PGA and damage has been put into question by various authors (Elenas 2000; Wu et al. 2003). Giovinazzi and Lagomarsino (2004) have proposed a direct correlation of the two methods by introducing a definition of damage states and DPM as function of the I_v using the definition of the EMS-98 macroseismic scale (Grünthal 1998). This approach has been further developed in the European RISK-UE project for larger number of building typologies and vulnerability classes (Lagomarsino and Giovinazzi 2006).

The EMS-98 scale (Grünthal 1998) is in itself a DPM approach, where vulnerability classes are defined across different construction typologies. The uncertainty inherent in the attribution of a typology to a class and of its response to a seismic event in terms of damage level is dealt with by assuming a central value and a fuzzy set membership, so that both vulnerability and damage can be expressed in descriptive (few, many, most) rather than numerical terms. A method to compute total probability of damage of a given typology spreading over more vulnerability classes is proposed in Jaiswal et al. (2011).

A first attempt at deriving generic fragility curves was made by Spence et al. (1992) with the Parameterless Scale Intensity (PSI), aimed at providing fragility curves for different building typologies and at quantifying benefits from upgrading and strengthening interventions of the building stock. The advantage of this approach is that damage grades and fragility curves are independent of macroseismic intensity scales, as they are defined relative to each other, on the assumption that for each building type, it is possible to define the level of the scale corresponding to the median of the fragility curve for level of damage D3 (structural damage). Limitations of applicability are however related to the extensive need for observations to calibrate each fragility curve and to the difficulty to correlate observed or expected damage into construction and structural characteristics in a deterministic way.

Analytical Methods

Analytical methods present the advantage of framing the problem of seismic vulnerability of masonry structures in structural engineering terms, defining a direct relationship among construction characteristics, structural response to seismic action, and damage effects.

The development of attenuation equations for specific seismic regions and corresponding derivation of seismic hazard maps in terms of spectral ordinates, as opposed to macroseismic intensity or PGA, has given impetus to the development of analytical methods. These methods tend to feature more detailed and transparent

vulnerability assessment algorithms with direct physical meaning. In the development of analytical fragility functions for masonry structures, two methods can be identified: (i) correlation between damage index and damage thresholds and (ii) correlation between acceleration/displacement capacity curves and spectral demand curves, following the HAZUS99 (FEMA 2001) or N2 method (Fajfar and Gašperšič 1996). These two procedures, in line with the performance-based design for new built, define the seismic assessment of existing building stock and prediction of losses. The required analysis steps are (i) classification of buildings by typology and seismic design, (ii) definition of damage states, (iii) assignment of capacity curves, (iv) definition of demand spectra (associated with return periods and performance targets), and (v) evaluation of building response in terms of performance points. The two procedures, applied to large sets of buildings, allow to derive fragility curves and damage scenarios for given sites and as a function of ground motion parameters which are linked with hazard levels. The damage levels are directly related to the demand parameter, which is expressed in terms of displacement or drift. As the fragility curves are developed on the basis of lognormal distribution, once the typologies have been defined, it is not necessary to have a detailed knowledge of the building stock. All required are the parameters defining the capacity curve for each typology, various damage thresholds, and the number of buildings belonging to each typology. Once capacity curves are developed, then the range of behavior and variability of fragility within a building class or stock can be analyzed by parametric analysis, providing important insight for retrofitting (see D'Ayala 2005). Analytical approaches to define seismic vulnerability of masonry buildings are becoming more and more popular, as improved engineering knowledge on the behavior of masonry structures increases confidence on the reliability of such models. In the past decade, a relatively significant number of procedures aimed at defining reliable analytical vulnerability functions for masonry structures in urban context have been proposed (Lang and Bachmann 2004; Erberik 2008; Borzi

et al. 2008). Although they share similar conceptual hypotheses, they differ substantially in modelling/numerical complexity and treatment of uncertainties. Two main limitations are common to all: limited geographic applicability and limited number of failure mechanisms. Specifically, for the latter, most of the analytical models only consider in-plane or frame-like behavior, disregarding overturning and out-of-plane mechanisms, often occurring at lower levels of shaking and hence substantially affecting the seismic vulnerability in an urban context. Analytical vulnerability assessment methods for existing masonry buildings feature in many risk assessment integrated systems; however, their choices of capacity curves are predetermined. Among nonlinear analysis methods, the collapse-mechanism or limit-equilibrium method presents the advantage of requiring few input parameters and allowing consideration of different failure modes. Procedures using this approach are based on collapse load multipliers which identify the occurrence of different possible mechanisms for given typology and structural characteristics. Bernardini et al. (1990) developed a numerical routine (VULNUS), combined with a fuzzy set theory, in recognition of the limited knowledge associated with many of the parameters. Only one in-plane and one simple out-of-plane mechanism were initially considered as possible failures. D'Ayala and Speranza (2003) further enhanced this approach by developing the FaMIVE method, a mechanical approach based on a suite of 12 possible failure mechanisms directly correlated with in situ observed damage. The FaMIVE algorithm produces vulnerability functions for different building typologies and quantifies the effect of strengthening and repair intervention on reduction of vulnerability. The method has been applied in several locations worldwide and recently in Abruzzo, Italy, following the 2009 L'Aquila earthquake (D'Ayala and Paganoni 2011).

Hybrid Methods

Hybrid methods combine post-earthquake damage statistics with analytically derived nonlinear behavior using pushover analysis (e.g., Kappos et al. 1998; Barbat et al. 1996). Recently, Kappos

et al. (2008) have applied it for estimating direct losses for masonry buildings in Thessaloniki (Greece). This procedure is very useful when the damage data collection of an area of interest with a specific intensity is only partially available. However, the use of different data sources derived from different procedures, for which a direct cross-correlation is not readily available, might not necessarily result in reduced uncertainty of the output.

An application of this approach to masonry structure within the Risk-UE project shows the importance of knowledge of the building stock for reliable seismic vulnerability assessment, as increased level of uncertainties is compounded both on capacity and demand curves (Lagomarsino and Giovinazzi 2006). Application made using code prescription in terms of capacity curves provides a good first approximation but needs extensive in situ calibration as shown by Erberick (2008).

A summary of the methods reviewed above is presented in Table 1. While this is by no means an exhaustive list of the many applications of seismic vulnerability assessment for masonry structures available in literature, it concentrates on procedures that have been specifically developed for vulnerability assessment at territorial scale. For this reason procedures aimed at the assessment of single buildings are not included. The choice of the most suitable procedure is highly dependent on the resources available for the data collection, the computational expertise available, and ultimately the scale and aim of the study. Empirical procedures can be used for fairly large-scale studies to define damage scenarios; however, if the purpose of the study is to identify within a district or urban center specific buildings in need of strengthening, so as to increase their seismic capacity, then a suitable analytical procedure should be preferred.

performed with the Failure Mechanisms Identification and Vulnerability Evaluation (FaMIVE) analytical method (D'Ayala and Speranza 2003; D'Ayala 2005). The FaMIVE method uses a nonlinear pseudo-static structural analysis with a degrading pushover curve to estimate the performance points by way of a variant of the N2 method (Fajfar and Gašperšič 1996), included in EC8 part 3 (CEN 2005). It yields as output collapse load multipliers which identify the occurrence of possible different mechanisms for a given masonry construction typology, given certain structural characteristics.

It is based on computing the collapse load factor for 12 different failure modes, shown in Fig. 1. Each mode of failure corresponds to different constraints and conditions between the façade and the rest of the structure; hence a collapse mechanism can be univocally defined and its collapse load factor computed for each mechanism developing

over either part or the whole façade. As shown in the flowchart of Fig. 2, the program FaMIVE first calculates the collapse load factor for each façade in a building and then, taking into account geometric and structural characteristics and constraints, identifies the one which is most likely to occur considering the combination of the largest portion mobilized with the lowest collapse load factor at building level.

The FaMIVE algorithm produces vulnerability functions in terms of ultimate lateral capacity for different building typologies and quantifies the effect of strengthening and repair intervention on reduction of vulnerability. In its current version, it also computes capacity curves and performance points and outputs fragility curves for different seismic scenarios in terms of intermediate and ultimate displacements or ultimate acceleration. Within the FaMIVE database, capacity curves and fragility functions are available for

Seismic Vulnerability Assessment: Masonry Structures, Fig. 2 Flowchart setting out the rationale of the FaMIVE procedure

various unreinforced masonry typologies, from adobe to concrete blocks, for a number of reference typologies studied at sites in Italy, Spain, Slovenia, Turkey, Nepal, India, Iran, and Iraq. The procedure has been validated against the EMS-98 vulnerability classes and recently used to produce capacity curves and fragility curves for use in the USGS PAGER environment. The mechanism's characteristics are used to derive an equivalent nonlinear single degree-of-freedom capacity curve to be compared to a spectrum demand curve and eventually define performance points as illustrated in the flow-chart in Fig. 2.

In order to derive fragility curves, limit state performance criteria correlated to damage states need to be defined. This step is fraught with uncertainties, as very limited consolidated evidence exists to perform such correlation over a wide range of building typologies and shaking levels. While robust database of damage states exist in literature, no attempt has been so far made to record permanent drift and corresponding ground shaking in a consistent way so as to provide empirical evidence for capacity curves. As an alternative, a number of authors have worked on correlating performance indicators and damage indicators on experimentally obtained capacity curves, by way of shaking table tests or pushover tests.

Definition of Capacity Curve

Capacity curves can be derived for each façade on the basis of the following steps. The first step is to calculate the lateral effective stiffness for each wall and its tributary mass. As the floor and roof structures in traditional masonry buildings have relatively modest in-plane stiffness, it is assumed that redistribution of inertia forces among walls will be ineffective and torsional effects are not considered. The effective stiffness of each external wall is calculated on the basis of the type of mechanism attained, the geometry of the wall and layout of opening, the constraints to other walls and floors, and the portion of other walls involved in the mechanism:

$$K_{\text{eff}} = k_1 \frac{E_t I_{\text{eff}}}{H_{\text{eff}}^3} + k_2 \frac{E_t A_{\text{eff}}}{H_{\text{eff}}} \quad (1)$$

where H_{eff} is the height of the portion involved in the mechanism; E_t is the estimated modulus of the masonry as it can be obtained from experimental literature for different masonry typologies; I_{eff} and A_{eff} are the second moment of area and the cross-sectional area, respectively, calculated taking into account extent and position of openings and variation of thickness over height; and k_1 and k_2 are constants which can assume values equal or greater than 0, depending on edge constraints and whether shear and/or flexural stiffness are relevant for the specific mechanism. For instance, for in-plane mechanisms, the inclusion of shear stiffness in Eq. 1 will depend on the slenderness of the pier and the relative stiffness between piers and spandrels of the façade being assessed.

The tributary mass Ω_{eff} is calculated following the same approach, and it includes the portion of the elevation activated by the mechanisms plus the mass of the horizontal structures involved in the mechanism:

$$\Omega_{\text{eff}} = V_{\text{eff}} \delta_m + \Omega_f + \Omega_r \quad (2)$$

where V_{eff} is the solid volume of the portion of wall involved in the mechanism, δ_m is the density of the masonry Ω_f , Ω_r are the masses of the horizontal structures involved in the mechanism. Effective mass and effective stiffness are used to calculate a natural period T_{eff} , which characterizes an equivalent single degree-of-freedom (SDoF) oscillator:

$$T_{\text{eff}} = 2\pi \sqrt{\frac{\Omega_{\text{eff}}}{K_{\text{eff}}}} \quad (3)$$

The mass is applied at the height of the center of gravity of the collapsing portion with respect to the ground, and a linear acceleration distribution over the wall height is assumed. The elastic limit acceleration S_{ay} is also computed depending on the failure mechanism identified; for failure

mechanisms involving flexural strain limit (assuming no tensile capacity in the material), for instance, S_{ay} will be the value of lateral acceleration that, combined with gravitational load resultant, will cause a triangular distribution of compression stresses at the base of the overturning portion, just before the onset of cracking:

$$\begin{aligned} S_{ay} &= \frac{t_b}{6h_0} g \text{ with corresponding displacement} \\ S_{de} &= \frac{S_{ay}}{4\pi^2} T_{\text{eff}}^2 \end{aligned} \quad (4)$$

where t_b is the effective thickness of the wall at the base of the overturning portion, h_0 is the height to the ground of the center of mass of the overturning portion, and T_{eff} is the natural period of the equivalent single degree-of-freedom (SDoF) oscillator. The maximum lateral capacity S_{au} is defined as

$$S_{au} = \frac{\lambda_c}{\alpha_1} g \quad (5)$$

where λ_c is the collapse load factor of the mechanism chosen, calculated by FaMIVE, and α_1 is the proportion of total mass participating to the mechanism. This is calculated as the ratio of the mass of the façade and sides or internal walls and floor involved in the mechanism Ω_{eff} to the total mass of the involved macroelements (walls, portion of floors, and portion of roof supported by the wall). The displacement corresponding to the damage threshold of structural damage, S_{ds} is

$$3S_{dy} \leq S_{ds} \leq 6S_{dy} \quad (6)$$

as suggested by (Tomazevic 2007). The range in Eq. 6 is useful to characterize masonry fabric of diverse levels of regularity and its integrity at ultimate conditions, with the lower bound better describing the behavior of adobe, rubblestone,

and brickwork in mud mortar, while the upper bound can be used for massive stone, brickwork set in lime or cement mortar, and concrete blockwork. The near collapse condition is determined by the displacement S_{du} identified by the condition of loss of vertical equilibrium which, for overturning mechanisms, can be computed as a lateral displacement at the top or for in-plane mechanism by the loss of overlap of two units in successive courses as quantifiable with one of the two alternative expressions in Eq. 7:

$$S_{du} \geq t_b/3 \quad \text{or} \quad S_{du} \geq l_u/2 \quad (7)$$

where t_b is the thickness at the base of the overturning portion and l_u is the typical length of units forming the wall. In the case of in-plane mechanism, the geometric parameter used for the elastic limit is, rather than the wall thickness, the width of the slender pier.

The threshold points identified by Eqs. 4, 5, 6, and 7 can be associated to corresponding states of damage. Specifically **DL**, *damage limitation*, corresponds to the elastic lateral capacity threshold (S_{de} , S_{ay}) defined by Eq. 4; **SD**, *significant damage*, corresponds to the peak capacity threshold (S_{ds} , S_{au}) defined by Eqs. 5 and 6; and **NC**, *near collapse*, corresponds to incipient or partial collapse threshold (S_{du} , S_{au}) defined by either conditions of Eq. 7.

The procedure's approach allows a direct analysis of the influence of different parameters on the resulting capacity curves, whether these are geometrical, mechanical, or structural. By way of example, Figs. 3 and 4 show a comparison of average capacity curves obtained by grouping the results using different criteria for the same sample of buildings in L'Aquila. In Fig. 3 the average curves represent the behavior according to the classes of mechanisms as per Fig. 1. In Fig. 4 the capacity curves are obtained by considering different structural typologies, as classified by the WHE-PAGER project (Jaiswal et al. 2011) and shown in Table 2. It can be seen

Seismic Vulnerability Assessment: Masonry Structures,

Fig. 3 Average capacity curves for sample grouped by collapse-mechanism classes

Seismic Vulnerability Assessment: Masonry Structures,

Fig. 4 Average capacity curves for sample grouped by structural typology

that the correlation between mode of failure and structural typology is qualitatively good but not univocal, and the grouping affects both ultimate lateral capacity and drift at all damage states.

Such results bring in sharper focus the limitation and inaccuracy of using idealized models and average curves without adequately considering the inherent aleatoric variation associated with any given site where the assessment is conducted and the importance of a detailed knowledge of the local construction characteristics when sampling the building representative of

the building stock. The lack of such knowledge determines a non-negligible epistemic error.

In Figs. 3 and 4 the capacity curves show a fourth point, which represents the collapse of the façade corresponding to a lateral displacement S_{dc} and a lateral acceleration S_{ac} as computed in Eq. 8:

$$S_{dc} \geq t_b/2 \text{ or } S_{dc} \geq l_u, \quad S_{ac} = \frac{S_{au}}{2} \quad (8)$$

Such relationship are estimated on the basis of experimental work available in literature.

Seismic Vulnerability Assessment: Masonry Structures, Table 2 Structural typologies classification according to PAGER (Jaiswal et al. 2011)

Load-bearing material	PAGER code	Description
Stone masonry	RS3	Local fieldstones with lime mortar
	RS4	Local field stones with cement mortar, vaulted brick roof, and floors
	DS2	Rectangular cut stone masonry block with lime mortar
	DS3	Rectangular cut stone masonry block with cement mortar
	DS4	Rectangular cut stone masonry block with reinforced concrete floors and roof
	MS	Massive stone masonry in lime or cement mortar
Brickwork or blockwork	UFB1	Unreinforced brick masonry in mud mortar without timber posts
	UFB3	Unreinforced brick masonry in lime mortar. Timber flooring
	UFB4	Unreinforced fired brick masonry, cement mortar. Timber flooring
	UFB5	Unreinforced fired brick masonry, cement mortar, but with reinforced concrete floor and roof slabs
	UCB	Unreinforced concrete block masonry with lime or cement mortar

Damage Thresholds and Performance Indicators

In the previous section capacity curves have been determined as polylines characterized by four notable points which represent as many damage thresholds. A method for assessing the overall behavior by use of a global performance indicator is the computation of the performance point. In order to calculate the performance point, it is necessary to intersect the capacity

curve derived above with the demand spectra for different return periods in relation to the performance criteria considered. Two broadly equivalent approaches for the derivation of the nonlinear demand spectra exist: the N2 method (Fajfar 1999) included in the EC8 and the capacity spectrum method (CSP) (FEMA 2001). The two methods differ essentially in the way the nonlinear demand spectrum is arrived at: the N2 method uses a reduction factor R , function of the structure expected ductility μ , while the CSP uses a fictitious damping factor derived from the hysteresis loop of the structure. In the following the N2 method will be used to illustrate the derivation of performance points.

The original version of the N2 method was derived for elastic-perfectly plastic SDoF oscillator, and the relationship between the reduction factor R and the ductility μ , used to determine the nonlinear response spectrum, is dependent on the bilinear shape of the capacity curve. Alternative relationships between the reduction factor, the ductility, and the natural period of the system, R - μ - T , have been developed to determine the inelastic displacement ratios and the inelastic response spectra for structures characterized by quadri-linear backbone curves, characterized by a plateau of reduced capacity and further ductility, after a negative slope branch (see Miranda 2001; Dolsek and Fajfar 2004; Vamvatsikos and Cornell 2005).

In the case of the capacity curves derived with the FaMIVE procedure however, as mentioned above, the behavior beyond the near collapse performance point is fraught with uncertainty and hence the descending branch of the curve is ignored, and the simplified relationship for bilinear curves is used.

To calculate the coordinates of the performance point in the displacement-acceleration space, the intersection of the capacity curve with the nonlinear demand spectrum for an appropriate level of ductility μ can be determined as shown in Eq. 8, given the value of ultimate lateral capacity of the equivalent SDoF oscillator, S_{au} :

$$\begin{aligned}
& \text{if } T^* < T_c \\
& \text{if } S_{au} \geq S_a(T^*) \Rightarrow S_d^*(\mu) = \frac{T_c^2(S_{ae}(T^*) - S_a(T^*))^2}{(\mu - 1)^2} * \frac{g\mu}{4\pi^2 S_a(T^*)} \\
& \text{if } S_a(T_c) < S_{au} < S_a(T^*) \Rightarrow S_d^*(\mu) = \frac{T_c^2(S_{ae}(T^*) - S_{au})^2}{(\mu - 1)^2} * \frac{g\mu}{4\pi^2 S_{au}} \\
& \text{if } S_{au} \leq S_a(T_c) \Rightarrow S_d^*(\mu) = \frac{gT_c^2(S_{ae}(T^*))^2}{4\pi^2 \mu S_{au}} \\
& \text{if } T^* \geq T_c \\
& \text{if } S_{au} \geq S_a(T^*) \Rightarrow S_d^*(\mu) = \frac{gT_c^2(S_{ae}(T^*))^2}{4\pi^2 \mu S_a(T^*)} \\
& \text{if } S_{au} < S_a(T^*) \Rightarrow S_d^*(\mu) = \frac{gT_c^2(S_{ae}(T^*))^2}{4\pi^2 \mu S_{au}}
\end{aligned} \tag{9}$$

where two different formulations are provided for values of ultimate lateral capacity S_{au} greater or smaller than the nonlinear spectral acceleration $S_a(T_c)$ associated with the corner period T_c marking the transition from constant acceleration to constant velocity section of the parent elastic spectrum. Figure 5 shows an example of calculation of performance points for median capacity curves for some different types of mechanisms (see Fig. 1).

Derivation of Fragility Functions

Once capacity curves and limit state points are identified on them, fragility curves for different limit states are obtained by computing the median and standard deviation values of the performance point displacements for each index building in a given set of buildings surveyed on-site or created through randomization of the input parameters. The median and standard deviation are used to derive equivalent lognormal distributions. To this end the median displacement for each limit state can be calculated as:

$$\hat{S}_{ds_i} = e^{\bar{\mu}_i} \text{ with } \bar{\mu}_i = \frac{1}{n} \sum_{j=1}^n \ln S_{ds_i}^j \tag{10}$$

and the corresponding standard deviation as:

$$\begin{aligned}
\beta_{ds_i} &= e^{\bar{\mu}_i + \frac{1}{2}\sigma_i^2} \sqrt{e^{\sigma_i^2} - 1} \text{ with } \sigma_i \\
&= \sqrt{\frac{\sum_{j=1}^n \left(\ln S_{ds_i}^j - \ln \bar{S}_{ds_i}^j \right)^2}{n}} \tag{11}
\end{aligned}$$

Figures 6 and 7 show the set of fragility curves obtained for the damage limit states of damage limitation and significant damage as computed for the two Italian sites of Nocera Umbra and Serravalle considering separately the three types of structural behavior. Once a structural typology has been assigned, the values of the mechanical characteristics are the same across the two samples, while the structural details are accounted for directly in the three classes of mechanisms. Hence the variability observed between samples in each chart can be related directly to geometric differences and masonry fabric, i.e., to the local aspects of the construction practice and architectural layout. Curves on the left of the diagrams relate to corresponding capacity curves with a stiffer elastic branch in the case of damage limitation and with lower ductility in the case of significant damage. However the distribution does not bare consistency across the three classes of mechanism for the two sites.

Conducting Seismic Vulnerability Assessment

As seen in the previous section, an analytical method based on limit state analysis and mechanism approach has the advantage of employing specific structural models to assess the seismic behavior of masonry buildings of different typologies, represented through capacity curves and performance points, while at the same time

Seismic Vulnerability Assessment: Masonry Structures,

Fig. 5 Example of calculation of performance points for median capacity curves for types of mechanisms triggered (*COMB* combined mechanism, *IP* in-plane mechanism, *OOP* out-of-plane mechanism; see also Fig. 1)

Seismic Vulnerability Assessment: Masonry Structures,

Fig. 7 Fragility curves for limit state of significant damage for the three classes of collapse mechanisms for two different Italian sites

being applicable to relatively large numbers of buildings. Hence procedures of this type, if properly developed, are particularly suitable for the seismic assessment of building aggregates in historical centers (Novelli and D'Ayala 2014) or

when a group of heritage structures at territorial scale are considered (D'Ayala and Ansal 2012).

A robust approach for seismic vulnerability assessment at territorial scale needs to address a number of issues, mainly related to a correct

Seismic Vulnerability Assessment: Masonry Structures,

Fig. 8 Fragility curves for two different samples – (a) 30 buildings and (b) 200 buildings – represented as actual distribution and lognormal distribution (Eqs. 10 and 11)

representation of the existing exposure so as to obtain meaningful fragility and vulnerability functions, while explicitly accounting for the uncertainties related to modelling limitation, the inherent randomness of the sample, and the randomness of the response. Given a territorial distribution, uncertainties are also present about the seismic action, relating to record to record, attenuation, soil characteristics, etc. Hence specific attention and due consideration should be given to the following aspects of a process leading to a seismic vulnerability assessment at territorial scale and identification of rehabilitation strategies.

Such process can be articulated in 10 steps:

- Consideration on the urban fabric and study area

- Identification of typologies and construction details
- Size and heterogeneity of sample to be surveyed
- Data collection
- Data analysis
- Safety and conservation requirements
- Seismic hazard
- Definition of performance points
- Definition of fragility functions
- Rehabilitation decisions

A detailed discussion of each step is beyond the scope of this document. However some observations in relation to specific applications of FaMIVE can help in highlighting some of the issues.

In relation to the sample size and heterogeneity, for instance, Fig. 8a, b shows the resulting

distributions for two different cases. The first sample included 30 buildings, which were considered relatively homogenous in terms of structural typology and materials but differing in geometry and quality of connections. The second one is made up of more than 200 buildings of varied characteristics. As it can be seen, the assumption of a lognormal model to describe the fragility cumulative distribution is more reliable as the size and heterogeneity of the sample increases.

Figure 8a also shows that results are highly affected by data collection and data analysis: the three cumulative distributions are obtained for the same sample of buildings when the presence of anchors or good wall connection is in turn ignored or considered. Because the collection and interpretation of this type of data is very sensitive to the expertise of the surveyor and the analyst, results can be highly affected by either incorrect interpretation of this information on the basis of the survey or use of a modelling tool that cannot properly simulate the behavior of the buildings when these constraints are in place.

The requirement of the codes and the limitations imposed by conservation principles also affect the way in which the fragility functions can be derived and used.

The reliability of the results obtained in the previous section can be considered within the framework set out in the EC 8 (CEN 2005), whereby the reliability associated to the results of a seismic assessment of a structure is expressed as a function of the level of knowledge and quantified by means of the confidence factor. Hence this can be considered a measure of the epistemic uncertainty. EC 8 (CEN 2005) recognizes three levels of knowledge (limited, normal, and full) and three fields of knowledge (geometry, construction details, and materials). As data used in the FaMIVE approach are collected by on-site visual inspection with some measurement and in situ accurate observation of construction details, while only very limited in situ nondestructive test on materials are performed and material characteristics are otherwise assigned based on literature or surveyor experience, then the level of knowledge is

superior to KL1, *limited*, but not quite equal to KL2, *normal*. For this level of knowledge, a static nonlinear analysis, such as the limit state mechanism approach, leading to a capacity curve is deemed appropriate. Hence according to the recommended values, the confidence factor CF should be in the range 1.2 to 1.35 depending on how closer the actual knowledge can be considered to the reference level identified by KL2. The confidence factor is then used in EC8 to reduce the capacity values as obtained from the assessment.

The FaMIVE procedure uses a measure of uncertainty of the input data to determine the uncertainty of the output. Depending on whether data, in each section of the data collection form, has been collected and measured directly on-site, or collected on-site and confirmed by existing drawings or photograph, or collected from photographic evidence only, three levels of uncertainty are considered, as high, medium, and low, respectively, to which three confidence ranges of the value given for a parameter can be considered corresponding to 10 % variation, 20 % variation, and 30 % variation. The parameter value attributed during the survey is considered central to the confidence range so that the interval of existence of each parameter is defined as $\mu \pm 5\%$, $\mu \pm 10\%$, and $\mu \pm 15\%$, depending on highest or lowest uncertainty. The uncertainty applied to the output parameters, specifically lateral acceleration and limit states' displacement, is calculated as a weighted average of the uncertainty of each section of the data form, with minimum 5 % confidence range to maximum 15 % confidence range.

In Fig. 9 the cumulative distribution for drift at the structural damage state threshold is compared with the curve obtained assuming a confidence factor of 1.25 in agreement with EC8 knowledge level and with the confidence boundaries computed by FaMIVE according to the procedure outlined above.

The major limitation of using confidence factors in the way suggested by EC8 is the possible underestimation of the overall capacity of the sample and hence an appropriate representation of epistemic uncertainty.

Seismic Vulnerability Assessment: Masonry Structures,

Fig. 9 Cumulative distribution for drift at structural damage threshold: comparison with curve obtained for an EC8 confidence factor of 1.25 and with FaMIVE confidence boundary

FaMIVE can also be used to foresee the shift in seismic performance of the building stock of a historic center if certain interventions are implemented to improve the seismic behavior. Among possible interventions, the improvement of cohesion of the masonry through grouting of multi-leaf walls with lime-based grout and the introduction of ties connecting walls together are seen as meeting the conservation principles of like for like, minimum intervention, and, in the case of ties, reversibility. Figure 10a, b shows the change in the median capacity curves when these interventions are considered: it can be seen that the response is different depending on the typology; in general both interventions cause an increase in lateral capacity. In some cases also a change in ductility and/or in the behavior up to structural damage as the intervention causes a change in the prevalent failure mechanisms.

Summary

Traditionally seismic vulnerability of historic buildings has been evaluated using empirical methods based either on damage observation or construction data. In the last decade, analytical methods for assessment of masonry structures have increased in number and quality. However, most of them assume only in-plane failure behavior reducing the walls to frame-like

behavior. This approach has serious limitations and it is nonconservative, as it overlooks out-of-plane behavior which might occur for structures with insufficient out-of-plane wall capacity. Nevertheless, recommendations of the EC 8 (CEN 2005) only consider basic in-plane behavior, either controlled by flexure or controlled by shear, and set limit drifts for this performance criterion. The application of the FaMIVE procedure to a number of cases in regions of different seismicities shows the relevance of considering separately different failure mechanisms to identify realistic risks of failure. A procedure for the computation of the performance point given performance criteria and hazard return period is introduced to show the variability of performance points for different failure behaviors and how they affect probability of failure computed as cumulative. The random uncertainty associated with this type of analysis is presented in terms of fragility curves that can be modelled as lognormal distribution. In the same way, the epistemic uncertainty associated with the modelling procedure is also evaluated using the same approach. Results show that the reliability approach set out in FaMIVE correctly accounts for epistemic uncertainty and it is of the same order of magnitude as the confidence factor suggested by EC8, although this only accounts for negative effects.

Introduction

Seismic vulnerability can be defined as the degree of loss to a given element at risk (e.g., buildings) resulting from the occurrence of an earthquake event (Coburn and Spence 2002). The development of methodologies for seismic vulnerability assessment is an essential tool for seismic risk management and for prioritizing pre-earthquake strengthening of the built environment.

Seismic risk can be approached through different methodologies. Most of them aim to deconstruct the problem into the typical elements defining any kind of risk: (i) hazard,

(ii) vulnerability, and (iii) exposure, and they are based on the total probability theorem.

Available seismic vulnerability methods, i.e., empirical, analytical, or hybrid (e.g., Calvi et al. 2006), developed in the last 30 years, differ because of the nature of tools and data employed. In the following only analytical approach to seismic vulnerability is considered, given the significance that such approach had in the last years. Analytical vulnerability methods stand at the basis of current worldwide codes and guidelines for seismic design and assessment of structures.

Therefore, next-generation codes (e.g., FEMA P-58-1 2012) are proceeding toward an explicit quantification of seismic risk through the Performance-Based Earthquake Engineering (PBEE) framework. Section “[Performance Earthquake Engineering Framework](#)” of this entry describes how in PBEE seismic risk assessment is deconstructed through the total probability theorem. PBEE’s deconstruction of seismic risk in hazard, structural, damage, and loss analysis emphasizes how structural and damage analyses are strictly related to vulnerability assessment in strict sense.

Notwithstanding the fact that PBEE is a generalized methodology that can be applied for any kind of structure, the case of reinforced concrete (RC) structures is specifically addressed in the following. As far as the relationship between intensity measure and engineering demand parameter arises in PBEE, it is the phase in which it is necessary to focus on the nonlinear behavior of RC structural elements (section “[Behavior of RC Elements and Non Structural Elements](#)”), in order to approach analytical modeling (section “[Analytical Modeling of RC Structures](#)”), and qualify and quantify components damage measures (section “[Damage Measures](#)”). A review of experimental and analytical results collected in the last decades is provided herein. It aims at the quantification of the behavior of RC structures and, in turn, of RC elements. Most significant results on vulnerability assessment of RC structures are collected together, and they allow emphasizing future challenges and needs (section “[Future Challenges and](#)

Concluding Remarks) that scientific community and practitioners should take on in the next years.

The focus in the following is the quantification of nonlinear parameters of RC elements aimed at a reliable modeling of their behavior. Emphasis is also given to consolidated and more recent literature results that have been included in codes and guidelines.

Performance Earthquake Engineering Framework

“PBEE implies design, evaluation, construction, monitoring the function and the maintenance of engineered facilities whose performance under common and extreme loads respond to the diverse needs and objectives of owners-users and society. It is based on the premise that performance can be predicted and evaluated with quantifiable confidence to make, together with the client, intelligent and informed trade-offs based on life cycle considerations rather than construction costs alone” (Krawinkler and Miranda 2004). Guidelines and codes, since the 1990s, have partially implemented, in their general framework, the basic concepts of PBEE in various forms, resulting in the attempt to tie design criteria to a performance level, usually that of collapse prevention. The Pacific Earthquake Engineering Research (PEER) Center has focused for several years on the development of procedures, knowledge, and tools for a comprehensive seismic performance assessment of buildings and bridges. The efforts made have resulted in a general framework that is now shared by the earthquake engineering community all over the world. Different publications describe the basic steps of PBEE methodology (e.g., Cornell and Krawinkler 2000; Krawinkler 2002; Moehle 2003; Porter 2003; Deierlein et al. 2003; Krawinkler and Miranda 2004; Moehle and Deierlein 2004), and a comprehensive document for a punctual methodological description of last enhancements of PBEE is available in FEMA P-58-1 document (2012).

Sharing a common vision and approach allows placing further enhancements and progresses in

this PBEE consolidated framework, thus aiming at the final challenge to contribute effectively to the reduction of losses and the improvement of safety (Cornell and Krawinkler 2000).

The basis of performance assessment can be summarized in a single equation (see Eq. 1). This equation suggests a generic structure for coordinating, combining, and assessing the many considerations implicit in performance-based seismic assessment.

$$\lambda(DV) = \iiint |G(DV|DM)dG(DM|EDP)dG(EDP|IM)d\lambda(IM)| \quad (1)$$

Based on total probability theorem, Eq. 1 allows deconstructing the problem in four steps: (i) hazard analysis, (ii) structural analysis, (iii) damage analysis, and (iv) loss analysis. Each step carries out a specific generalized variable: *intensity measure (IM)*, *engineering demand parameter (EDP)*, *damage measure (DM)*, and *decision variable (DV)*. The key issue of PBEE methodology is to identify and quantify *DV* of primary interest to the decision makers with consideration to all important uncertainties. *DVs* have been defined in terms of different quantities, such as repair costs, downtime, and casualty rates.

First member of Eq. 1 is a probabilistic description of the *DV*, such as the mean annual frequency of the *DV* exceeding a specified value. $\lambda(DV)$ might be the mean annual frequency of the direct dollar loss (repair cost) exceeding 50 % of the replacement cost of the facility. The terms $dG(EDP|IM)$, $dG(DM|EDP)$, and $G(DV|DM)$ or their derivatives on the right side of Eq. 1 are conditional probabilities relating one quantity to another, while $d\lambda(IM)$ is the derivative of the hazard curve, relating ground motion intensity measure to its mean annual frequency of exceedance.

Aimed at facilitating probability calculation, but mostly aimed at compartmentalizing discipline-specific knowledge, the above PBEE framework should choose intermediate variables (*EDP* and *DM*), so that conditional probabilities

are independent of one another (Deierlein et al. 2003). A brief intro to each step of PBEE is provided herein. It is a general methodological framework description that does not refer yet specifically to RC structures.

Hazard Analysis

Hazard analysis allows describing earthquake hazard in a probabilistic manner. The result of this phase is a hazard curve, which shows the variation of the selected *IM* versus mean annual frequency of exceedance (*MAF*). Probabilistic seismic hazard analysis, for a specific site, passes through four main steps: (i) characterization of the seismic sources (e.g., identified faults or geographical areas), in which it is generally assumed that the occurrence of an event at one source does not affect the occurrence of events at other sources; (ii) characterization of magnitude distribution, generally obtained through a truncated exponential distribution or through characteristic magnitude distribution estimated for specific faults; (iii) ground motion estimation evaluated through prediction equation of the considered *IM*; and (iv) probability analysis for the evaluation of the hazard curve (see also McGuire 2004). Hazard analysis can be performed with different intensity measures, provided the appropriate prediction equation. Notwithstanding the fact that advanced intensity measures have been considered in literature (e.g., Tothong and Luco 2007) and prediction equations for these *IMs* are available (e.g., Tothong and Cornell 2006; De Luca et al. 2014a), still the employment of peak ground acceleration (*PGA*) and, more commonly, of spectral acceleration at the fundamental period of the structure, *Sa(T)*, represents the basic practice.

Hazard analysis is generally performed for the evaluation of a target spectrum finally aimed at ground motion selection, if the assessment is made through nonlinear dynamic analysis. It is worth to note that according to FEMA P-58-1 (2012), hazard analysis for vulnerability assessment and loss assessment can be performed with three different approaches according to the final aim of the study: intensity-based, scenario-based, and time-based.

Notwithstanding the fact that hazard analysis is a common step for each structural typology to which PBEE methodology is applied, it is worth noting that it is also the step in which most of the variability of the whole problem is considered. The so-called record-to-record variability is the source of the most significant variability in risk evaluation (e.g., Goulet et al. 2007). On the other hand, such source of variability is also a common aspect for each structural typology, and it is not an aspect that strictly characterizes RC more than other structural typologies (e.g., steel, masonry, etc.).

Structural Analysis

Structural analysis is the phase of PBEE in which structural simulations are performed for the evaluation of *EDPs* at given *IMs*. At this step, a structural model is built up for the estimation of *EDPs*, such as internal member forces and local or global deformations, including structural collapse. The computational model is built up taking into account uncertainties in model parameters. A proper nonlinear model of a structure is the result of a reliable analytical model of the elements of the structure considered and of the analysis of experimental behavior of the elements.

The choice of *EDPs* depends on the performance target and on the type of system of interest. The general approaches for the evaluation of $dG(EDP/IM)$ is to perform incremental dynamic analyses or other kinds of nonlinear analyses; see also FEMA P-58-1 (2012).

Damage Analysis

Damage analysis is the third step of PBEE methodology. It relates the *EDPs* to *DMs*. The *DMs* include quantitative descriptions of damage to structural elements, nonstructural elements, and contents. This quantification must be in sufficient detail to enable subsequent quantification of the necessary repairs, disruption of function, and safety hazards (Moehle and Deierlein 2004). The *EDPs* considered in structural analysis are the input to a set of fragility functions that model the probability of various level of physical damage, conditioned on structural response. Physical damage is described at a detailed level, defined relative to particular repair efforts required to

restore the component to its undamaged state. The current approach is a component-based approach (e.g., Aslani 2005; FEMA P-58-1 2012). The study of experimental behavior of components is still a key issue for reliable evaluation of damage measures.

Loss Analysis

The last step of a PBEE loss assessment is the probabilistic estimation of performances through *DVs*. *DVs* represent the outcome parameters of PBEE and allow a transformation of engineering evaluations in terms of variables of interest for stakeholders (e.g., dollars, deaths, downtime); see Porter (2003). Different studies are available in literature for the evaluation of direct and indirect losses (e.g., Mitrani-Reiser 2007), and results of such studies are now the basis of the loss assessment framework provided by FEMA P-58-1 (2012). It is worth noting that loss analysis works on repair costs and downtime that, in turn, are strictly related to the social and economical environment in which they are evaluated.

Behavior of RC Elements and Nonstructural Elements

The basis of a reliable vulnerability analysis for any structural material passes through a solid modeling approach. PBEE assessment framework naturally points to nonlinear dynamic analysis as the reference structural analysis tool for RC structures. Thus, it is necessary to consider reliable nonlinear hysteretic models of all components of RC structures. Structural modeling of RC elements is based on the observation and interpretation of experimental tests and post-earthquake evidence from which it is possible to carry out nonlinear models of element behavior. It is important to state that a significant difference has to be made between elements with and without seismic detailing. In fact, existing elements are susceptible of various modes of failure, while capacity design in seismic detailed elements prevents brittle modes of failure.

Seismic vulnerability assessment has to account for all typical modes of failure that RC

elements can show; so, in the following, behavior of RC elements is described considering the case of existing elements that represent the most general situation in vulnerability assessment problems. This section is primarily focused on the vulnerability of RC frame structures; thus the behavior of columns and beam-column joints is specifically addressed. At the end of this section, behavior of masonry infills is also considered. Masonry infills are considered because of the significant effect they can have on vulnerability of RC frame structures. In fact, they provide on one hand the strength and stiffness increase and on the other hand, the local interaction between infill and RC frame.

RC Members

The specification of nonlinear structural component models in the form of monotonic backbone curves and hysteretic rules for RC structures is one of the key targets for the earthquake engineering community worldwide. Monotonic backbone curves and hysteretic rules should be able to capture the experimental behavior of RC elements. Any RC element component model is defined as function of specific parameters, such as shear span ratio, materials' strengths, longitudinal and transversal reinforcement ratios, and axial load ratio (e.g., CEB 1996; Elwood 2004; Elwood and Moehle 2005a, b; Zhu et al. 2007; Haselton et al. 2008; Biskinis and Fardis 2010a, b). Specific combinations of the above ruling parameters end up to the different definitions of wall, beam, or column. Furthermore, the structural difference between walls, beams, and columns is also made by the structural typology in which the above prismatic RC members are included, and by the structural role they play with respect to loads they are subjected to (e.g., gravity loads, earthquake loads, etc.).

In particular a prismatic RC member that carries gravity loads through shear and bending and that is designed under the assumption of uniaxial load with zero axial force is referred as a beam in RC frame structures. Again, a prismatic RC member in which the ratio between the two nondominant dimensions (i.e., width and depth of the cross section) is higher than four is typically defined as wall. This latter geometrical

assumption implies that a “wall” resists lateral forces mainly in one direction, and it can be designed for such unidirectional resistance by assigning flexural resistance to the two far ends of the section and shear resistance to the web (Fardis 2009). The classification of an RC prismatic elements as “column” is the more general possible; it covers the widest range of parameters ruling RC component modeling (e.g., variable axial load ratio, biaxial load, variable reinforcement ratios). Therefore, in the following, specific attention is given to modeling issues related to RC columns rather than beams or walls.

Notwithstanding the fact that columns are characterized by biaxial loading and by the widest variety of ruling parameters, experimental data more commonly available address the case of typical columns in RC frame structures. More specifically, most test specimens have rectangular cross section, symmetric reinforcement, and nonzero axial load, and rarely they are characterized by biaxial loading. The latter is the reason why most reliable nonlinear structural component models are conceived for columns under uniaxial loading. It is worth noting that recent experimental and modeling efforts have been made for the characterization of biaxial component models (e.g., Bousias 1993; Bousias et al. 2002; Di Ludovico et al. 2013), and some guidelines now provide recommendations for their employments. On the other hand, biaxial modeling efforts are still in a preliminary phase, and most common PBEE nonlinear analysis applications are performed discarding biaxial nonlinear component models. Thus, in the following, the only uniaxial behavior of elements is described.

Failure Mode Classification of RC Elements

Columns are generally subjected to the contemporary presence of axial load, shear forces, and bending moment. The interaction between those internal forces strictly affects the response of structural elements and consequently their mode of failure. Interaction effects, i.e., the influence of shear forces on flexural deformations and that of normal stress resultants on shear deformations, are important. In general, they cannot be neglected,

especially for inelastic cyclic loading for non-capacity-designed elements. Flexural response can be affected by the interaction with shear also in linear elastic phase, when plastic shear capacity of the element is not attained. Conversely, in the case of inelastic response, shear capacity can decrease after yielding as a result of increasing ductility demand in the element. In fact, damage caused by cyclic degradation in flexural response decreases post-cracking shear capacity mechanisms (e.g., aggregate interlock, loss of anchorage of transverse reinforcement, etc.) resulting in a decrease of shear capacity.

In Fig. 1, two experimental tests on rectangular RC columns from PEER database by Berry et al. (2004) are shown. The first column, Fig. 1a, is characterized by flexural-dominated behavior, while the second column, Fig. 1b, is characterized by post-yielding interaction between flexure and shear.

The above observations allow indentifying three different failure modes for columns resulting from flexure–shear interaction, as shown, schematically, in Fig. 2. The analytical classification of different modes of failure can be made only considering degrading shear capacity models which account for shear capacity degradation after yielding.

1. Shear failure mode, S – initial shear capacity (V_o), i.e., not affected by cyclic degradation, is lower than the plastic shear capacity (V_p), and flexural response is modified by a preemptive shear failure in the elastic response phase of the element. Deformation capacity (i.e., drift, chord rotation) is very limited. Subsequent response of the element is characterized by a strictly degrading behavior with significant shear strength reduction and a consequently loss of axial load-carrying capacity; see Fig. 2a.
2. Flexure–shear failure mode, FS – V_o is higher than V_p , and flexural response is characterized by an inelastic phase. However, if degraded shear strength (V_d), the lower red dotted branch in Fig. 1, is lower than V_p , the inelastic flexural response is modified by a shear failure that occurs at an intermediate shear strength

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 1 Experimental results for Berry et al. (2004) database. Experimental tests by (a) Legeron

and Paultre (2000) and (b) Pujol (2002) (Adapted from Haselton et al. 2008)

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 2 Collapse modes of RC elements subjected to axial load, shear, and bending

moment: (a) shear failure mode, S; (b) flexure–shear failure mode, FS; (c) flexural failure mode, F

between V_0 and V_d . The corresponding deformation capacity is higher with respect to that of case (1). The behavior of the element succeeding this kind of shear failure is strictly

degrading up to the loss of axial load-carrying capacity; see Figs. 1b and 2b.

3. Flexural failure mode, $F - V_d$ is higher than V_p , and flexural response is not affected by

interaction with shear. Thus, the element is characterized by inelastic deformation dominated by flexure and its typical damage, such as local buckling of longitudinal reinforcement and concrete spalling. This damage typically corresponds to the ultimate flexural capacity (θ_f). The softening branch of shear force–displacement envelope ends up to the loss of vertical load-carrying capacity; see Figs. 1a and 2c. This is the failure mode typical of capacity-designed elements in which shear–flexure hierarchy is controlled during the design process (see also De Luca and Verderame 2013).

The classification of failure mode is made on the basis of the ratio between plastic shear capacity V_p and degrading shear strength V_n . Several models have been developed to represent the degradation of shear strength with increasing inelastic deformations (Watanabe and Ichinose 1992; Aschheim and Moehle 1992; Priestley et al. 1994; Biskinis et al. 2004; Sezen and Moehle 2004).

In particular, the shear-degrading model proposed by Sezen and Moehle (2004) estimates column shear strength as the summation of shear carried by concrete (V_c) and shear carried by transverse reinforcement through a 45° truss model (V_s). This shear strength model is calibrated on 51 experimental column tests, and it has the form shown in Eq. 2.

$$\begin{aligned} V_n &= k \cdot V_o = k \cdot (V_c + V_w) \\ &= k \cdot \left[\left(\frac{0.5\sqrt{f_c}}{L_v/d} \cdot \sqrt{1 + \frac{P}{0.5 \cdot \sqrt{f_c} \cdot A_g}} \right) \cdot \right. \\ &\quad \left. 0.8A_g + \frac{A_{sw} \cdot f_{yw} \cdot d}{s} \right] \end{aligned} \quad (2)$$

Shear strength contribution carried by concrete depends on concrete compressive strength, (f_c); shear span, (L_v); section depth, (d); axial load, (P); and gross area section, (A_g), while shear strength contribution carried by reinforcements depends on transverse reinforcement area (A_{sw}) within a spacing (s) in the loading direction,

yielding steel strength (f_y), and section depth (d), computed as distance from the extreme compression fiber to centroid of tension reinforcement. This model takes into account shear strength degradation after yielding through a degradation coefficient (k); k is defined to be equal to 1.0 for displacement ductility less than 2, to be equal to 0.7 for displacement ductility exceeding 6, and to vary linearly for intermediate displacement ductilities. The degradation coefficient k is applied to both V_c and V_s , under the assumption that concrete component degrades due to increased cracking and degradation of the aggregate interlock mechanism, while steel component likewise degrades due to hoop opening and bond degradation. This shear capacity model is adopted in ASCE/SEI 41 guidelines (2007).

It is worth noting that the classification of column failure modes based only on shear strength and V_p can be still not adequate. Other column parameters may also influence the observed failure mode (Zhu et al. 2007). These considerations are reflected by ASCE/SEI 41 – supplement 1 provisions (Elwood et al. 2007) as follows: the expected failure is first evaluated based on the ratio between V_p and the shear capacity, and then, when classifying a column as flexure-controlled, further parameters are considered, namely, the transverse reinforcement ratio, assuming 0.002 as the lower limit, as in Zhu et al. (2007), and the tie spacing-to-section depth ratio, assuming 0.5 as the upper limit.

Characteristic points of shear force–displacement envelope (i.e., moment–chord rotation), for each failure mode, can be identified schematically through the representation shown in Fig. 2. Monotonic and cyclic deformation capacities to be attributed to each characteristic point can be found in literature. It is worth to note that if in the elastic phase the distinction between monotonic and cyclic deformation capacity can be unnecessary (pre-yielding phase), such distinction becomes significant in the inelastic phase (post-yielding), especially if those deformation capacities are employed in the analytical modeling of the element.

Monotonic deformation capacities are employed for the definition of the force–deformation envelope

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 3 Definition of yield displacement and effective stiffness from test data for

(a) yielding columns and (b) columns that did not yield (From Elwood and Eberhard 2009)

of the element. Successively, it is necessary to assign cyclic degrading rules. So, for example, a specific degradation percentage of peak force (conventional failure) is attained at a deformation capacity lower with respect to that considered on the monotonic envelope. When cyclic degrading rules are not modeled, the conventional failure has to be fixed at a displacement capacity that implicitly accounts for it (i.e., a value on the monotonic envelope that corresponds to the lower capacity degraded by cyclic effects). It is worth noting that the latter solution is obviously an approximated way for the estimation of a reliable deformation capacity. Cyclic degradation depends on the load path, and it cannot be accurately captured analytically with monotonic models. Still, for some specific failure modes, the monotonic degraded solution can be more straightforward with respect to the calibration of fulfilling cyclic models.

Yielding Displacement in RC Members

For the estimation of a reliable inelastic backbone of an RC element, the estimation of the yielding point is quite relevant. In literature, different empirical or hybrid models for the estimation of yielding drift capacity based on experimental observations are available. Direct estimations of yielding drift (Elwood and Eberhard 2009; Biskinis and Fardis 2010a) are generally based

on the assumption that yielding drift is the sum of three different components: a flexural component, a shear component, and a fixed end rotation component due to longitudinal bar slip; see Eq. 3. Alternatively yield drift can be evaluated indirectly from the estimation of yield stiffness (Elwood and Eberhard 2009; Biskinis and Fardis 2010a).

$$\delta_y = \delta_{y, \text{flex}} + \delta_{y, \text{shear}} + \delta_{y, \text{slip}} \quad (3)$$

Yield drift obtained through Eq. 3 is generally evaluated as the corner for an ideal envelope approximating a bilinear force deformation response of the element and not as the drift corresponding to the first yielding in the reinforcement steel (or equivalently in the concrete) at the first section of the element. Figure 3 shows the procedure by Elwood and Eberhard (2009) for the definition of yielding displacement on the envelope of measured lateral load–displacement relationship corrected for P-delta. Elwood and Eberhard's procedure covers both the cases in which yield force is attained in the envelope (Fig. 3a) and cases in which the calculated yield force is not attained (Fig. 3b); in fact, it provides an estimate of effective stiffness also in the case of columns that do not yield (see Fig. 3b).

Eurocode 8 part 3 (CEN 2005) recommends a three-component model for the estimation of yielding drift, while ASCE/SEI 41 (2007) provides an effective stiffness to be computed as function of the axial load to which the element is subjected. Experimental databases on which the above formulations are calibrated are often characterized by modern code-conforming elements with proper seismic detailing. In the case of nonconforming elements, such formulations have still shown a fair agreement; emphasizing that seismic detailing does not affect strictly yielding capacity (Biskinis and Fardis 2010a). It is worth noting that nonconforming definition changes according to the specific code considered; on the other hand, this definition is generally referred to lack of detailing in transversal reinforcements, smooth bar presence, and lack of confinement (e.g., no 135° hooks, poor stirrup spacing, etc.). Analogously, database of nonconforming elements with smooth bars have shown a fair agreement with empirical formulations based on conforming elements with ribbed bars (e.g., Ricci et al. 2013).

Ultimate Drift in RC Members

Other characteristic point of RC member force–displacement response is the ultimate drift capacity for each failure mode considered. Ultimate drift capacity is generally evaluated at the drift characterizing a 20 % loss of the maximum shear strength (FIB 2003) attained in the element; see Fig. 4. According to the failure mode, different empirical ultimate drift capacity formulations are available in the literature. Most experimental databases are characterized by cyclic tests and few monotonic tests. Thus, most of those empirical formulations account implicitly for cyclic degradation.

Zhu et al. (2007) provide an ultimate drift capacity model for two collapse modes. They consider a database of 125 nonconforming columns. Tests are divided in two different sub-databases according to a binary classification approach: Zone S columns (shear-dominated failures) and Zone F columns (flexural-dominated failures). Zone F is composed of 85 tests, while Zone S is composed of 40 tests that include both

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 4 Conventional criterion for the evaluation of ultimate drift capacity independently of the failure mode observed

shear- and flexure–shear-dominated failures. Classification is made on the basis of three column parameters: ratio of plastic shear demand to strength ratio (V_p/V_n), the aspect ratio (a/d), and the transverse reinforcement ratio (ρ''). The two sub-databases are employed for the estimation of the median ultimate drift capacity (20 % degradation of maximum shear strength) in the two cases, with characterization of logarithmic standard deviations. Equations 4 and 5 show the median estimates for Zone S and Zone F ultimate drift capacity, respectively. Zone S ultimate drift is function of hoop spacing to depth ratio (s/d), aspect ratio (a/d), and normalized axial force (v). Zone F ultimate drift depends on longitudinal reinforcement ratio (ρ_l), mechanical transversal reinforcement ratio ($\rho''f_{yt}/f_c$), s/d , and v .

$$\delta_s = 2.02\rho'' - 0.025\frac{s}{d} + 0.013\frac{a}{d} - 0.031v \quad (4)$$

$$\delta_f = 0.049 + 0.716\rho_l + 0.120\frac{\rho''f_{yt}}{f_c} - 0.042\frac{s}{d} - 0.070v \quad (5)$$

An alternative solution for the characterization of ultimate drift capacity for flexure–shear mode of failure (i.e., after yielding) is provided by Elwood and Moehle (2005a) based on a

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 5 (a) Monotonic and (b) cyclic behavior of component model used in the calibration study by Haselton et al. (2008) (From Haselton et al. 2008)

database of 51 lightly transversal-reinforced columns (Sezen and Moehle 2004); see Eq. 6. This ultimate drift depends on the maximum nominal shear stress (v), ρ'' , and v .

$$\delta_s = \frac{3}{100} + 4\rho'' - \frac{1}{40} \frac{v}{\sqrt{f_c}} - \frac{1}{40} v \geq \frac{1}{100} \quad (6)$$

For flexural-dominated behavior, an empirical ultimate drift capacity is provided by Biskinis and Fardis (2010b). It represents the evolution of the first formulation provided by Panagiotakos and Fardis (2001). This formulation is based on a database of 1,352 uniaxial columns with good detailing and continuous bars (299 monotonic and 1,053 cyclic tests). According to the loading of the test, Fardis and his coauthors provide two empirical formulations for ultimate drift capacity, one for monotonic loading (see Eq. 7) and one for cyclic loading (see Eq. 8). Biskinis and Fardis' formulations depend on v , f_c , shear span ratio (L_v/h), longitudinal mechanical reinforcement ratio in compression and tension (ω' and ω , respectively), confinement effectiveness factor (α), transversal reinforcement ratio (ρ_w or ρ''), transversal reinforcement yielding strength (f_{yw} or f_{yt}), and diagonal reinforcement ratio (ρ_d).

$$\delta_f = 0.028 \cdot (0.3^v) \left[\frac{\max(0.01; \omega')}{\max(0.01; \omega)} f_c \right]^{0.225} \times \left[\min \left(9; \frac{L_v}{h} \right) \right]^{0.35} 25^{\frac{\alpha \rho_w f_{yw}}{f_c}} 1.25^{100 \rho_d} \quad (7)$$

$$\delta_f = 0.016 \cdot (0.3^v) \left[\frac{\max(0.01; \omega')}{\max(0.01; \omega)} f_c \right]^{0.225} \left[\min \left(9; \frac{L_v}{h} \right) \right]^{0.35} 25^{\frac{\alpha \rho_w f_{yw}}{f_c}} 1.25^{100 \rho_d} \quad (8)$$

Considering a database of 48 cyclic tests, Biskinis and Fardis (2010b) provide a correction factor to Eq. 8 that accounts for poor detailing (i.e., older columns), and it is equal to (1/1.20). For substandard elements with smooth bars (based on 31 tests), the same authors provide an additional correction factor, equal to 0.95, to be applied to Eq. 8 (see also Verderame et al. 2010).

Flexural Component Model

For flexural-dominated behavior, Haselton et al. (2008) provide a complete calibration based on Berry et al. (2004) database for the specification of a complete nonlinear structural component model based on the beam-column element model developed by Ibarra et al. (2005). Figure 5 shows the monotonic and cyclic behavior of the component model employed by Haselton et al. (2008). Parameters to be considered for the employment of Haselton et al. (2008) model are (1) M_y , yielding moment; (2) θ_y , yielding rotation; (3) θ_{cap} , monotonic chord rotation at onset of strength loss (i.e., capping); (4) K_s , hardening stiffness; (5) θ_{pc} or K_c , post-capping stiffness; (6) λ , normalized hysteretic energy degradation capacity (i.e., cyclic degradation

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 6 Example of Haselton et al.'s calibration for test specimens 193 and 212 (see Fig. 1)

characterized by (a) flexural failure mode and (b) flexure–shear failure mode (Adapted from Haselton et al. 2008)

parameter); and (7) c , exponent term to model rate of deterioration (i.e., cyclic parameter). This model accounts for cyclic degradation directly through the modeling of hysteretic behavior. It is significantly different with respect to the other models considered and also more complete. On the other hand, drift capacity thresholds that implicitly account for cyclic degradation cannot be evaluated on the monotonic backbone provided by this model. In fact, the monotonic backbone by Haselton without the degrading parameters λ and c is incomplete and nonconservative for RC elements capacity evaluation through static methods.

It is worth to note that Haselton et al. make a calibration effort for most of columns of Berry et al. database considering both columns that failed in flexural mode and columns characterized by flexure–shear mode. In Fig. 6, an example of the calibration made by Haselton et al. (2008) is shown for the two experimental test specimens provided in Fig. 1. The comparison of the two examples of calibration emphasizes that this component model is very well fitted for columns characterized by flexural behavior and less accurate for flexure–shear-dominated columns.

Loss of Vertical Carrying Capacity

Some of the experimental tests characterized by shear-dominated failure have shown, after the

attainment of ultimate deformation, a loss of vertical carrying capacity. In particular, Elwood and Moehle (2005b), on the basis of 12 tests characterized by flexure–shear mode of failure, observed that the drift ratio at axial load failure (δ_a) of a shear-damaged column is inversely proportional to the magnitude of the axial load and directly proportional to the amount of transverse reinforcement. Based on the classical shear friction model, Elwood and Moehle (2005b) propose a model for the drift at axial failure for shear-damaged columns. The axial load on a shear-damaged column is assumed to be supported by a combination of compression of the longitudinal reinforcement and force transfer through shear friction on an idealized shear failure plane (see Fig. 7).

The effective coefficient of friction from the classical shear friction equation is related to the drift ratio at axial failure using the results from 12 full-scale pseudo-static column tests. The effective coefficient of friction along the critical shear failure plane can be calculated using equilibrium and subsequently related to the drift ratio at axial failure. Elwood and Moehle found that the effective coefficient of friction calculated by ignoring the contribution of longitudinal reinforcement provided good agreement with the experimental data. According to the above observations, the empirical formulation provided in Eq. 9 is proposed for the evaluation of drift at

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 7 Free body diagram of column after shear failure (From Elwood and Moehle 2005b)

loss of axial load-carrying capacity, where θ is equal to 65° , d_c is the depth of the column core (centerline to centerline of transverse reinforcement), and A_{st} and s are area and spacing of transverse reinforcement, respectively.

$$\delta_a = \frac{4}{100} \frac{1 + \tan(\theta)^2}{\tan(\theta) + P \left(\frac{s}{A_{st} f_{yt} d_c \tan(\theta)} \right)} \quad (9)$$

Elwood and Moehle's model is successively recalibrated by Zhu et al. (2007). Zhu et al. employed a database of 28 column specimens. All tests are unidirectional pseudo-static tests and were terminated after loss of axial load capacity. All the considered columns experienced flexural yielding prior to shear failure. Zhu et al. provide Eq. 10 for the evaluation of drift ratio at loss of vertical load-carrying capacity (axial failure), in which μ is the effective coefficient of friction evaluated according to Eq. 11. The same ruling parameters are assumed with respect to Eq. 9, and θ is equal, again, to 65° . Both Eqs. 9 and 10 are

based on the same model, but the most recent study (i.e., Eq. 10 by Zhu et al.) is based on a larger database, and it also provides a coefficient of variation equal to 0.35 for the median estimate of Eq. 10.

$$\delta_a = 0.184 \exp(-1.45\mu) \quad (10)$$

$$\mu = \frac{\frac{P}{A_{st} f_{yt} d_c / s} - 1}{\frac{P}{A_{st} f_{yt} d_c / s} - \tan \theta} \quad (11)$$

Beam-Column Joints

The performance of beam-column joints has been identified as a critical issue in the seismic resistance of RC moment-resisting frames (RC MRF). In RC MRF structures under severe ground motions, beam-column connections are subjected to moment reversals across the joint due to the adjacent beams and columns. As a result, the joint regions undergo significant horizontal (and vertical) shear forces whose magnitudes are much larger than those in the adjacent members (CEB 1996); see Fig. 8.

As a result, beam-column joints are susceptible to shear failure which generally involves a brittle process. Such brittle shear failure must be avoided through appropriate design to ensure ductile response of the frame. Despite the importance of shear design of RC beam-column joints, the research community has not yet developed a commonly accepted approach for the determination of the shear strength of RC beam-column joints, probably due to the complexity of joint behavior.

Many reinforced concrete (RC) buildings constructed without transverse steel shear reinforcement in the beam-column joint region still widely exist in seismically active regions, since the transverse reinforcement requirements for the design of beam-column joints were not addressed in earlier code provisions. Such unreinforced joints are considered vulnerable to brittle shear failure under earthquake shaking due to insufficient shear reinforcement in the joint region. These problems have been highlighted, in recent past, by the damage observed after

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 8 Shear forces within the joint. M_c , V_c , M_b , and V_b are column and beam moment and

shear, respectively. V_{jh} and V_{jv} are horizontal and vertical joint shears (Adapted from Fardis 2009)

devastating earthquakes in different countries; moreover, many tests have proven the poor seismic performance of unreinforced joints, especially of exterior joints.

Design recommendations for beam–column joints in code provisions have been considerably revised since the ACI-ASCE Committee 352 (ACI 352R-02 2002) published its first seismic design guidelines in 1976. Still, nominal joint shear strengths proposed in current code provisions are only applicable to joints satisfying the minimum requirements of transverse reinforcement in the joint region. Some analytical models (Vollum 1998; Hwang and Lee 1999; Lowes and Altoontash 2003; Wong 2005) for predicting joint shear strength have been developed based on the strut-and-tie (SAT) idealization incorporating Mohr’s strain compatibility and softening concrete behavior, e.g., the modified compression field theory (MCFT) proposed by Vecchio and Collins (1986). However, LaFave and Shin (2005) indicated that the strength prediction using the MCFT tends to underestimate the shear strength of lightly reinforced and that of unreinforced joints.

Therefore, current code provisions and available analytical models may be inappropriate to predict the shear strength of unreinforced joints; see also Park and Mosalam (2013) for details.

Alternatively, ASCE/SEI 41 (2007) provides recommendations for the shear strength and joint shear stress–strain relationship of unreinforced joints for seismic rehabilitation purposes based on the pre-standard developed in FEMA 273 (FEMA 1997) and FEMA 356 (FEMA 2000). According to ASCE 41, nominal joint shear strength (V_n) is defined according to Eq. 12; it is a function of a coefficient γ_n , joint width (b_j), column depth (h_c), and concrete tensile strength ($\sqrt{f_c}$)

$$V_n = \gamma_n \sqrt{f_c} b_j h_c \tag{12}$$

The values of γ_n for joint shear strength calculation are presented in Table 1. To investigate the relevance of the strength recommendations in ASCE 41, Park and Mosalam (2012) collected 62 previous unreinforced exterior or corner joint test data. The evaluation of the joint shear

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 9 Effect of the joint aspect ratio: (a) SAT idealizations for two joint aspect ratios and (b)

evaluation of the database against joint aspect ratio (Adapted from Park and Mosalam 2012)

strength for the collected database reveals that ASCE 41 may underestimate the shear strength of unreinforced exterior joints. This parametric study shows that the shear strength of unreinforced exterior joints is affected by the joint aspect ratio, defined as the ratio of beam to column cross-sectional heights. The effect of the joint aspect ratio can be explained by the SAT idealization where a steeper diagonal strut is developed in the unreinforced joint with a high aspect ratio; see Fig. 9. Consequently, this steeper diagonal strut results in less effective shear resistance to equilibrate the horizontal joint shear force. Hence, the shear strength of unreinforced exterior joints decreases with the increase of the joint aspect ratio. Similar results are reported by Kim and LaFave (2007), Vollum and Newman (1999), and Bakir and Boduroğlu (2002).

Another key parameter, joint shear demand calculated from beam longitudinal bars and frame geometry, has been suggested by Anderson et al. (2008) based on results of unreinforced interior joint tests by Walker (2001) and Alire (2002). Depending on the joint shear demand, two types of joint failure have been commonly

recognized by other researchers (Wong 2005; Kim and LaFave 2007):

1. Joint failure prior to beam longitudinal reinforcement yielding (referred to as J type failure)
2. Joint failure after beam longitudinal reinforcement yielding (referred to as BJ-type failure)

The joint shear strength in most code provisions is pertinent to joint failure independent of beam longitudinal bars yielding or not, whereas the maximum joint shear stress for the BJ-type failure is directly determined from the joint shear demand dictated by the yielding of the beam longitudinal reinforcement. Conversely, experimental results show that the joint shear strength of unreinforced joints increases with the beam longitudinal reinforcement ratio. This evidence can be explained as follows: (i) increasing the beam longitudinal reinforcement ratio leads to the increase of the horizontal joint shear force without the yielding of the beam longitudinal bars, i.e., larger horizontal joint shear force is imposed with less deterioration of bond resistance around the beam longitudinal bars in the

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 10 Experimental results of unreinforced exterior joint: (a) effect of beam-column

joint failure on the sub-assembly; (b) effect of anchorage failure (Adapted from Pantelides et al. 2002)

joint region; (ii) this more stable bond resistance produces a wider diagonal strut which can carry the larger horizontal joint shear force. Some strength models use either ductility factor (Park 2002; Hakuto et al. 2000) to predict the joint shear strength of BJ type of joint failure. A similar approach is adopted to predict the shear strength of columns (Sezen and Moehle 2004).

In general, experimental results on beam-column joints without transverse steel shear reinforcement emphasize a strictly degrading behavior caused, on one hand, by the shear behavior of the joint panels and, on the other hand, by the bond-slip behavior of longitudinal reinforcements anchored in it; see Fig. 10. Experimental research on the seismic performance of the beam-column joints (Walker 2001; Alire 2002; Pantelides et al. 2002) has revealed that the joint shear stress-strain response, typically, has a degrading envelope and a highly pinched hysteresis. Moreover, the common practice of terminating the beam's bottom reinforcement within the joints makes the bottom reinforcement prone to pullout under a seismic excitation. Insufficient beam bottom bar anchorage precludes the formation of bond stresses necessary to develop the yield stress in the beam's bottom reinforcement.

Finally, as described in section “**Loss of Vertical Carrying Capacity**,” axial failure of a shear-damaged column can occur by sliding along an inclined crack plane, with resistance provided by

transverse reinforcement clamping the crack and longitudinal reinforcement supporting axial force directly. Axial failure of a joint may be viewed similarly (Hassan 2011). After developing joint shear failure, the axial load will be supported by shear friction on the diagonal shear failure plane and the axial capacity of column reinforcing bars. Two axial capacity models designed for unconfined joints were developed. However, this result is obtained based on a small dataset.

Infills

The practice of realizing RC frames with masonry infill panels is very common in European countries. Masonry infill walls affect the strength and stiffness of infilled RC frame structures. The general approach to discard their contribution in design and assessment could be acceptable when proper capacity design rules are employed, since code recommendations account implicitly for their contribution through proper acceptance criteria and drift limitations (CEN 2004; ASCE/SEI 41 2007; DM14/01/2008 2008). In addition, their contribution to overall strength and stiffness is less significant in modern designed structures (e.g., Dolšek and Fajfar 2001). On the other hand, assessment of RC structures often involves substandard buildings in which the presence of masonry infill can strictly affect the structural behavior. Typical two-layer hollow clay brick infills employed in the Mediterranean area and very common in existing RC buildings cannot be neglected.

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 11 Example of (a) cyclic- and (b) monotonically loaded specimens of RC-infilled frames (From Mehrabi et al. 1996)

Their contribution represents the first capacity source to earthquake shaking in this kind of buildings (e.g., De Luca et al. 2014b; Manfredi et al. 2014), and, at the same time, they can lead to preemptive brittle failures due to local interaction between infill and RC frame (e.g., Verderame et al. 2011).

Notwithstanding the above considerations, it is worth noting that these elements are considered as *nonstructural* in the design process, and they are not subjected to the same acceptance and quality controls of RC elements. Thus their behavior can be significantly affected by specific executive practice and very different material properties.

Experimental investigations of the last decades (e.g., Mehrabi et al. 1996; Mosalam 1996; Colangelo 2003; Calvi et al. 2004, among others) emphasized a considerable reduction in the response of infilled frames under reversed cyclic loading. This behavior is due to the rapid degradation of stiffness, strength, and low energy dissipation capacity, resulting from the brittle and sudden damage of the unreinforced masonry (URM) infill walls. In Fig. 11 an example of cyclic (Fig. 11a) and monotonic (Fig. 11b) behavior of masonry infill frames from the experimental campaign by Mehrabi et al. (1996) is shown.

Based on both experimental and analytical results of the last decades, different failure mode classifications of masonry-infilled frames

have been proposed. Infill failure can be classified into five distinct modes (e.g., Shing and Mehrabi 2002; Calvi et al. 2004; Asteris et al. 2011). Infill failure graphical examples according to Shing and Mehrabi (2002) are shown in Fig. 12.

- *Sliding shear mode* represents horizontal sliding shear failure through bed joints of a masonry infill. This mode is associated with infill of weak mortar joints and a strong frame.
- *Diagonal cracking mode* is seen in the form of a crack across the compressed diagonal of the infill panel and often takes place with simultaneous initiation of the sliding shear mode. This mode is associated with a weak frame or a frame with weak joints and strong members infilled with a rather strong infill.
- *Diagonal compression mode* represents the crushing of the infill within its central region. This mode is associated with a relatively slender infill, where failure results from out-of-plane buckling of the infill.
- *Corner crushing mode* represents the crushing of the infill in at least one of its loaded corners. This mode is usually associated with infilled frames consisting of a weak masonry infill panel surrounded by a frame with weak joints and strong members.
- *Frame failure mode* is seen in the form of plastic hinges developing in the columns or

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 12 Failure mode according to the classification made by Shing and Mehrabi (2002), (a)

midheight crack, (b) diagonal crack, (c and d) corner crushing, (e) horizontal slip (Adapted from Calvi et al. 2004)

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 13 (a) Strut model analogy of infilled frame (From Asteris et al. 2011); (b) Fardis and Panagiotakos (1997) analytical model for infills (From Fardis 2009)

the beam–column connections. This mode is associated with a weak frame or a frame with weak joints and strong members infilled with a rather strong infill.

Analytical modeling of infills can be carried out according to different macro-modeling approaches. Equivalent strut macro-model approach is the simplest way to model the global interaction between infill and RC elements; see Fig. 13a; it is also explicitly suggested by codes (e.g., ASCE/SEI 41 2007). On the other hand, the

characterization of the strut can be made according to different formulations. In literature are available different overviews of the different analytical approaches (e.g., Crisafulli 1997; Chrysostomou and Asteris 2012, among others). Some analytical approaches are able to account for all the failure modes considered above (e.g., Bertoldi et al. 1993), other macro-models does not account explicitly for all the five modes of failure but show a fair agreement with experimental results (e.g., Fardis and Panagiotakos 1997); see Fig. 13b.

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 14 Idealized models of RC elements (Adapted from Deierlein et al. 2010)

Local interaction between infills and RC frame can be captured by multiple strut macro-models (e.g., Crisafulli 1997) or by single strut macro-models with ends located at the edge of the column or of the beam (e.g., ASCE/SEI 41 2007). Notwithstanding the fact that it can be quite hard to distribute strength among the different struts of the analytical model, still modeling local interaction allows to check if brittle failures are likely to occur in the RC elements (e.g., Verderame et al. 2011).

Analytical Modeling of RC Structures

Inelastic analytical structural component models can be differentiated by the way that plasticity is distributed through the member cross sections and along its length. Modeling approaches can be divided in three main groups: (i) lumped plasticity models, (ii) distributed plasticity models, and (iii) finite element micro-modeling. The main difference between lumped plasticity, distributed plasticity, and finite element models resides in the parameters employed for the definition of inelastic behavior. In the first case, moment–rotation relationships are employed, while, in the other two options, moment–curvature or stress–strain relationships are assumed, and it is necessary to pass through a numerical integration step.

The analysis of experimental behavior of structural elements in section “[Behavior of RC Elements and Nonstructural Elements](#)” allowed

the definition of nonlinear structural component models for RC buildings, in terms of $M-\theta$. It was emphasized that component models are generally defined on the basis of experimental results, and often curvature is not the easiest parameter to be employed for the description of all the modes of failures characteristic of RC element. Thus, most commonly, PBEE applications employ lumped plasticity models. On the other hand, it is possible to find PBEE loss and vulnerability assessment applications on RC structures that employ fiber models for low-intensity levels (e.g., Mitrani-Reiser 2007).

In the following, a brief description of both analytical modeling solutions is provided. A more complete overview of modeling approaches is provided in Deierlein et al. (2010). In Fig. 14, the comparison of different idealized model types for simulating the inelastic response of elements is shown.

Lumped plasticity models concentrate the inelastic deformations at the end of the element, such as through a rigid-plastic hinge or an inelastic spring with hysteretic properties (Fig. 14a). By concentrating the plasticity in zero-length hinges with moment–rotation model parameters, these elements have relatively condensed numerically efficient formulations.

Distributed plasticity models are different according to the way the element is discretized, and numerical integration is carried out resulting in finite length hinge models (Fig. 14b) or fiber

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 15 Shear spring in series model using limit state material model (From Elwood 2004)

model (Fig. 14c). In the finite length hinge model, cross sections in the inelastic hinge zones are characterized through either nonlinear moment–curvature relationships or explicit fiber-section integrations that enforce the assumption that plane sections remain plane. The inelastic hinge length may be fixed or variable, as determined from the moment–curvature characteristics of the section together with the concurrent moment gradient and axial force. The fiber formulation models distribute plasticity by numerical integrations through the member cross sections and along the member length. In this latter case, stress–strain relationship is defined and plane-sections-remain-plane assumption is enforced; see Deierlein et al. (2010). Distributed fiber formulations do not generally report plastic hinge rotations, but instead report strains in concrete cross-section fibers. The calculated strain demands can be quite sensitive to the moment gradient, element length, integration method, and strain hardening parameters on the calculated strain demands. These modeling approaches allow capturing the interaction between axial load and biaxial components of bending moment at section level, under cyclic loading.

Finally, finite element models (Fig. 14d) represent a detailed micro-modeling solution in which material constitutive relationships are assigned to each element. It is obvious that this

latter approach represents the most detailed way to represent the elements; on the other hand, it is computationally demanding, and it asks for the definition of numerous input parameters that, in turn, need to be calibrated.

While distributed plasticity formulations capture variations of stress and strain through the section and along the member in more detail, important local behaviors, such as strength degradation due to local buckling of steel reinforcing bars or nonlinear interaction of flexural and shear, are difficult to capture without sophisticated and numerically intensive models. Phenomenological concentrated hinge/spring models may be better suited to capture the nonlinear degrading response of members through calibration (see Fig. 15), using member test data, on experimental moment rotations and hysteresis curves (Deierlein et al. 2010); see Fig. 6. It is worth noting that even when opting for lumped plasticity models, it is possible to refine the analytical modeling choice in different ways, and the accuracy of results is consequently affected; see, for example, Yavari et al. (2009).

Beam–column joint modeling is still at an early and less mature stage with respect to member modeling (i.e., beam and columns), and practical available solutions are to consider rotational springs capable to describe the beam–column joint behavior that is governed by shear and

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 16 Existing beam-column joint models: (a) Alath and Kunnath (1995), (b) Biddah and Ghobarah (1999), (c) Youssef and Ghobarah (2001),

(d) Lowes and Altoontash (2003), (e) Altoontash (2004), and (f) Shin and LaFave (2004) (From Celik and Ellingwood 2008)

bond-slip deformation; see some modeling scheme examples in Fig. 16 as collected by Celik and Ellingwood (2008). Alath and Kunnath (1995) modeled the joint shear deformation with a rotational spring model with degrading hysteresis (Fig. 16a). Biddah and Ghobarah (1999) modeled the joint shear and bond-slip deformations with separate rotational springs (Fig. 16b). Youssef and Ghobarah (2001) proposed a joint element in which two diagonal translational springs connecting the opposite corners of the panel zone simulate the joint shear deformation, and 12 translational springs at the panel zone interfaced simulate all other modes of inelastic behavior (Fig. 16c). Lowes and Altoontash (2003) proposed a 4-node 12° of freedom joint element that explicitly represents three types of inelastic mechanisms of beam-column joints under reversed cyclic loading (Fig. 16d). Successively Altoontash (2004) simplified the model by Lowes and Altoontash introducing a four

zero-length rotational springs located at beam-column joint interfaces (Fig. 16e). Shin and LaFave (2004) represented the joint by rigid elements located at the edges of the panel zone and rotational springs embedded in one of the four hinges linking adjacent rigid elements (Fig. 16f).

Damage Measures

The nature and amount of structural damage depends necessarily on the quality of the materials that compose structural and nonstructural elements, and on the configuration and type of structural systems. In the early years of modern earthquake engineering, damage definition was basically approached in qualitative terms (e.g., through the definition of probable localization of such damage in a structure). This kind of approach relied fundamentally on the observation of damaged structures after seismic events or it

was based on experimental tests. The first studies for damage quantification of RC structural members date back to late 1980s (e.g., Park and Ang 1985; Fardis et al. 1992). The availability of experimental data allowed more and more detailed approaches to damage analysis up to the most recent PBEE applications.

Most recent studies on damage analysis employ component-based approaches (e.g., Aslani 2005; Mitrani-Reiser 2007). The PBEE damage analysis overpasses the approach to global estimate of damage implicit in previous damage scales (e.g., ATC-13 1985; Grunthal 1998; NIBS 1999) and switch to a component-based damage analysis that allows a more accurate definition of losses. On the other hand, component-based approach requires a significant amount of data, such as experimental data, earthquake experience, expert opinion, and some combination of these.

For component-based approaches, it is necessary to define fragility functions for various damage states for each structural and nonstructural component in typical RC frames. In literature, there are available different benchmark studies for damage assessment of RC buildings (e.g., Aslani 2005; Mitrani-Reiser 2007). FEMA P-58-1 (2012) provides a list of fragility specifications for structural components, nonstructural components, and contents.

The functional form most commonly used for components' fragility functions is the lognormal distribution that asks for the definition of median and logarithmic standard deviation. Therefore, for each component, it is necessary to define median capacity and logarithmic standard deviation ($\sigma_{\log}$) in terms of EDP for each damage state.

In section "Examples of Damage Analysis", there is a brief overview of component-based damage analyses for RC structural components and infills according to different authors. This overview is aimed at providing an example of damage evaluation made for the elements whose behavior was considered in section "Behavior of RC Elements and Non Structural Elements." Notwithstanding the fact that quantitative approaches to component damage analysis rely on experimental databases, they are still based on a limited

number of data, and they cannot be considered fully reliable yet, since they need further numerical refinement.

Finally, in section "Code Limit States," a brief overview of code acceptance criteria for RC elements at different limit states is provided, and compared with the information provided in section "Examples of Damage Analysis." The two sections allow a comparison between next-generation performance-based codes (i.e., section "Examples of Damage Analysis") with respect to current performance-based codes (i.e., section "Code Limit States").

Examples of Damage Analysis

Various damage indices or EDP thresholds are used to quantify damage of RC structural members. As an example, Mitrani-Reiser (2007) employed for beam and columns' damage states the fragility curves developed by Beck et al. (2002) and, in turn, based on Williams and Sexsmith (1997) studies. Beck et al.'s fragility functions use a deformation damage index (DDI) that can be evaluated from chord rotations obtained in structural analyses. This approach allows the definition of four damage states for RC members. On the other hand, Aslani (2005) provides fragility functions for RC columns with light transversal reinforcement in terms of IDR, evaluated from experimental data, and based on the component modeling provided in section "Behavior of RC Elements and Non Structural Elements." For both approaches, four damage states are defined resulting in damage descriptions compared in Table 2. Notwithstanding the fact that Aslani refers specifically to lightly reinforced RC columns (i.e., non-ductile columns), similar damage descriptions are provided in Table 2. In both approaches, the typical lognormal shape is adopted for the fragility curve, so that for each damage state, a median EDP and a $\sigma_{\log}$ are estimated.

Aslani estimates median and $\sigma_{\log}$ for each damage states, based on a database of 92 lightly reinforced columns. The preliminary result of this estimation leads to a significant dispersion for all damage states; so an additional parameter (α) is considered in the regression to reduce the

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Table 2 Comparison of damage states for columns

Williams and Sexsmith (1997) – ductile columns		Aslani (2005) – non-ductile columns	
Damage state	Damage description	Damage state	Damage description
None	None or small number of light cracks, either flexural (90°) or shear (45°)		
Light	Widespread light cracking or a few cracks >1 mm or light shear cracks tending to flatten toward 30°	DS1: light cracking	Visible cracks; crack widths smaller than 0.3 mm. Light repair to improve aesthetic appearance
Moderate	Significant cracking, e.g., 90° cracks >2 mm; 45° cracks >2 mm; 30° cracks >1 mm	DS2: severe cracking	Wider and deeper crack widths, more extensive compared to DS1
Severe	Very large flexure or shear cracks, usually accompanied by limited spalling of cover concrete	DS3: shear failure	Deterioration of shear capacity after yielding (that occurs at earlier stages of loading compared to ductile columns) leads to shear failure
Collapse	Very severe cracking and spalling of concrete; buckling, kinking, or fracture of rebar	DS4: axial failure	Loss of vertical carrying capacity. This damage state has possible disastrous consequences, if there is no possibility to redistribute vertical load to other members

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Fig. 17 Probability of being at each damage state for non-ductile RC columns characterized by different α parameter

resulting $\sigma_{\log}$ of the fragilities and to adjust the estimated median IDR at each damage states. The parameter $\alpha = P/(A_g \rho'' f_c)$ is function of axial load (P), gross area section (A_g), concrete compressive strength (f_c), and transversal reinforcement ratio (ρ''). In Fig. 17, the probability of being in a specific damage state for lightly reinforced

columns is shown, and the effect of α is emphasized through the comparison of the curves in Fig. 17a, b. It is worth noting that α affects strictly shear failure and axial failure as it can be expected by the observation of the parameters ruling equations shown in section “Behavior of RC Elements and Non Structural Elements.”

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Table 3 Damage state definition for interior and exterior beam–column joints according to Aslani (2005)

Damage state	Damage description
DS1: sever cracking in the beam	Wide and extensive cracking of the beam
DS2: severe cracking in the column	Wide and extensive cracking of the column
DS3: severe cracking in the joint	Severe cracking at the beam–column joint
DS4: joint spalling	Spalling of the concrete cover of the beam–column joint
DS5: loss of vertical carrying capacity	The joint collapses under its gravity load

For beam–column connections, Aslani considers different fragility curves for interior beam–column connections and exterior beam column connections. Damage state definitions are identical in the two cases, and they are shown in Table 3, while fragility functions, based on experimental data, can be really different. The numerical estimation for joints is again affected by high uncertainties.

Fragility functions for masonry infill panels are not available in the damage and loss studies cited up to this point. On the other hand, experimental tests (e.g., Mehrabi et al. 1996; Colangelo 2003) and post-earthquake damage observations (e.g., Ricci et al. 2011; De Luca et al. 2014b; Manfredi et al. 2014) have shown that this kind of elements can have a significant impact on both damage and loss analysis of RC structures, especially in the Mediterranean area, in which this kind of structural typology is quite common. Notwithstanding the fact that damage observations based on experimental tests are available in literature and macro-modeling approaches and component modeling backbones as well are available in literature, still characteristic parameters for infill fragilities are characterized by significant differences according to different authors (e.g., Gu and Lu 2005; Özcebe et al. 2012; Colangelo 2013). The point is that in the case of damage analysis of infills, authors do not even agree on damage states' qualitative definitions. The damage degrees are distinguished on the basis of the description of physical damage in

terms of cracking, crushing, etc. and the feasibility of repair. As an example, Table 4 provides damage description at different damage states according to different authors; see Colangelo (2013). Significant differences can be found in damage descriptions and, as consequences, also in the fragility function parameters estimated from each description (see also Colangelo 2013).

Despite the significant differences that can be found in literature formulations for component fragilities of infills, it is worth noting that widely employed damage scales for RC structures that interpret global damage of buildings often refer to infill damage. An example is the EMS 98 scale (Grunthal 1998) in which the first three grades of global damage are mainly characterized by damage description of masonry infills; see, for example, De Luca et al. (2014b) and Manfredi et al. (2014), in which infill damage analysis is employed as analytical proxy for damage classification of the whole RC building. On the other hand, EMS 98 damage scale is not a component-based approach, but the single most damaged element represents the damage classification of the whole structure.

Code Limit States

Current PBEE approach is also the result of the huge effort made in ATC-58 project. The purpose of this project is to develop next-generation seismic design procedures that will provide a more reliable means of predicting and designing performances of structures. On the other hand, PBEE has been already implemented in codes providing target performance levels. As an example, FEMA 356 (FEMA 2000) and successively ASCE/SEI 41 (2007) do not attempt to quantify the probability of achieving a given performance level or to quantify losses; but, both FEMA 356 and ASCE/SEI 41 address component-level and system-level damage states, and they relate damage to life safety and post-earthquake operability. The damage states given in FEMA 356 tend to be qualitative and open to multiple interpretations. In Table 5, target performance levels according to FEMA 356 and ASCE/SEI 41 are shown.

ASCE/SEI 41 (2007) succeeded FEMA 356 as document for the seismic assessment of existing

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Table 4 Damage state definition for masonry infills according to Colangelo (2013)

Damage state	Damage description (Colangelo 2013)	Damage description (Gu and Lu 2005)	Damage description (Özcebe et al. 2012)
DS1	Onset of cracking in the bricks, associated with the first noticeable reduction of stiffness	Minor cracking and falling of plaster; only local repair needed with function maintained; maximum strength	Negligible cracks; maximum strength (i.e., base shear)
DS2	Moderate cracks before attaining the maximum strength (i.e., base shear)	Continual diagonal cracking and flaking; repairable damage; 30 % reduction of the maximum strength	Appreciable damage; maximum stress in the infill
DS3	Extensive cracks with tensile splitting and falling of the outer layer of a few bricks; repairable damage	Loss of wall integrity; 70 % reduction of the maximum strength	Ultimate strain in the infill
DS4	So many broken bricks that repair is unreasonable; reconstruction needed		

buildings; it provides a performance-based engineering framework whereby deformation and force demands for different seismic hazards are compared against deformation and force capacities for various performance levels. Elwood et al. (2007) provided an update to concrete provisions in ASCE/SEI 41 given new data available in literature and considering that practitioners observed that previous concrete provisions tend to err on the conservative side. In their update to concrete provisions, Elwood et al. provide modeling parameters and acceptance criteria modifications for columns, beam–column joints, etc. Regarding columns, the classification described in section “RC Members” is considered. As an example, for columns, drift limits at the different acceptance criteria change according to the classification of the expected mode of failure.

European code for the assessment of RC elements (CEN 2005) provides, as collapse prevention acceptance criteria for RC members, the value of the ultimate rotation capacity according to Biskinis and Fardis (2010b); as life safety acceptance criteria, 75 % of the ultimate rotation capacity according to Biskinis and Fardis (2010b); and, as immediate occupancy acceptance criteria, the value of yielding rotation

according to Biskinis and Fardis (2010a). All these chord rotation capacities are intended as member capacity thresholds if shear capacity evaluated according to Biskinis et al. (2004) is not attained, and a preemptive brittle failure (computed through a force-based approach) does not occur before the attainment of such chord rotations.

Regarding acceptance criteria for infills, codes (e.g., CEN 2004), in general, do not provide specific drift limits for infill elements, since it is not taken for granted the fact that infills are explicitly modeled. On the other hand, immediate occupancy and operational acceptance criteria are evaluated to implicitly account for damage to masonry infills.

In FEMA 356 and ASCE/SEI 41, four nonstructural performance levels are classified (see Table 5). The limit for exterior walls differs from the limit for heavy partitions (light partitions may be drywall partitions with studs, for instance) for both occupancy and life safety performance level. For the occupancy level for heavy partitions, the limit is 0.5 %, the same as Eurocode 8 (CEN 2004), while for exterior walls, the limit is 1 %. For life safety level, the above occupancy limits double. The Italian code (DM14/1/2008 2008) also prescribes 0.5 % for

Seismic Vulnerability Assessment: Reinforced Concrete Structures, Table 5 Damage control and building performance level extracted from Table C1-2 in FEMA 356 (FEMA 2000) and ASCE/SEI 41 (2007)

	Collapse prevention level	Life safety level	Immediate occupancy level	Operational level
Overall damage	Severe	Moderate	Light	Very light
General	Little residual stiffness and strength, but load-bearing columns and walls function. Large permanent drifts. Some exits blocked. Infills and unbraced parapets failed or at incipient failure. Building is near collapse	Some residual strength and stiffness left in all stories. Gravity-load-bearing elements function. No out-of-plane failure of walls or tipping of parapets. Some permanent drift. Damage to partitions. Building may be beyond economical repair	No permanent drift. Structure substantially retains original strength and stiffness. Minor cracking of facades, partitions, and ceilings as well as structural elements. Elevators can be restarted. Fire protection operable	No permanent drift. Structure substantially retains original strength and stiffness. Minor cracking of facades, partitions, and ceilings as well as structural elements. All systems important to normal operation are functional
Nonstructural components	Extensive damage	Falling hazards mitigated but many architectural, mechanical, and electrical systems are damaged	Equipment and contents are generally secure but may not operate due to mechanical failure or lack of utilities	Negligible damage occurs. Power and other utilities are available, possibly from standby sources

occupancy, while 0.5 % times 2/3 is prescribed to ensure operation for civil protection. Moreover, with regard to existing buildings, in the commentary to the Italian code (CM 617 2009), both limits are reduced if the analysis model includes the infills. In such a case, the limits become the same as for the masonry buildings, which are equal to 0.3 % and 0.2 % to ensure occupancy and operation, respectively.

Future Challenges and Concluding Remarks

The overview of the seismic assessment framework for RC building provided in this entry has been organized according to the most recent state of the art and guidelines that provide a vision for next-generation codes for RC structures. On the other hand, there are still different aspects on which research and, in turn, code standards should focus.

In particular, behavior of RC elements and their modeling still requires significant experimental and numerical efforts. Behavior of

non-ductile RC elements (e.g., characterization of axial load failure) should be better characterized on the basis of higher number of experimental tests in order to better characterize both modeling issues and damage analysis issues in terms of median and logarithmic standard deviation. Same considerations can be made on beam-column joints and masonry infills.

Finally, masonry infills represent a relevant issue for all countries in the Mediterranean area in which this kind of construction practice is very common. Despite the huge efforts made in the last decades, the characterization of nonstructural component modeling and damage is still challenging considering that they are not subjected to the same design and control process to which new RC elements are subjected to.

Performance evaluation of RC structure according to the methodological framework of FEMA P-58-1 (2012) provides a significant enhancement toward a more reliable performance evaluation for stakeholders and decision makers. Still, some procedures need to be codified in simpler and more user-friendly tools to be employed by practitioners and professional

engineers in any structural performance evaluations as current and consolidated practice.

Summary

The framework in which modern design and assessment of reinforced concrete structures are placed is the well-known Performance-Based Earthquake Engineering (PBEE) framework. The most recent methodological organization of PBEE tools is represented by FEMA P-58-1 document. The brief analysis of the main steps of PBEE provides the basis to introduce where, in such framework, the specific structural material – in this case RC – plays a role. In particular, when the relationship between intensity measure and engineering demand parameter arises in PBEE, it is the phase in which it is necessary to focus on the behavior of RC structural elements, in order to approach analytical modeling, and quantify components damage measures.

Seismic vulnerability assessment has to account for all the typical modes of failure that RC elements can show. Thus, behavior of RC elements (e.g., beams, columns, beam–column joints) is described considering the case of existing elements representing the most general situation for vulnerability assessment problems. The behavior of masonry infills is also considered, given the significant effect they can have on vulnerability in terms of strength and stiffness increase, and in terms of occurrence of brittle failures caused by local interaction of infill and RC frame. Critical review of behavior of RC structures and, in turn, of RC elements, allows emphasizing future challenges and needs that the scientific community and practitioners should take on in the next years.

Arrays; Beamforming; fk-analysis; Seismic arrays

Introduction

Definition and Purpose

In seismology, the term “array” (of seismometers) has been known for more than 50 years. Today this phrase is often used for any group of seismic stations in the sense as defined in Macmillan’s online dictionary, where an array is described as “a number of pieces of equipment of the same type, connected together to do a particular job” (Macmillan 2013). In this chapter, the term “seismometer arrays” is used with a more restricted definition, as it was originally introduced to seismology. A seismometer array can be defined as (Schweitzer et al. 2012): “A seismic array is a set of seismometers deployed so that characteristics of the seismic wavefield at a specified reference point, within or close to the array, can be inferred by analyzing the waveforms recorded at the different sites. A seismic array differs from a local network of seismic stations mainly by the techniques used for data analysis. Thus, in principle, a network of seismic stations can be used as an array, and data from an array can be analyzed as data from a network. The size of an array is defined by its aperture, which is the largest horizontal distance between two sensors of the array. In practice, the geometry and the number of seismometer sites of an array are determined by the intended scientific purpose and economic limits.” The main purpose to install a seismic array is threefold. At first, an array can be steered as an antenna to amplify the signals of interest by stacking (summing) the seismic wave energy recorded at

the different array sites after applying appropriate phase delays. With these so-called “beamforming” techniques, arrays show superior signal detection capabilities with respect to single 3-component (3C) seismic stations. The second main purpose to install a seismic array is the capability to estimate the station-to-seismic source azimuth (backazimuth, BAZ) and the apparent velocity of unknown seismic signals crossing the array. Thirdly, a single seismic array often provides enough information about the incoming seismic signals that an automatic algorithm can be used to estimate a first (preliminary) solution of the seismic source location.

History of Seismometer Arrays

The history of seismometer array installations is going back to the 1950s. At that time, the idea of installing arrays of sensors to improve the signal-to-noise ratio (SNR) of a seismic onset was adopted from radio astronomy, radar, acoustics, and sonar. Since then, classified arrays deployed to monitor nuclear test activities at teleseismic distances have been built worldwide. In 1958, “The Conference of Experts to study the methods of detecting violations of a possible agreement on the suspension of nuclear tests” was held under the auspices of the United Nations in Geneva. This conference was followed up by several initiatives for improving the quality of seismic stations worldwide. Many of these classified arrays became known in the 1990s and are today part of the International Monitoring System (IMS) for the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) (see e.g., Douglas 2002; Dahlman et al. 2009) as primary or auxiliary stations, e.g., AKASG (Malin, Ukraine), ASAR (Alice Springs, Australia), BRTR (Keskin, Turkey), CMAR (Chiang Mai, Thailand), ESDC (Sonseca, Spain), ILAR (Eielson, Alaska), and KURK (Kurchatov, Kazakhstan). Many of these arrays have quite diverse geometries (Fig. 1) and in some cases comprise different installations for short-period (frequencies above 0.5 Hz) and long-period (frequencies below 0.1 Hz) signals as, e.g., the Belbaşı array nearby the Keskin array. Similar to arrays of seismometers, the

Seismometer Arrays, Fig. 1 Seismic arrays equipped with short-period or broadband seismic sensors in operation in December 2013 as part of the International Monitoring System (IMS) for the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO). The code name

with which it is registered in the international registry of seismic stations at the International Seismological Centre (<http://www.isc.ac.uk/registries/>) is provided for each array. All array maps are plotted in the same scale (Courtesy of S. J. Gibbons, NORSAR)

IMS includes also arrays of infrasound sensors and hydrophones, and similar data analysis techniques are applied as for data from seismic arrays.

To the best of knowledge, the first experimental seismic array with more than four elements and openly available data was established in February 1961 by the United Kingdom Atomic Energy Agency (UKAEA) on the Salisbury Plain (UK), followed in December 1961 by the Pole Mountain array (PMA, Wyoming, USA), in June 1962 by the Eskdalemuir array (EKA, Scotland, UK), and in December 1963 by the Yellowknife array (YKA, Canada). This array type

(known as UK array) is orthogonal linear or L-shaped, with apertures between 10 and 25 km. Later, arrays of the same type were built in Australia (Warramunga), Brazil (Brasilia), and India (Gauribidanur).

In the 1960s, arrays with very different apertures and geometries were tested, from small circular ones with apertures of a few kilometers to huge arrays with apertures of up to 200 km. The largest arrays were the Large Aperture Seismic Array (LASA) in Montana (USA), opened in 1965 and in operation until 1978 with 525 seismometer sites, and the original Norwegian

Seismic Array (NORSAR) in southern Norway, consisting of 132 sites over an aperture of approximately 100 km with altogether 198 seismometers, which became fully operational in spring 1971. The original NORSAR array was reduced in 1976 to seven subarrays and was assigned the new code name NOA.

LASA, NORSAR, and the UKAEA arrays had narrowband short-period seismometers (for signal frequencies around 1 Hz) at all sites and additional long-period seismometers (for signal periods around 20 s) at selected sites in their original configurations. In Germany, a new array type was planned and installed in the 1970s with an aperture of about 110 km. The Gräfenberg-Array (GRF) was installed on the limestone plateau of the Franconian Jura as the world's first seismometer array equipped entirely with broadband sensors (for frequencies between 0.01 and 8 Hz). Since then, the short-period and long-period sensors of many arrays were or will be in the near future exchanged with broadband seismometers.

In the 1980s, the geometry of the so-called regional arrays was developed. This is often called a NORES-type array design and has array sites located on concentric rings (each with an odd number of sites) spaced at log-periodic intervals. It is now used for the design of most modern, small aperture arrays; only the number of rings and the aperture (diameter of the outermost ring of sites) differ from installation to installation.

Another approach to seismometer arrays was developed in the 1990s. In parts of the world, the networks of seismometer stations became so dense that data from these single station networks could be combined and analyzed as data from a seismic array. Examples are the J-array in Japan, the German Regional Seismic Network, the Californian array, the Kyrgyz Network (K-Net), and the ongoing USArray project with semi-temporary stations. Most of the known array techniques could be applied to analyze data from these and other networks.

Array installations demonstrated during the last decades of the twentieth century that seismic arrays could facilitate detection and

characterization of seismic signals that was superior to that of single three-component (3C) stations. Today, many of the seismic stations of the IMS for the CTBTO are arrays (e.g., Dahlman et al. 2009).

During the last two decades, temporary, very small aperture arrays (apertures usually below 1 km) were used to investigate the distribution of (mostly) S-wave velocities below and nearby the array installation. Knowing S-wave velocities of the uppermost layers is essential for seismic hazard mitigation; for details see, (e.g., Schweitzer et al. 2012).

Further details about different array configurations can be found in the literature (e.g., Barber 1958; Haubrich 1968; Harjes and Henger 1973; Mykkeltveit et al. 1983). As examples of seismic arrays, Fig. 1 shows maps of all primary and auxiliary IMS arrays in operation in December 2013; note the huge variety in geometries, number of sites, and apertures.

Basics of Array Seismology

Basic Requirements for Seismometer Arrays

The observed apparent-velocity range and the dominant frequency content of seismic signals are quite different for different types of signals (i.e., local, regional, or teleseismic observations, body waves, or surface waves). Thus, the geometry, aperture, and instrumentation of seismic arrays have to be adjusted with respect to the scientific requirements of an array installation.

Proper analysis of array data depends on a stable, high-precision relative timing of all array elements. This is required because most of the parametric information calculated using an array involves the measurement of (usually very small) time differences (phase shifts) between the seismic signals recorded at the different sensors. Most array-data analysis algorithms assume that seismic energy crosses an array as a plane wave. From the theory of signal processing, it is known that signals can be constructively summed up as long as the time shift between the signals is not larger than about $\frac{1}{4}$ of the dominant signal period T . This rule applies also to the case of

seismic signals observed with an array. Many different effects can influence the arrival time of seismic onsets and thereby disturb the plane-wave approximation and should be taken in account when analyzing array data:

- Seismic waves usually propagate with spherical (in the case of body waves) or circular geometry (in the case of surface waves). Therefore, the aperture of an array should be small enough that the plane-wave approximation is still valid, i.e., the (theoretical) arrival-time differences with respect to the plane-wave approximation should be so small that they do not influence the analysis results.
- Since the fundamental work of Hans Benndorf (1870–1953) and Emil Wiechert (1861–1921) during the first decade of the twentieth century, it is known that in the case of a body wave, there is a direct relation between the observed (apparent) propagation velocity of a seismic wave, the ray parameter (the derivative of the travel-time curve), and the seismic velocity at the turning point of the observed seismic wave within the Earth. With an array of seismometers, this (apparent) velocity can be directly measured as long as all sensors are located in one horizontal plane.

In the case that the sensors are not located on one horizontal plane, the theoretical time shifts between the array sensors do not only depend on the propagation direction and (apparent) velocity of the plane wave but also on the wavelength-dependent seismic velocities below the array sites. If travel-time effects due to array topography become larger than about one fourth of the signal period, it becomes important for the accuracy of data analysis results to take this effect in account. However, analysis algorithms then become rather complicated, and if one plans for a new array, one should try to avoid this additional complexity and locate all seismometer sites on one horizontal plane.

- The seismic wavefield is always influenced by lateral heterogeneities in the Earth, which can disturb the plane-wave approximation due to velocity inhomogeneities. In particular local

lateral heterogeneities can have large effects. To avoid this, many arrays are built on homogeneous geological units, but this is not everywhere possible, and uniform geology at the Earth's surface does not guarantee that deeper structures are similarly homogeneous. Therefore, it is necessary to investigate recorded data from each seismic array for systematic effects which may disturb the plane-wave approximation.

- There are many examples of how timing-system errors at single array sites can produce difficulties for array-data analysis. However, stable and correct relative timing can be achieved by installing at the array a central clock, which distributes a common time signal to all digitizers at all array sites. Even in the case that this central timing system fails and has some offset to absolute time, all array-analysis algorithms can still be applied. So, whenever it is possible, a central timing system should be considered for new array installations.

The previously mentioned “beamforming” techniques delay (phase shift) and stack the signals from the different sensors. Due to constructive interference of the signals, the SNR is then enhanced, whereas the (random and uncorrelated) background noise is suppressed. One can show that a seismic array can theoretically improve the SNR by a factor of $\sqrt{M}$, where M is the number of array elements. Figure 2 shows an example from the GERES array in Germany. The tiny onset of a P phase, which was reflected at the Earth's core, was recorded with vertical sensors at 20 sites of the array. Figure 2 shows these data in blue and on top the array beam in red. On many single traces the signal is hardly discernible, but it is clearly visible on the beam trace due to the drastically improved SNR. To achieve the theoretical factor of $\sqrt{M}$, most array-data processing techniques require not only high clock stability of the recording systems at the different array sites and best knowledge about possible deviations from the plane-wave approach but also high signal coherency across the array.

Waveforms of seismic signals can be influenced by interference with wave energy

Seismometer Arrays, Fig. 2 Vertical seismograms (blue) with the onset of a tiny P onset reflected from the Earth's core (PcP) and recorded at 03:29:29.5 on 13 December 1990 with the GERES array after an earthquake in the Tyrrhenian Sea at an epicentral distance of

about 1,070 km. The top trace (red) shows the array beam of the shown vertical records after applying “delay-and-sum” processing. All data are Butterworth band-pass filtered between 0.8 and 4 Hz and equally scaled

scattered at heterogeneities along the entire ray path, and as a result, waveforms observed at different seismometer sites may significantly differ. Since high signal coherency is required for seismic arrays, such waveform-altering effects should be minimized by avoiding array locations close to known lateral inhomogeneous structures. This constitutes an additional reason to prefer installing seismic arrays at one relatively homogeneous geological unit, almost transparent to seismic waves. Since such local site effects are signal frequency dependent, signal coherency over the array also becomes frequency dependent, and this may impose constraints on array geometry, spatial extent, and instrumentation.

As mentioned earlier, seismometer arrays can provide estimates of the station-to-event azimuth (backazimuth, BAZ) and the apparent velocity of seismic signals. These estimates are important both for event location purposes and for signal identification and classification, e.g., as P, S, local, regional, or teleseismic phases. The slowness resolution of an array – i.e., how accurately

the propagation direction and the apparent velocity of a wave front can be measured – improves with increasing array aperture. However, the apparent velocity of a seismic onset changes with epicentral distance and the shape of a seismic waveform can change drastically due to interference with other seismic phases; in addition, signal coherency diminishes with increasing sensor separation. Therefore, when building an array, one has to find a balance between coherency and theoretical slowness resolution.

Finally, some remarks about the instrumentation of arrays. Traditionally, arrays were equipped with vertical sensors at all sites and only a few sites with additional horizontal sensors. This was mostly related to the additional costs for more sensors, data transmission, and data storage. However, many studies have shown that arrays equipped with more 3C sensors are superior in analyzing S-type onsets. Since costs for data transmission and storage have drastically dropped, one should always consider installing 3C instruments at all sites for new array installations.

The Array-Transfer Function

In signal-processing theory, the process of steering a seismic array to a specific target, i.e., optimizing the array beam for a given BAZ and apparent velocity of a seismic wavefield, can be described as a linear filter, which allows only signals with these characteristics to pass. In the case of an array, it is a two-dimensional filter, which is defined in the frequency-wavenumber (fk) space. The wavenumber k of a signal is defined as $k = 2\pi f/v$ or $k = 2\pi/\lambda$, where f is the frequency, λ is the wavelength, and v is the apparent velocity of the signal. Filter-transfer functions are mathematical descriptions of the filter characteristics (bandpass filter). The two-dimensional array filter is described by the sharpness of its main lobe (maximum of passing signals) and the position and relative height of eventually existing side maxima (side lobes). The narrower the main lobe and the smaller are eventual side lobes, the better the array's performance as a filter for signals with very specific BAZ and apparent velocity. For more details on the theory of seismic arrays, one may look in, e.g., Capon (1973), Aki and Richards (1980), Buttkus (2000), Johnson and Dudgeon (2002), Schweitzer et al. (2012), and the citations therein. By comparing array-transfer functions, the quality of an array of seismometers as a frequency-wavenumber filter can be discussed. The amount of literature about general criteria used to evaluate array-transfer functions for a given array geometry is huge, and some suggestions for more details are, e.g., in Harjes and Henger (1973) or Schweitzer et al. (2012) and the references therein. However, some general rules about transfer-function characteristics of seismometer arrays can be formulated as follows (from Harjes and Henger 1973; and Schweitzer et al. 2012):

1. The aperture a of an array defines the resolution of the array for small wavenumbers k . The larger the aperture is, the smaller the wavenumbers that can be measured with the array. The upper limit for the longest wavelength λ that can be resolved by array techniques is approximately similar to the aperture of the array. The array behaves like a single station for signals with $\lambda \gg a$.

2. The number of sites controls the quality of the array as a wavenumber filter, i.e., its ability to suppress seismic energy crossing simultaneously the array with a different slowness than the one on which the array is steered.
3. The distances between the seismometers define the position of the side lobes of the array-transfer function and the largest resolvable wavenumber: the smaller the mean distance, the smaller the wavelength of a resolvable seismic phase will be (for a given apparent velocity).
4. The geometry of the array defines the azimuth dependence of the aforementioned points.

Figure 3 shows two examples of such array-transfer functions, the ARCES array in northern Norway and the Yellowknife array in northern Canada for a 1 Hz signal. The geometry and aperture of these two arrays is included in Fig. 1. The ARCES shows no differences for signals from different azimuths, and the side lobes of the transfer function are far away (outside the plot) from the main lobe. However, because of the small aperture of only 3 km, this array cannot distinguish between waves with small wavenumber differences, as can be seen in the relatively wide main lobe of the transfer function. In contrast, in the case of Yellowknife, the main lobe is very narrow because of the much larger aperture of the array of about 25 km. This results in a much higher resolution in measuring small apparent-velocity differences. However, the array shows resolution differences for the different azimuths: the many side lobes of the transfer function along north-south and east-west oriented lines are caused by its cross-shaped geometry and the relative large distances between the single array sites.

For further reading, reviews on array theory, together with quite comprehensive citation lists, see, e.g., Douglas (2002), Rost and Thomas (2002, 2009), and Schweitzer et al. (2012).

Data Analysis Algorithms for Seismometer Arrays

One standard analysis technique for array data is the earlier described beamforming algorithm,

Seismometer Arrays, Fig. 3 The array-transfer functions of the circular ARCES array (*left*) and of the cross-shaped Yellowknife array (*right*) for a 1 Hz signal as

relative power (*color coded*) of the array response normalized with its maximum in [db] (Modified from Schweitzer et al. 2012)

also referred to as “delay-and-sum” processing. In seismic prospecting, “beamforming” is called “stacking.” An extension of this concept is the so-called “double-beam” technique, in which not only data of seismometer arrays are stacked but also the array beams of different seismic sources closely located to each other (Krüger et al. 1993).

Another standard array-data analysis technique is frequency-wavenumber analysis (fk-analysis). This method, originally developed for narrowband filtered one-component data, determines the slowness vector (i.e., BAZ and apparent velocity) for a single signal at a single frequency. Fk-analysis can be performed either in the frequency domain or the time domain (see Schweitzer et al. 2012). Fk-analysis applies systematically different phase shifts (or delay times) to a selected time window of the different array-site data and calculates the power of the seismic wave. By searching for the maximum power, the algorithm estimates the corresponding BAZ and apparent velocity of the signal. A variety of fk-analysis algorithms have been developed, which mostly differ in the method applied to find this maximum: e.g., maximum-likelihood method (Levin 1964; Capon et al. 1967, 1973), maximum-entropy method (Burg 1964), multiple

signal classification (MUSIC) algorithm (Schmidt 1986), and various adaptive algorithms for the estimation of spectral power density (e.g., Goldstein and Archuleta 1991). Later, fk-analysis was expanded to wider frequency bands and 3C data (Kværna and Doornbos 1986), the inversion for spherical waveforms (Almendros et al. 1999), and arrays with incoherent data (Gibbons et al. 2008, 2012).

One can also directly measure signal-arrival times at the different array sites and invert the observed travel-time differences for the best fitting plane wave. The (relative) arrival times can be either determined by an analyst or by automatic arrival-time-picking algorithms, as, e.g., by correlation analysis (Cansi 1995).

One widely applied technique to analyze data observed with an array is the VElocity SPectrum Analysis (VESPA) process (Davies et al. 1971), also called *vespagram*. This algorithm is very similar to the time-domain version of the fk-analysis, but it measures the power of seismic signals from a constant BAZ with different apparent velocities as function of time to investigate apparent-velocity changes for the different onsets in a seismogram. Later, the *vespagram* concept was expanded by calculating the observed power from different azimuths for a constant, specific

apparent velocity. In this case, the vespagram is a very useful tool to investigate the BAZ of the seismic phases, their precursors, and in particular the scattered energy of seismic waves arriving after seismic onsets.

Seismological Research with Seismometer Arrays

There are numerous publications from authors using data of seismometer arrays, which cannot be discussed in detail herein. In the following, only some general topics are named to illustrate the diversity of array-seismology applications.

Seismic array data have been used to detect and investigate all kinds of small amplitude phases: seismic onsets observed in front of seismic phases, which had traversed the Earth's core (PKP), were often interpreted as regular seismic phases, which led to many, quite controversial velocity models of the lower part of the outer core of the Earth. Using array observations it could be shown that these precursors are scattered energy from lateral heterogeneities in the Earth's interior and not regular seismic phases. There exist numerous array-data studies of the global and local structure of the lower mantle, the laterally heterogeneous lowermost part of the mantle directly above the core-mantle boundary (known as D'' region), the core-mantle boundary, and the inner-core boundary.

Also strong-motion instruments have been installed in array configurations at the Earth's surface, as well as in boreholes to study near-field effects of earthquakes, and arrays were used to track the aftershock activity after larger earthquakes or to monitor earthquake swarms. In combination with cross-correlation techniques, this became a very powerful tool to lower the detection thresholds for seismic events in monitored areas. Similar is the quite recent approach to track the earthquake slip process itself with array data observed at teleseismic distances. For such studies data from seismic networks are combined to virtual arrays and analyzed.

Seismic arrays have been used to measure dispersion curves of surface-wave velocities.

This technique became recently quite important in context with seismic risk and hazard studies. Since ambient noise mostly consists of surface-wave energy, one can use local dispersion-curve data, measured with temporary, very small aperture arrays, to invert for the near-surface S-velocity structure; for further details see, e.g., Schweitzer et al. (2012).

Seismic arrays are also used to investigate the nature and source regions of microseisms and to locate and track volcanic tremor for analyzing complex seismic wavefield properties in volcanic areas.

The capability of seismometer arrays to locate seismic events was already mentioned at the beginning of this chapter. The data analysis of arrays can be automated for signal detection and fk-analysis of the detected onsets. Then, BAZ observations can be used together with additional travel-time constraints to automatically group the onsets to events. The observed apparent velocities can be used to classify the type of seismic onset, together with other signal characteristics, as, e.g., the dominant frequency. This way, P- and S-type onsets from local and regional events can be automatically identified with the use of small aperture, regional arrays and the associated seismic event can be located. A detailed description of such an automatic regional event location algorithm can be found in (Schweitzer et al. 2012).

Apparent-velocity observations from seismic arrays of at least 10 km aperture can be directly inverted to an epicentral distance for the first arriving P-type onsets from seismic events at teleseismic distances (i.e., from about 22° to about 100° epicentral distance). Knowing the epicentral distance, the observed BAZ can then be used to define the epicentral coordinates. This algorithm cannot be applied to local or regional events because measurable apparent velocities of the P-wave onsets can no longer directly be inverted to epicentral distance. At distances beyond ~90°, these derivatives become again very small for P waves, and in the Earth's shadow zone (distance >100°), the interpretation of the different core-phase onsets is also quite difficult and limits the location capabilities

of a seismic array. The described event location technique has been in use at least since the 1960s, and a quick look in the bulletins of the International Seismological Centre shows the huge amount of reported teleseismic event locations made with, e.g., the Large Aperture Seismic Array (LASA) in Montana, USA, the Yellowknife Array (YKA) in Northern Canada, the Gräfenberg Array (GRF) in Bavaria, Germany, or the large Norwegian Seismic Array (NOA) in southern Norway.

For further reading, more details on the research topics mentioned herein and for many more array applications in seismology, together with quite comprehensive citation lists, see, e.g., Gibbons et al. (2008, 2012), Rost and Thomas (2002, 2009), and Schweitzer et al. (2012).

Summary

A seismometer array is a set of seismic sensors deployed so that characteristics of the seismic wavefield at a specified reference point can be inferred by analyzing together the waveforms recorded at the different array sites. Seismometer arrays have been shown to be superior to single, 3C stations: they are able to lower the detection threshold for seismic onsets due to beamforming; they are able to measure the apparent velocity of seismic onsets and their propagation direction; they can be used to locate seismic events in an automated data processing scheme; and they are very successful tools to investigate the Earth's interior on local, regional, or global scale.

Introduction

Seismometer self-noise is usually not considered when selecting and using seismic waveform data in scientific research as it is typically assumed that the self-noise is negligibly small compared to seismic signals. However, instrumental noise is part of the noise in any seismic record, and in particular, at frequencies below a few mHz, the instrumental noise has a frequency-dependent character and may dominate the noise. When seismic noise itself is considered as a carrier of information, as in seismic interferometry (e.g., Chaput et al. 2012), it becomes extremely important to estimate the contribution of instrumental noise to the recordings.

Noise in seismic recordings, commonly called seismic background noise or ambient Earth noise, usually refers to the sum of the individual noise sources in a seismic recording in the absence of any earthquake signal. Site noise (e.g., cultural sources, nearby tilt signals, etc.) and noise introduced by the sensitivity of an instrument to non-seismic signals (e.g., temperature and pressure variations, magnetic field changes, etc.) both contribute to the ambient seismic noise levels. The background noise ultimately defines a lower limit for the ability to detect and characterize various seismic signals of interest. Background noise levels have also been found to introduce a systematic bias in arrival times because the amplitude of the seismic phase must rise above the station's noise levels (Röhm et al. 1999). The upper limit of useful signals is governed by the clip level of the recording system (the point at which a recording system's output is no longer a linearly time-invariant representation of the input).

Site noise can be reduced by careful site selection (e.g., hard rock far from strong noise sources) and by emplacing instruments in good vaults or boreholes. It is also possible to reduce sensitivity to non-seismic signals by thermal insulation and appropriate shielding such as pressure chambers (Hanka 2000). At quiet sites with well-installed instrumentation, instrument noise may be the dominant noise source

(Berger et al. 2004); this is especially true for long-period seismic data (>100 s period) on very broadband instruments (e.g., Streckeisen STS-1 seismometer). The interpretation of such data only makes sense if the instrumental noise level is known. Also, research on noise levels in seismic recordings, the effect of noise reduction by the installation technique, and the nature and contribution of different noise sources to the recordings require knowledge of instrumental self-noise to rule out bias from the instrumentation self-noise.

A number of tests have been developed, under the assumption that instrument self-noise is approximately constant as a function of time (e.g., Evans et al. 2010; Holcomb 1989, 1990; Sleeman et al. 2006). Only recent studies have started to look at the potential time dependence of instrument self-noise (e.g., Sleeman and Melichar 2012). Understanding the self-noise of a given piece of recording equipment helps station operators to better identify sites that can take advantage of low-self-noise instruments. This knowledge also allows a network operator to provide higher-quality data with limited resources by making better use of their high-quality instruments. Having a rough understanding of an instrument's self-noise also gives a first-order diagnostic for determining if the recording system, as installed, is performing satisfactorily.

In order to estimate the self-noise of a seismometer, it is necessary to remove non-instrumental noise signals (e.g., earthquakes and ambient Earth noise) from the data. This is often accomplished by using coherence analysis techniques. In its simplest form, one can select a quiet time period at a low-noise site and attribute all recorded noise to the sensor (one-sensor method). However, it can be difficult to find stations with sufficiently low site noise to evaluate high-quality broadband seismometers. This is especially true at periods between the primary and secondary microseism (approximately 4–22 s period). In such cases, more sophisticated techniques, where one removes coherent signals using colocated instruments, are required. This can be done using a second instrument or two additional instruments (two- and three-instrument methods). For passive sensors, it

is possible to obtain an estimate of the self-noise by locking the mass of the instrument.

This is a general overview on the various methods currently used for estimating the instrument self-noise when using one, two, or three sensors. As there is no universally “best” method for all types of instruments and test conditions, some of the advantages and disadvantages of each method are discussed. Variants of these methods, such as rotating horizontal components of Earth motions to maximize the coherence and correcting for misalignments, are also included. Finally, the test setup used for estimating self-noise for the various methods is discussed and examples of corresponding test results are given.

Methods

To discuss the various methods currently in use for estimating the self-noise of a seismometer, a mathematical framework common to all the methods is developed. The system under test is assumed to be a linear time-invariant system (LTI) making the system completely determined by its impulse response (Scherbaum 2007).

Basic Assumptions and Conventions

Let x_i denote an input seismic signal, h_i denote the seismometer's impulse response, and n_i denote the self-noise of instrument i . Then the instrument's output signal y_i can be modeled, in the time domain, as

$$y_i = h_i * (x_i + n_i) \quad (1)$$

where “*” denotes convolution (Holcomb 1990; Sleeman et al. 2006). It is possible to write this in the frequency domain as

$$Y_i = H_i \cdot (X_i + N_i), \quad (2)$$

where capital letters denote the Fourier transforms of the corresponding lowercase letter time domain terms of index i . With the assumption that the self-noise of two different instruments is incoherent, the term $N_{ij} = N_i N_j$ is zero for $i \neq j$. It is

Seismometer Self-Noise and Measuring Methods, Fig. 1 Self-noise estimates of the vertical component of the STS-2 seismometer for the minimum noise (green) and the mode (red) of sensor noise measured at the Conrad Observatory, Austria. The light gray and dark gray bands

depict the 95 % and 68 % percentile power spectral density (PSD) estimates. Finally, median (blue) and minimum (black) self-noise estimates for the STS-2 are taken from the data at the Albuquerque Seismological Laboratory (ASL)

also assumed that the self-noise and the input signal are incoherent, $X_i N_j$ is zero for $i \neq j$. The cross power between instrument i and j is denoted by P_{ij} so for $i \neq j$ we can write the cross power as

$$P_{ij} = H_i X_i \overline{H_j X_j} \quad (3)$$

where the bar denotes the complex conjugate. The coherence between instruments i and j is given by

$$\gamma^2 = \frac{|P_{ij}|^2}{P_{ii} P_{jj}} \quad (4)$$

Finally, it is assumed that all of the instruments in the test have common output units so that they have similar ground motion units (e.g., m/s or m/s²) after removing the instrument response. This assumption can generally be made true by using an “omega correction” (multiplying or dividing by $\omega = 2\pi f$, where f is the frequency) in the frequency domain (Stearns 1975).

Noise levels are often compared to absolute Earth noise models such as Peterson’s New Low-Noise Model (NLNM) and New High-Noise Model (NHNM), which are global seismic

noise models derived from the 74 Global Seismographic Network (GSN) stations along with one additional station (Peterson 1993). This NLNM represents the lower envelope of 2,000 data records and represents an approximation of the lowest observed seismic noise levels, whereas the NHNM represents the upper envelope of the same 2,000 data records and represents an approximation of the highest observed seismic noise levels (Fig. 1).

Single-Sensor Method

When testing instruments at locations where the site noise is well below the self-noise of the instrument, it is possible to attribute the power in a given frequency band entirely to the instrument’s self-noise (Fig. 2). This often occurs when testing strong-motion accelerometers in a quiet vault or lower-grade sensor in almost any good site (Evans et al. 2010). In such cases the simple relation is obtained:

$$N_{ii} = \frac{P_{ii}}{H_i \overline{H_i}} \quad (5)$$

assuming that $X_i \ll N_{ii}$. Even when this assumption is not satisfied across the entire frequency

Seismometer Self-Noise and Measuring Methods,

Fig. 2 Self-noise estimates for a strong-motion accelerometer using the single-sensor method (red), the Sleeman (Sleeman et al. 2006) three-sensor method (green), and the Holcomb (Holcomb 1989) two-sensor method (blue). For reference the New Low-Noise Model (NLNM) is included (black)

band, it is often possible to get an initial estimate of the instrument's self-noise in a specific frequency band (e.g., outside the primary and secondary microseism bands for state-of-the-art accelerometers). The single-sensor method can also be used to get an upper bound on the self-noise of an instrument. If this upper bound is obtained at a relatively quiet location, it might characterize the self-noise sufficiently well to identify the suitability of an instrument at a station with potentially much higher site noise. This method gives a first approximation of an instrument's self-noise, which can be valuable when testing time is limited or there are insufficient resources to use multiple sensors.

Two-Sensor Methods

Estimating self-noise using two sensors has been the traditional method for noise testing broadband seismometers for many years (Holcomb 1989). As very few locations have background noise levels below that of high-quality broadband sensors across a wide frequency range, it becomes important to remove the local background noise (Fig. 3). Assuming that the colocated sensors are recording similar seismic

signals (same ground motion), $X_i = X_j$, it is possible to derive the self-noise of instrument i from Eq. 2. Recalling the assumption that $N_{ij} = 0$ for $i \neq j$ we have

$$N_{ii} = \frac{P_{ii}}{|H_i|^2} - \frac{P_{ij}}{H_i H_j^*}. \quad (6)$$

Under the assumption that the sensors both have well-known responses, the instrument corrected output, from the two sensors, should only differ in instrumental self-noise. By estimating the coherent signal between the two records, the coherence signal is removed resulting in the incoherent signal which is attributed to the self-noise. It can be seen from this estimate of the self-noise that it is critical to have well-described transfer functions for both instruments i and j . Since the transfer functions are used in the calculation, errors in the transfer function will produce errors in the self-noise estimates of the instrument. This method was originally proposed by Holcomb (1989), who later characterized error sources (Holcomb 1990). In the latter work, Holcomb also suggested alternative two-sensor methods, under the assumptions that the two sensors

Seismometer Self-Noise and Measuring Methods, Fig. 3 Comparison of five different methods for estimating the self-noise using vertical broadband sensor data: the one-sensor (direct power spectral density (PSD)) method (blue), the three-sensor Sleeman (Sleeman et al. 2006) method (green), the two-sensor Holcomb (Holcomb 1989) method (light gray), the two-sensor γ^2 Holcomb

method (red), and the two-sensor Tasič (Tasič and Runovc 2012) method (cyan) (for the different methods, see text). The cyan and red lines overlay at frequencies less than approximately 0.01 Hz. For reference the New Low-Noise Model (NLNM) is the solid black line. The elevated noise in the microseism band is caused by misalignment

under test have equal noise and a high signal-to-noise ratio (ratio of input signal to instrument self-noise). In this case, it is possible to derive the following estimate for the self-noise of instrument i :

$$N_{ii} = \frac{\left(P_{ii} \frac{(1 - \gamma^2)}{\gamma^2} \right)}{H_i \overline{H_j}}. \quad (7)$$

Using a related approach, Tasič and Runovc (2012) develop a different method for estimating the self-noise using two instruments. In their approach the self-noise of instrument i is given by

$$N_{ii} = \frac{P_{ii}(1 - \gamma^2)}{(H_i \overline{H_j})} \quad (8)$$

where again they assume the signal-to-noise ratio is large.

Three-Sensor Method

Using three colocated sensors, it is possible to estimate the self-noise of each instrument while minimizing errors in the estimate due to uncertainty in the transfer functions (Sleeman et al. 2006). This method has become the preferred approach for estimating self-noise for broadband sensors, even though it requires additional resources and setup; it typically “sees through” site noise more deeply to extract lower estimates of instrument noise.

Using Eq. 2 and the assumption that $X_i = X_j = X_k$, one can estimate the self-noise of instrument i as

$$N_{ii} = \frac{\left(P_{ii} - P_{ij} \frac{P_{ik}}{P_{jk}} \right)}{H_i \overline{H_l}}. \quad (9)$$

The term P_{ik}/P_{jk} can be viewed as a “relative transfer function” H_{ij} between instruments i and j . The three-sensor method is related to the

Seismometer Self-Noise and Measuring Methods,

Fig. 4 Self-noise estimate of the Geotech GS-13 geophone using a theoretical self-noise model (blue) versus the estimated low self-noise model of the Geotech GS-13 (red) from 11 self-noise measurements; the median self-noise from these 11 tests is also shown (green). The self-noise of the digitizers used, Quanterra Q330HRs, is also shown after correction with the response of the Geotech GS-13 (cyan). For reference the New Low-Noise Model (NLNM) is included (black)

two-sensor method developed by Tasič and Runovc (2012) when one compares relative transfer functions. It is important to note that the transfer function of instrument i is only used to convert the noise estimate to units of ground motion; thus, errors in the transfer functions do not propagate to the self-noise estimate before deconvolution with the individual instrument (Ringler et al. 2011). Because the three-sensor method is not as sensitive to errors in the transfer functions, it extracts the self-noise with a potentially higher accuracy than the two-sensor method (Fig. 3).

Other Techniques

When instrument designers are selecting components for building a seismometer, they often have noise estimates for each electronic component as well as estimates of fundamental noise contributions (e.g., Brownian noise). Through modeling these individual noise sources, it is possible to estimate the total self-noise of a seismometer without having a working prototype. A modeling example for Brownian noise is described by Aki and Richards (2002), using the physical parameters of a simple gravitational pendulum. Such methods often give a first approximation of the instrumental noise to be aimed for during design (Fig. 4).

Such theoretical methods for estimating the self-noise of an instrument have been applied to a number of seismometers in conjunction with their digitizers (Rodgers 1994). However, when such methods are used, a number of assumptions must be made (e.g., that the pendulum obeys the small-angle approximation and all electronic components perfectly match their specified noise levels).

For seismometers that are not controlled by feedback but having self-noise well below any available test site's ambient noise, such as geophones at high frequency (e.g., GeoTech GS-13), it is possible to estimate the self-noise using a "locked mass" test (Havskov and Alguacil 2004). This test is performed by locking the mass of the instrument and recording the output of a single instrument. This test provides a lower noise-bound estimate but may not fully characterize the self-noise of the instrument because it lacks noise contributions from moving hinges and other mechanical sources.

Testing and Analysis

Characterizing the self-noise of a seismometer requires attention to detail in the test setup,

Seismometer Self-Noise and Measuring Methods,

Fig. 5 Three colocated Geotech GS-13 short-period seismometers setup for test to be sensitive to vertical ground motion. All three are sitting on a granite slab supported at three points and are in the Albuquerque Seismological Laboratory (ASL) underground vault. On the back right is a reference Streckeisen STS-2 seismometer in a steel bell jar (not used in the test)

careful selection of data windows to avoid transients, identification of potentially non-seismic noise sources, and methods for selecting data to analyze. In both the two- and three-sensor methods, it is necessary to make sure all instruments truly are recording the same ground motion.

Test Setup

Both the two- and three-sensor methods assume that all instruments are recording the same ground motion. In order for this to be true, it is critical that the instruments be colocated and co-aligned. Furthermore, since local tilt signals can vary widely over even a few inches, one must take care to insure that all three instruments are measuring similar tilt signals so that they can be removed using coherence analysis. Locating all instruments on a stiff slab (e.g., granite or gabbro) with a three-point suspension is usually sufficient for this purpose (Fig. 5).

It is also important to isolate the instruments from non-seismic noise sources (e.g., temperature variations, pressure variations, locally induced tilt). These noise sources can increase the self-noise estimate of the individual instruments as they generally do not respond coherently to such sources (Anderson et al. 2012). Misalignment of the horizontal components can

also contribute to a decrease in signal coherency and increase the estimate of the self-noise. Such relative errors in misalignment can be seen by elevated incoherent noise-level estimates in the microseism band (Fig. 6), so it is possible to reduce such misalignment errors by rotating the instrument outputs numerically to maximize coherence (Tasič and Runovc 2012). Recent work by Gerner and Bokelmann (2013) shows that the leakage of microseism signals into the self-noise can be eliminated successfully by numerical rotation of the three-component traces and using the three-sensor method. Their study optimally aligns two RefTek 151-60A sensors with a third one and shows that self-noise estimates outside the microseism bands are not compromised by misalignment errors.

Finally, if one wants to isolate the self-noise of a seismometer, it is critical that the digitizer and other recording equipment have self-noise levels well below that of the sensor. This can be a problem on low-gain instruments, such as strong-motion accelerometers. Verifying that the digitizer's self-noise levels are below that of the seismometer requires a terminated-input test of the digitizer, using a terminating resistor similar to the output impedance of the sensors to be tested. When the digitizer's noise level is not below the seismometer noise level for any of the

Seismometer Self-Noise and Measuring Methods, Fig. 6 Self-noise estimates from three horizontal very broadband Metrozet M-2166 seismometers (flat to velocity from 0.0028 to 10 Hz) using Sleeman (Sleeman et al. 2006) three-sensor self-noise estimate (solid lines). Single-sensor estimates are in dotted lines. In order to minimize incoherent tilt noise, all three instruments were

installed with the same orientation on the same baseplate and the baseplate is supported at three points only. The relatively small increase in the self-noise in the secondary microseism frequency band (at approximately 0.125–0.25 Hz) suggests all three instruments are well aligned to one another

frequency range of interest, digitizer preamps generally can be used for low-noise amplification of the sensor signal to a level above the digitizer noise level.

Data Selection

Data selection is currently an important item in the development of algorithms and techniques to estimate self-noise. This requirement makes it necessary to estimate self-noise during only “quiet” time periods (e.g., during nighttime and periods with low pressure-induced tilt noise). No current agreement exists as to whether data selection should be applied or not, or which criteria should be used for data selection. In particular, when features in the data are not fully understood, the debate on data selection is ongoing and not yet entirely resolved, though a best-case result seems to require such minimization (Ringler et al. 2011). For example, the

occurrences of periodic pulsing in the data are not yet understood (though many have been named “popcorn noise,” “spherics,” and so forth and are tentatively explained in various ways). Some of these noise sources could properly be considered either as part of the self-noise of the instrument or as transient external signals that would artificially elevate the self-noise if included (Sleeman and Melichar 2012). The discussion on data selection of time segments becomes even more controversial when limited amounts of data are available. By using multiple quiet time segments, it is possible to understand the self-noise of an instrument in at least a best-case scenario (Ringler and Hutt 2010). One such example of a best-case scenario, along with a self-noise estimate using the median of multiple tests, is shown in Fig. 4. This example also suggests that even when using coherency analysis techniques, it is important to do such tests in a

low-noise environment. The selection of time segments is additionally controversial when limited amounts of test data exist, because the assumption that the self-noise of a seismometer is time invariant is only approximately true, as seen in the relatively large gray bands in Fig. 1, which depict the 95 % and 68 % of the self-noise of the Streckeisen STS-2 seismometer as recorded under very stable conditions at the Conrad Observatory (Vienna, Austria) over an entire year.

A synthetic-data experiment by Sleeman and Melichar (2012) shows that the three-sensor technique can reliably extract instrumental noise even for high “seismic-signal-to-instrumental-noise (SNR)” ratios, but is in practice limited to lower ratios due to misalignments or mis-leveling between the sensors. As discussed earlier, small alignment or leveling differences between the sensors decrease the coherency between the recordings and thus affect the noise estimate. It was found that an alignment error of 0.2° in any axis allows the technique to extract self-noise for SNR values up to 60 dB, which was confirmed in their associated experiment using real data. As this order of misalignment between corresponding axes in similar colocated sensors is in agreement with the precision of best-practices manufacturing, one should only use data taken during “quiet” time periods (SNR below 60 dB, e.g., during night and periods with minimal pressure-induced tilt). Even during these times, microseism noise can make it difficult to estimate the self-noise of broadband sensors in the period bands of 4–8 s and 18–22 s for instruments (Ringler et al. 2011).

Analysis Parameters

As in any time series analysis, appropriate time window lengths, number, and overlapping must be used to resolve the low frequencies of interest while minimizing variance. For very broadband seismometers, it is often of interest to understand the self-noise for periods up to several thousands of seconds, which corresponds to a total window length of at least 8 h divided into overlapping sub-windows, each of about an hour (e.g., Table 1 of Evans et al. 2010).

To directly compare results between noise tests, it is important that the tests be conducted using similar methods (e.g., settling time, installation methods, data selection, and spectral processing parameters).

Expected Results and Caveats

A discussion on the expected self-noise results for various types of seismometers now follows. This discussion is in no way exhaustive but simply discusses some of the more common situations and what is generally expected for various test scenarios.

Strong-Motion Accelerometers

The noise levels of strong-motion accelerometers make estimating the self-noise of such sensors easier than typical low-noise broadband sensors (Fig. 2). Since the user community is generally only interested in strong motions with frequencies from a few Hz to a few tens of seconds period, it is often possible to resolve the self-noise using relatively short testing intervals.

As noted earlier, one must be careful to make sure that the digitizer noise is below that of the sensor. Since strong-motion accelerometers are generally sampled at higher rates than broadband sensors (≥ 100 sps), it is necessary to identify the self-noise to much higher frequencies than for broadband sensors (Cauzzi and Clinton 2013). At these higher frequencies, it becomes more difficult to isolate the instrument from potentially non-seismic noise sources such as electrical power grid frequencies (e.g., 50 Hz in Europe and 60 Hz in North America) noise. At these higher frequencies, the coherency between recordings from colocated sensors presumably decreases, but this decrease in coherency is typically compensated by decreasing ambient noise and increasing instrument self-noise.

Broadband Seismometers

After installing a broadband seismometer, it is important to let the instrument fully settle down from mechanical stresses that can build up during transport and adjust to temperature before

Seismometer Self-Noise and Measuring Methods, Fig. 7 Colocated Streckeisen STS-2 sensors at the Conrad Observatory, Austria. Sensor casings are co-aligned by parallel grooves in the underlying glass plate. Thermal

insulation consists of thin layers of neoprene around the sensors, which also reduces the noise contribution due to air convection around the sensors

attempting to estimate the self-noise. What constitutes an instrument that is “fully settled” is not well understood and currently a topic of some controversy. After the instrument has been allowed to settle, one can estimate the self-noise by using long-running quiet time periods (Hutt et al. 2010). Local changes in wind and pressure can introduce incoherent elevated noise levels on horizontal channels at long periods (e.g., >100 s period) as well as short (e.g., <1 s period).

Estimates Using Other Data Selection Techniques

Although the process of self-noise measuring is not yet mature, the methods and techniques are rapidly improving. As manufacturers’ abilities to reduce sensor noise levels improves, methods for measuring the self-noise will also need to improve. A better understanding of the sensitivity of seismometers to non-seismic phenomena and techniques to thermally isolate the sensors (e.g., Fig. 7) or correct the data from these sources will be needed. Although there has been initial work on this subject (e.g., Forbriger et al. 2010; Zürn et al. 2007) with promising results, there is still much to be done before these methods become widely used by the seismological community.

Other Geophysical Instruments

The above methods for estimating seismometer and accelerometer self-noise can be applied more generally to other instruments and recording

systems. As the only assumptions are that all instruments will have a common input signal and output units, it is also possible to estimate the self-noise of digitizers (a “terminated noise” test), infrasound sensors (Hart et al. 2007), tilt meters, gravimeters, and rotational seismic sensors.

In all cases, the general approach for estimating the self-noise will be similar, though the details may differ (e.g., test setup logistics, frequency band of interest, etc.). For a discussion on applying the three-sensor self-noise technique to digitizers, the reader is referred to Kromer (2006) and Sleeman et al. (2006). Details on applying self-noise techniques to other geophysical instruments are beyond the scope of this entry.

Summary

With the suite of various methods for testing seismometer self-noise, it is possible to get an initial estimate of the self-noise of a seismometer even in less-than-ideal testing situations. For instruments with relatively high self-noise, simple (one-sensor) self-noise methods may prove sufficient.

Using additional high-quality sensors and more sophisticated techniques (two- or three-sensor methods) can help to eliminate common signals when there is concern of the local background noise being above the sensor’s self-noise.

This will almost always be the case when testing broadband seismometers, but will not necessarily be the case when testing accelerometers though at least microseisms are above the noise floor of the state-of-the-art accelerometers even at an inland continental site.

Equally important to the two- and three-sensor methods is that the common seismic signals be coherent among all instruments in the test. As discussed, this can be done by installing the instruments in a quiet vault on a granite slab or other stiff material to increase the coherence among sensors. Care should also be taken to reduce the influence on instruments under test from local non-seismic noise sources such as pressure or temperature variations and that adequate thermal settling time be provided before testing.

Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the US government.

Introduction

Until the advent of the broadband seismometer (Wielandt and Streckeisen 1982), electrodynamic geophones were used for picking up short-period (1 s and less) earth movement, and LP (long period) seismometers were used for anything with lower frequency than one second. Owing to their bulk and weight, LP seismometers are not practical for use in the field; they typically require a controlled observatory-type environment. Most types of geophones, on the other hand, are by their very nature field worthy, compact, and cheap. This is because they are mass-produced for use in seismic exploration where they are typically deployed in large numbers (hundreds or thousands). The downside is that their natural frequency is usually 4.5 Hz or more. Some geophones designed for scientific use have a natural frequency of 1 Hz, but this low-frequency limit comes at the expense of

significant bulk and weight and an unwelcome increase in mechanical complexity.

Thus, combining the ruggedness of the short-period geophone with the extended frequency response of an LP seismometer has long been a goal for researchers and instrument makers alike.

Geophone Frequency Response

In its simplest form, a geophone consists of a mass suspended by a spring. To pick up the relative motion between the mass (which, due to inertia, tends to remain steady) and the frame (which will follow the motion of the Earth's surface), a moving coil system is typically used. A coil that is attached to the suspended mass moves in a magnetic field provided by a permanent magnet attached to the frame, thus providing an electrical output voltage that is proportional to the relative velocity between mass and frame.

If the suspended mass were an ideal oscillator (i.e., without any damping forces at play), a geophone would not pick up Earth motion very faithfully. In fact, a single impulse would cause it to oscillate forever at its natural frequency. A certain amount of damping is always provided by mechanical damping (friction) and electromagnetic damping, with the latter being responsible for the major part of damping. Electromagnetic damping is a consequence of Lenz's law (in a closed circuit moving inside a magnetic field, a current is induced which in turn generates a magnetic field opposed to the original magnetic field, thus resulting in a force counteracting the movement of the conductor), and is proportional to the sum of the coil resistance and the external load on the coil (the input resistance of the amplifier or recorder).

In a plain geophone (without any active electronics involved), the minimum amount of damping is given by the open circuit damping (typically in the range 0.25–0.5, but some commercially available geophones go down to 0.02 (Rodgers 1993)), meaning there is no external load connected. With no external load connected,

Seismometer, Extended Response,

Fig. 1 Geophone frequency response for different damping factors (normalized to be 1.0 for $f \gg f_0$)

the circuit is open, no current flows through the coil, and no additional damping is contributed by the coil. The other extreme is a shorted coil – in this case, the external load is $0 \, \Omega$, and only the intrinsic resistance (inductive reactance, to be more precise) limits the amount of current flowing. Consequently, this setup provides the maximum possible amount of damping (this is why classical geophones should be transported only with the output coil(s) shorted – the high damping will help inhibit extraneous mass movement).

The modulus of the complex transfer function of an electrodynamic geophone with respect to ground velocity depends on damping as follows (Bormann 2012, Chapter 5.2):

$$H_V(\omega) = \frac{\omega^2}{\sqrt{(\omega_0^2 - \omega^2)^2 + 4h^2\omega^2\omega_0^2}} \quad (1)$$

where h is the damping factor expressed as the ratio of actual to critical damping (when $h = 1$), ω is angular frequency, and ω_0 denotes the natural angular frequency.

Figure 1 shows the modulus of a geophone's transfer function to ground velocity over a wide range of frequencies for different damping

factors, ranging from open circuit (very low damping, strong resonance peak) to 1.0. Usually, the desired value is 0.707 of critical damping (thick line). At this setting, the modulus of the transfer function at the natural frequency is 0.707 ($0.5\sqrt{2}$).

Since open circuit damping is lower than the desired value of 0.707, an external damping resistor (often referred to as a “shunt”) is used to achieve higher damping. An inevitable consequence of shunting the geophone coil is that its output decreases (because the external resistor and the geophone coil resistance form a voltage divider). In the flat part of the transfer function, the geophone's output is proportional to

$$\left(\frac{R_d}{R_d + R_{\text{coil}}} \right) \quad (2)$$

where R_d is the damping (shunt) resistance, and R_{coil} is the coil resistance.

This fact has been deliberately omitted from Fig. 1; all curves have been normalized to 1.0 for frequencies much higher than the natural frequency.

For frequencies $\ll f_0$, the geophone's output rolls off at $-12 \, \text{dB/octave}$ (proportional to f^2). For frequencies $\gg f_0$, the transfer function is flat.

Methods of Frequency Response Extension

Extending the low-frequency response of a geophone without increasing its bulk and weight can be achieved with several methods. The most common ones will be briefly outlined here.

Using an Inverse Filter

An electronic filter can be implemented to compensate the geophone's roll-off at low frequencies (Havskov and Alguacil 2004). In real life, the filter's transfer function cannot increase indefinitely towards lower frequencies. A new fictitious natural frequency is defined by the point where the filter's transfer function returns to being flat. Figure 2 shows the schematic function of an inverse filter (Lippmann 1982).

Intriguing as it may seem at first sight, this approach is plagued with many practical problems. Noise appearing in electronic circuits is not necessarily "white," i.e., equally distributed over a wide frequency range. There is one particularly annoying type of noise called $1/f$ noise, which, as its name implies, means it gets increasingly stronger the lower the frequency gets. This phenomenon occurs below a certain corner frequency

which, unfortunately, typically is found to be not less than a few Hz – a typical operation amplifier such as the OP-27 has a $1/f$ corner frequency of 2.7 Hz (Analog Devices 2006). Since the inverse filter method requires an increasing amount of amplification towards lower frequencies, intrinsic $1/f$ noise will be amplified overproportionally. Further, maintaining thermal stability of low-frequency circuits is not trivial. Thus, signal-to-noise ratio for low frequencies will be problematic. Also, the signal chain may take a prohibitively long time to recover from even a brief overload. Inverse filtering was applied in the 1960s–1980s but, owing to its drawbacks and the advent of superior methods, is no longer in practical use today.

Positive Feedback

As outlined previously, the bare-bones version of a geophone consists of a coil suspended by one or more springs, and moving in a magnetic field. When motion occurs, a voltage is induced across the coil's electrical terminals. However, fancier versions exist where a second coil is present. This coil is not a movable coil but is present so as to be able to feed an external current through it which, again through induction, will exert a force on the

Seismometer, Extended Response,

Fig. 3 Geophone frequency response for different(over) damping factors

suspended mass. This procedure is usually applied just for calibration (hence the name “calibration coil”) but can also be applied for positive feedback.

Hypothesizing the presence of such a coil, positive feedback could be applied by integrating the output signal (thus rendering it proportional to displacement) and feeding the integrated voltage back through the feedback coil (Lippmann 1982). When applied with the correct polarity, the feedback signal will “nudge” the mass so that the original movement will be amplified, thus counteracting the decay of sensitivity. The effect is similar to using a softer spring, leading to a smaller restoring force and, consequently, to a lower natural frequency. Like the inverse filter method, positive feedback has practical stability problems and is not in practical use nowadays.

Negative Feedback

Rather than integrating the output signal, this method differentiates it (thus rendering it proportional to acceleration of the suspended mass) and feeds it back through the second coil choosing the polarity so that it will not amplify but attenuate the mass movement. Ideally, the geophone mass would be damped so strongly that it does not perform any movement relative to the frame at

all; in other words, the mass is accelerated in exactly the same way as the Earth, and the current required to keep it steady with respect to the frame is proportional to acceleration for frequencies higher than the new corner frequency (it is not feasible to extend the bandwidth to arbitrarily low frequencies). Practical limitations of this method are two coils required (thus excluding cheap mass-produced exploration geophones) and stability problems of feedback electronics due to inductive coupling of signal and feedback coils (Lippmann 1982).

Broadband sensors also use negative feedback, but they use a capacitive transducer to pick up mass movement, thus avoiding the stability issues. However, it is a nontrivial undertaking to fit a capacitive pickup in an off-the-shelf exploration geophone, so this method, while promising, does not lend itself well to commercializing.

Response Extension Using NIC (Negative Impedance Converter)

Recalling Eq. 1, let us now extend the series of damping factors in Fig. 1 towards higher values, and we get this (Fig. 3).

It is evident that the higher the damping factor gets, the wider is the frequency range in which the output is proportional to acceleration. If a way can be found to achieve such high damping factors, the geophone will effectively be transformed into an accelerometer with a wide frequency range, albeit at the expense of output. As can be seen from Fig. 3, output decreases by several orders of magnitude in a certain frequency range.

Achieving Overdamping

Neglecting the mechanical contribution to damping (which is a reasonable simplification for typical geophones if a very high damping is required), we can limit our consideration to electrical damping which is proportional to the combined resistances of the generator coil and the external shunt resistor (Havskov and Alguacil 2004):

$$h = \frac{CDR}{R_{coil} + R_{shunt}} \quad (3)$$

where CDR is the total resistance needed to get $h = 1$ (critical damping resistor).

As we can see, the maximum amount of damping that can be achieved in a bare-bones geophone is when the signal coil is shorted ($R_{shunt} = 0$). In this case, only the intrinsic coil resistance is responsible for damping. Loading the coil with any external resistance at all will only decrease damping. In order to arrive at damping factors higher than short-circuit damping, a negative resistance would have to be used – clearly a feat that cannot be achieved using passive electronics. An NIC (negative impedance converter) provides exactly that functionality (Lippmann 1982; Ulmann 2005). In its simplest form, it is just an operational amplifier and two resistors.

A practical value for the negative resistance is 80 % of the coil resistance (Ulmann 2005). Completely compensating the coil resistance with close to 100 %, negative resistance is not practical for reasons of stability.

Practical Considerations

Linearity

Conventional geophones are plagued with linearity issues on account of the inherent nonlinearity of the suspension spring(s). Positive feedback would magnify this type of problems, whereas negative feedback (by overdamping) will actually alleviate them. Since, in a first-order approximation, the mass will remain steady, the suspension springs will be flexed only very little. Since spring nonlinearity increases with the amount of flexing or elongation, this is a very efficient means of suppressing spring-induced nonlinearity.

Amplification

Since, as seen in Fig. 3, output all across the acceleration proportional passband is significantly lower than the velocity proportional signal of the non-overdamped geophone, additional amplification is called for. However, it is not convenient to amplify the acceleration proportional signal since this would create dynamic range problems. Applying linear amplification by, say, a factor of 1,000 would lead to impractically large amplitudes for the high frequencies. It is a much more practical approach to apply amplification only after the acceleration proportional signal has been converted back to velocity proportional (see next section).

Converting the Output Signal Back to Velocity

The obvious solution of simply integrating the acceleration proportional signal back to velocity is not a very practical one. As can be seen in Fig. 3, the low-frequency roll-off of the standard damped seismometer is no longer seen in the overdamped transfer function, but there is still quite an amplitude gap to cover. The difference in amplitude is largest around the original corner frequency and decreases towards higher and lower frequencies, but it is especially towards lower frequencies that trouble is to be expected if one were to attempt a simple integration without any frequency band limitation. As an

Seismometer, Extended Response, Fig. 4 Design of integrating/differentiating filter

example, let's take a look at $0.01 f/f_0$. The output of the standard damping seismometer is down to 10^{-4} of its plateau output, and the overdamped (acceleration proportional) output is down even further, already off scale. Bringing these low frequencies back to "flat" would lead to extremely high amplification factors, leading to the same type of problems that were described above in "Using an Inverse Filter." Rather than simulating an extremely broadband seismometer, a band-limited approach is a lot more promising. To this end, a filter is needed that integrates frequencies above its corner frequency and differentiates those below. Figure 4 (after Lippmann 1982) schematically shows its functional principle. With a frequency proportional rise for $f < f_{0\text{NEW}}$, and a frequency proportional decay for $f > f_{0\text{NEW}}$, the result of multiplying the frequency proportional acceleration signal with the filter's transfer function will be exactly the transfer function of a geophone with a virtual natural frequency of $f_{0\text{NEW}}$. However, in order to arrive at an output

level comparable to the non-overdamped geophone, the filter must provide more amplification than shown in our schematic example. The exact amount of peak amplification depends on the ratio between the original and the new virtual natural frequency.

A filter with the desired characteristics (6 dB/octave roll-off on either side of a given frequency) is not difficult to implement – it is basically a combination of a first-order high-pass and a first-order low-pass filter, with both corner frequencies being set to the desired new f_0 and of course an amplification stage.

Environmental Influences

Except for a few broadband models, seismometers will typically be used in field scenarios, i.e., they have to work under adverse environmental conditions, and will have to maintain their characteristics over a wide range of temperatures.

The negative feedback principle outlined above basically amounts to measuring one small

physical entity (in our case, the current flowing through the generator coil when the coil starts moving), then adding a counteracting entity of similar magnitude (in our case, a current that will create a force to keep the coil steady). Effectively two similar entities are subtracted from each other. Consequently, if one or both of the two entities are susceptible to changes in environmental parameters, the result of the subtraction will also be susceptible to changes. The coil resistance is a “real” resistor consisting of many windings of copper wire whose value will increase with temperature. The negative impedance is implemented by active circuitry which will not be immune to temperature changes but will certainly react differently from the purely ohmic coil resistance. The following example from Lippmann (1982) illustrates the problem, focusing only on the coil.

A coil resistance of $600\ \Omega$ at $20\ ^\circ\text{C}$ will change to $640\ \Omega$ at $40\ ^\circ\text{C}$. If our negative resistance is $520\ \Omega$, the effective damping resistance will change from $80\ \Omega$ ($20\ ^\circ\text{C}$) to $120\ \Omega$ at $40\ ^\circ\text{C}$ – a 50 % increase, leading to drastic changes in the sensor’s characteristics.

Clearly, temperature compensation needs to be applied. Lippmann (1982) describes the measures and results.

Electronic Noise

Electronic noise is the prime limiting factor for how much the response can be extended since it defines the smallest detectable ground velocity amplitude. Electronic noise is generally frequency dependent. As outlined previously in the “Inverse Filter” entry, below a certain threshold frequency (which depends on the particular active electronic element, e.g., an operational amplifier), noise tends to be proportional to $1/f$. In other words, lower frequencies tend to exhibit more noise.

In an extended response seismometer using negative feedback and a subsequent integrating/differentiating filter, electronic noise can be considered separately for the acceleration proportional part (i.e., the combination of geophone and NIC) and for the filter/amplifier part. Lippmann (1982) reveals that the contribution of the

latter part is close to negligible, compared to the NIC’s contribution.

The only thing of relevance to the practitioner, though, is the composite noise, expressed not in electrical but in seismological units, i.e., in equivalent ground velocity or acceleration. The following slightly edited diagram from Wielandt (1991) shows the equivalent RMS velocity for two different types of Lennartz (2013) seismometers – the LE-3Dlite type based on physical 4.5 Hz geophones and converted to 1 Hz seismometers and the LE-3D/5 s type based on physical 2 Hz geophones and converted to 0.2 Hz (5 s) seismometers. For reference, the NLNM (New Low Noise Model, Peterson (1993)) and the noise level at the BFO (Black Forest Observatory) site are also given. Note that the noise levels have been calculated for frequency bins of constant relative bandwidth. For the 1/3 octave bandwidth shown here, the relative bandwidth is 23.2 %. For example, the 10 Hz bin is 2.32 Hz wide, whereas the 50 Hz bin is 11.6 Hz wide. Using constant relative bandwidth bins is best suited for comparing and converting noise measurements (Bormann 2012, Chapter 4.1) (Fig. 5).

It turns out that both seismometer types are able to resolve ground noise at a very quiet site like BFO over a wide range of frequencies. The vast majority of sites will exhibit much more pronounced noise than BFO, thus rendering the extended response seismometers useable over their full frequency range.

A Practical Implementation

The photo shows a classical, purely mechanical seismometer next to an electronically enhanced seismometer built around a 4.5 Hz geophone. In both cases, natural frequency is one hertz, and both are single-component instruments (Fig. 6).

Summary

Range-extended seismometers based on robust, readily available, and comparatively cheap

Seismometer, Extended Response, Fig. 5 Lε-xD Self Noise in 1/10 decade (1/3 octave)

Seismometer, Extended Response, Fig. 6 Classical Geophone (left) vs. Range-Extended Seismometer (right), both of them single-component, 1 Hz units

exploration-grade geophones provide a viable alternative to clumsy and delicate mechanical seismometers for short- and intermediate-period applications. Unlike typical broadband sensors,

range-extended seismometers do not contain physical elements tuned to very low frequencies and do not respond to very low frequencies. Consequently they usually require no shielding from

pressure and temperature changes and provide extended high-frequency response, typically up to and above 100 Hz. Inherent limitations such as electronic noise can be mitigated by proper design and implementation.

Selection of Ground Motions for Response History Analysis

Anastasios G. Sextos

Division of Structural Engineering, Department of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece

Synonyms

Earthquake records; Ground motion; Record scaling; Response history analysis

Introduction

The evolution in computational power and the parallel processing capabilities of modern engineering software make nowadays the use of complicated structural analysis methods an attractive alternative for the design and assessment of structures. In contrast to the past, when the elastic static analysis was almost exclusively used for the seismic design of structures, the state of practice has progressively moved toward dynamic-elastic, nonlinear-static (i.e., single mode or multi-modal “pushover”), and even nonlinear response history analysis. The latter, capturing more efficiently the hierarchy of failure mechanisms, the energy dissipation, the force redistribution among the structural members, and contact issues (such as gap, impact, sliding, and uplift), is deemed preferable in cases of significant material or geometrical nonlinearities and, as such, is used for the design of seismically isolated buildings and bridges or the assessment of existing structures with various degrees of damage. Elastic response history analysis is also extensively used, primarily for structures whose response is dominated by higher modes (mostly tall and irregular buildings and towers) or structures of high importance that are typically designed to remain elastic even for long return-period earthquake intensities (i.e., industrial facilities, power plants, dams, critical administrative buildings, etc).

In all cases, the main task of the design procedures is to achieve more predictable and reliable levels of safety and operability against different levels of seismic intensity, a framework known as performance-based design and assessment. Despite the above major advances made in terms of structural analysis, the reliability of the analysis output and the subsequent structural performance prediction strongly depend on the decisions made for the selection of the seismic input which is used as ground excitation. Research has shown that among all possible sources of uncertainty stemming from structural and soil material properties, the modeling approximations, and the design and analysis assumptions as well as the earthquake-induced ground motion, the latter has by far the highest effect on the variability observed in the structural response (Elnashai and McClure 1996; Padgett and Desroches 2007; Shome et al. 1998). Therefore, the selection of a “reliable” suite of earthquake ground motions constitutes an important prerequisite for the reliability of the structural analysis procedure as a whole.

Along these lines, numerous computational methods and tools have been developed for (a) selecting suites of earthquake records from available strong ground motion record databases (b) generating synthetic and artificial ground motions or (c) modifying existing ground motions until they present desirable target characteristics.

Objectives of Ground Motion Selection

Currently more than 40 methods exist for selecting, modifying, and scaling earthquake ground motions. These methods can be grouped conceptually by their objective as follows based on the Ground Motion Selection and Modification (GMSM) Program of the Pacific Earthquake Engineering Research (PEER) Center (Haselton 2009) in the following broad four categories:

- *Predict the Probability Distribution* (mean and dispersion) of *Structural Response* (i.e., engineering demand parameter, EDP) from ground motions that comply with an

earthquake scenario of *given magnitude, M , source-to-site distance, R , and, in some cases, faulting type or soil class (i.e., $V_{s,30}$) at the site of interest.*

- *Predict the Median or Mean of Structural Response* from ground motions that are selected (or generated) to *match a median target response spectrum* for a given M-R pair, obtained from a ground motion prediction equation (or attenuation relationship). Dispersion of structural response might also be of interest; however, minimizing the standard error of response quantities is not explicitly envisaged.
- *Predict the Probability Distribution* (mean and dispersion) of *Structural Response* using ground motions that satisfy a given *spectral acceleration at the fundamental period* of the structure, $S_a(T_1)$, that has resulted from an associated M and R (as well as fault mechanism and soil class or $V_{s,30}$) scenario. Notably, a priori knowledge of the structural properties (i.e., its fundamental period T_1) is a prerequisite.
- *Predict the Median or Mean of Structural Response* for a given set of $S_a(T_1)$, M , and R . In this case, the scenario refers to a Maximum Considered Earthquake $S_a(T_1)$ and not a MCE response spectrum.

A fifth objective can also be distinguished to *minimize the structural response discrepancy* by considering a threshold confidence level for the standard error of the response quantities, additional to conventional spectral matching (Katsanos and Sextos 2013). This involves consideration of structural analysis results within the GSM process.

Methodologies for Ground Motion Selection and Scaling

Independently of the ultimate objective of the GSM process, the various methodologies for developing earthquake ground motion sets for (linear or nonlinear) dynamic analysis of structures can also be classified based on the concept

of selection and the procedure of modulating or scaling ground motions. Naturally, method objectives and selection and scaling procedures are not fully correlated. The following classes of methods are listed below. A detailed review of most important methods is also performed elsewhere (Katsanos et al. 2010):

Selection by M and R and Scaling to a Target Intensity Measure

The simplest GSM method involves the formation of set (bin) of motions that satisfy, as close as possible but without explicit constraints, preliminary magnitude, M , source-to-site distance, R , and often seismotectonic or soil class criteria. It is recalled that the total number of sets N_{tot} that can be formed, from m , potentially eligible, records out of a larger group of s records, can be calculated by the following factorial formula of the binomial coefficient:

$$N_{\text{tot}} = \binom{s}{m} = \frac{s!}{m!(s-m)!} \quad (1)$$

Once eligible ground motions are selected, their accelerations are multiplied by a scaling factor to match a target intensity measure (IM), typically being the peak ground acceleration (PGA) or the spectral acceleration at the fundamental period of the structure, $S_a(T_1)$. In the latter case, it is evident that all ground motion spectra will have identical ordinates at period T_1 and different spectral accelerations in all other periods. More elaborative IMs have also been proposed, involving the spectral shape and the structural characteristics. Such IMs are expected to result into a relatively more accurate prediction of the seismic demand (Baker and Cornell 2005; Luco and Cornell 2007; Tothong and Luco 2007); however, the approximate definition of the seismic scenario is a significant limitation.

Selection and Scaling to a Target Uniform Hazard Spectrum

In the light of the above criteria, it is also common to envision matching of the response spectra of the selected acceleration time series with

a target, Uniform Hazard Spectrum (UHS) (Kramer 1996; American Society of Civil Engineers 2005; McGuire 2004), which is determined from (a) a ground motion prediction relationship, (b) a seismic hazard assessment for the site of interest, or (c) the seismic code provisions. In this case, ground motions are scaled with a single or individual scaling factors so that their individual spectrum, or the mean of their response spectra closely match and in fact exceed, in terms of “shape,” the ordinates of the target UHS, typically within a given range of periods around the fundamental period of the structure. When a uniform scaling factor is sought, it may be determined through the following expression:

$$sf_{\text{avg}} = \left\{ \min \left(\frac{Sa_{\text{avg}}(T_i)}{Sa_{\text{target}}(T_i)} \right) \right\}^{-1}, \quad i = 1 \text{ to } N \quad (2)$$

where T_i is the sample period and N is the size of the sample into which the prescribed period range is discretized.

Quite commonly, all eligible suites are ranked according to their “goodness-of-fit” to the target spectrum, as quantified by the normalized root-mean-square-error, δ , between the scaled average Sa_{avg} , and the target spectrum Sa_{trt} (Iervolino et al. 2010b):

$$\delta = \sqrt{\frac{1}{N} \cdot \sum_{i=1}^N \left(\frac{Sa_{\text{avg}}(T_i) - Sa_{\text{trt}}(T_i)}{Sa_{\text{trt}}(T_i)} \right)^2} \quad (3)$$

A wide variety of similar expressions have also been used in the literature. Further discussion on the efficiency of various spectral matching indicators can be found elsewhere (Beyer and Bommer 2007; Jayaram et al. 2011; Kottke and Rathje 2008; Naeim et al. 2004).

In addition to spectral shape, these methods may consider other earthquake, site, or ground motion parameters in selecting ground motions. Finally, the mean or the maximum (depending on the number of ground motions within the set) of the response quantities is used as the design value.

Seismic Codes of Practice

Most contemporary seismic codes and design recommendations, such as Eurocode 8 for buildings (CEN 2004) and bridges (CEN 2005), ASCE standards 7-10 (ASCE/SEI 2010) and FEMA P-750 (FEMA 2009a) as well as various national norms (New Zealand Standards, Italian Code, and Greek Seismic Code), describe relatively similar procedures that are based on spectral matching for the selection of earthquake ground motions in the framework of dynamic analysis of structures. In most cases, seismic motions can be represented by real, artificial, or simulated records, typically complying with the aforementioned preliminary criteria of earthquake magnitude, distance, the seismotectonic environment, and the local soil conditions. Differences among the codes can be summarized as follows:

Duration Strong-motion duration is not explicitly considered as an additional selection parameter in most documents inclusive of ASCE standards 7-10 (ASCE/SEI 2010) and the Eurocodes.

Simulated and Artificial Ground Motions Use of simulated ground motions is permitted in a number of seismic codes; however, it is restricted only to cases of inadequate number of real accelerograms in others, i.e., FEMA P-750 and Eurocode 8 Part 2 for bridge design (CEN 2005).

Near-Field Considerations Near-field effects are typically either ignored or considered in a quantitative manner in terms of direction of fault rupture and velocity pulses, an example being FEMA P-750 (FEMA 2009a). More detailed distinction is made in FEMA P695 (FEMA 2009b) by forming distinct far-field and near-field record sets. ASCE standards 7-10 prescribe different design quantities for sites within 3 miles (5 km) of the active fault that controls the hazard. In this case, each pair of ground motion components shall be rotated to the fault-normal and fault-parallel directions of the causative fault. Next, it shall be appropriately scaled so that the

average of the fault-normal components is not less than the MCE response spectrum for the period range of spectral matching (as described below).

Spectral Matching A distinction is typically made between two-dimensional and three-dimensional analysis, the latter involving selection and application of pairs of records for linear or nonlinear dynamic analysis. In principle, the procedure is similar among most important seismic codes and recommendations and involves the following steps: (a) the 5 %-damped elastic spectra are derived for each component of the eligible horizontal motions selected; (b) the mean of the individual (EC8-Part 1) or the square root of the sum of squares (SRSS spectra) of the individual elastic spectra ordinates is determined; (c) the mean spectrum of the ground motions is compared with the target code-prescribed spectrum; and (d) records are scaled so that the spectral ordinates of the mean spectrum (either from individual or SRSS spectra) exceed a lower bound of the target spectral acceleration (Table 1) within a prescribed period range (also depicted in Table 1).

Scaling Scaling of the individual records toward spectral matching can be performed either with the use of a uniform scaling factor (i.e., EC8-Part2, ASCE 7-10) or a record-dependent, individual scaling factor (FEMA P-750). Other codes (i.e., EC8-Part1) do not provide specific guidelines regarding the scaling of seismic records in order to establish the required compliance with the target design spectrum. New Zealand Standards (Standards New Zealand (SNZ) 2004) on the contrary prescribe two distinct scale factors k_1 and k_2 , the first minimizing the difference between recorded and target response spectrum in a least mean square scheme over the period range of interest, while the latter ensures that the energy in the spectrum of the strongest ground motion exceeds the energy of the target spectrum.

Design Quantities Structural analysis results are processed in a statistical manner, and the

Selection of Ground Motions for Response History Analysis, Table 1 Earthquake records selection and spectral matching criteria prescribed in the seismic codes and guidelines studied here

Seismic codes and guidelines	Selection criteria	Ensemble spectrum	Spectral matching period range	Lower bound of mean spectral acceleration	Scaling factor
EC8 Part 1 (buildings)	Seismotectonic features, soil type	Mean of individual spectra	$0.2-2.0 T_1$	$0.90 \cdot Sa(T)_{\text{design}}$	Not specified
EC8 Part 2 (bridges)	Source mechanism, M, R	Mean of SRSS spectra	$0.2-1.5 T_1$	$1.30 \cdot Sa(T)_{\text{design}}$	Uniform
FEMA P-750	Source mechanism, M, R	Mean of SRSS spectra	$0.2-1.5 T_1$	$1.17 \cdot Sa(T)_{\text{design}}$	Individual
ASCE/SEI 7-10	Source mechanism, M, R	Mean of SRSS spectra	$0.2-1.5 T_1$	$1.00 \cdot Sa(T)_{\text{design}}$	Uniform
NZS 1170.5	Seismotectonic features, soil type	Individual record scaling and matching	$0.4-1.3 T_1$	Matching as nearly as practicable	k_1 and k_2 factors
Taiwan seismic code	Source mechanism, M, R	Mean of individual spectra	$0.2-1.5 T_1$	$0.90 \cdot Sa(T)_{\text{design}}$	Not specified

design quantities are defined as either the mean (in case of seven records or more) or the maximum (in case of three records) of the engineering demand parameters of interest (EC8, FEMA P-750). Certain codes solely provide the option of obtaining the maximum response out of the three response history analyses (CPA 2011; Standards New Zealand (SNZ) 2004). The most refined to date provision to derive seismic design values is prescribed in ASCE 7-10 clearly distinguishing between (a) *force response parameters* that shall be multiplied for each ground motion analyzed by a factor I_e/R , where I_e is the importance factor and R is the Response Modification Coefficient, and (b) *drift response quantities*, which shall be multiplied by C_d/R , C_d being the deflection amplification factor. It is noted herein that the above methods refer to the design of new buildings according to modern seismic codes and do not apply to the probabilistic assessment of the nonlinear response of existing buildings (Jalayer and Cornell 2009). It is also noted that despite the simplification and applicability of the above code-based procedures, significant limitations also exist (Sextos et al. 2010).

More details on comparative seismic code provisions on ground motion selection and scaling can be found elsewhere (Hachem et al. 2010).

Selection and Scaling to a Target Conditional Mean Spectrum

An alternative group of methods for ground motion selection and scaling is similar to the aforementioned spectral matching, but the Uniform Hazard target Spectrum, the Conditional Mean Spectrum (CMS) (Baker 2011), is used instead. The main reason behind this substitution (Kottke and Rathje 2008; Lin et al. 2013a; Wang 2010) is that the UHS is shown to be unsuitable to serve the main purpose of dynamic analysis, which is to excite the structure under consideration with ground motions having a specified spectral acceleration at a given period. In fact, UHS compatible ground motions are often associated with large-amplitude spectral values in a wide range of periods. Furthermore, UHS can hardly be considered as a spectrum of a single earthquake event as it rather represents an envelope of spectra corresponding to different seismic events and sources. On the contrary, a Conditional Mean Spectrum (CMS) represents the expected (i.e., mean) response spectrum, *conditioned* on the occurrence of a target spectral acceleration at the period of interest, typically, though not exclusively, the fundamental period of the structure T_1 .

Similarly to the UHS, the target CMS is calculated for the scenario $S_a(T_1)$, magnitude, M , and source-to-site distance, R , together with

other preliminary criteria such as fault type or soil, if desirable. In simpler words, the CMS represents the expected response spectrum for the defined ground motion scenario, which is based on a target $S_a(T_1)$ at a single structural period, in contrast to the UHS, which represents equally rare $S_a(T)$ values at many periods (including T_1) simultaneously (Haselton 2009). To develop this new target spectrum, Probabilistic Seismic Hazard Assessment can be used to determine the spectral acceleration $S_a(T_1)$ that corresponds to the target probability of exceedance at the site of interest, denoted as $S_a(T_1)^*$. De-aggregation can then be used to estimate the mean values of magnitude, source-to-site distance, and “epsilon” (“ ϵ ”) ($\bar{M}$, $\bar{R}$, $\bar{\epsilon}$) that lead to an acceleration equal to $S_a(T_1)^*$. The definition of parameter “epsilon” is provided in the following section. The way in which spectral matching to the target CMS is achieved is similar to the procedures described above.

Selection and Scaling to a Proxy (“ ϵ ”) of the Target Conditional Mean Spectrum

A more advanced approach category of methods for ground motion selection and scaling to a target Conditional Mean Spectrum utilizes the parameter “epsilon” (“ ϵ ”) as a proxy of the desirable CMS spectral shape (Baker and Cornell 2006). It is recalled that “epsilon” was first defined by engineering seismologists as the number of standard deviations by which a given spectral acceleration, expressed in logarithmic terms, differs from the mean logarithmic spectral acceleration provided by a ground motion prediction (attenuation) equation. In other words, “ ϵ ” is derived by subtracting the predicted mean logarithmic spectral acceleration at given period T_1 ($\ln\{S_a(T_1)\}$) from the corresponding value ($\ln\{S_a(T_1)\}$) of the record under examination and then dividing by the logarithmic standard deviation estimated by the attenuation relationship. In practical terms, this implies that a record with “ ϵ of 1.5 at 0.5 s” has a spectral acceleration at a period $T_1 = 0.5$ s that is 1.5 standard deviations higher than the predicted mean spectral value.

An advantage of the “ ϵ ” parameter is that it is determined with respect to the unscaled record

and does not change in case of record scaling. On the other hand, it is also noticeable that for a given ground motion record, “ ϵ ” is clearly a function of the period of interest and depends on the particular ground motion prediction model used, since different attenuation relationships lead to different mean and standard deviation of $\ln\{S_a(T)\}$. Therefore, it is important to ensure that the ground motion prediction model used to compute ϵ is the same model used in the ground motion hazard assessment. This dependence of ϵ to attenuation relationships is perhaps the most important drawback in the use of this parameter.

Ground motion selection methods (Tothong and Luco 2007) that use “ ϵ ” as a proxy of the CMS spectral shape ensure that the value of “ ϵ ” at the fundamental period of the building, denoted as $\epsilon(T_1)$, is as close as possible to the target $\epsilon(T_1)$ of the ground motion scenario. This practically implies that the record-to-record variability at the fundamental period of the structure is reduced, and in turn, the discrepancy in the structural response of the corresponding SDOF system is also lower. Some concerns have been expressed regarding the appropriate choice of CMS and the conditioning period, primarily related to the importance of higher modes of vibration of MDOF systems and the anticipated period elongation under strong ground motions (Katsanos et al. 2014). However, it has been shown that risk-based assessments are relatively insensitive to the choice of conditioning period provided that the ground motions are carefully selected to ensure hazard consistency (Lin et al. 2013a).

Available Computational Tools and Databases

Strong Ground Motion Databases

Among numerous strong ground motion databases in Japan, Taiwan, and Europe (European Strong Ground Motion database, www.isesd.hi.is), the PEER-NGA Next Generation Attenuation strong-motion database is a continuously developing project currently consisting of 3,551 publicly available, three-component seismic records (i.e., about 10,650 individual earthquake

acceleration time series) that have been recorded during 173 shallow crustal earthquakes from active tectonic regions worldwide. The corresponding seismic events, which have been recorded primarily in California, range in magnitude from 4.2 to 7.9 and cover epicentral distances in the range 0.2–600 km. Apart from the magnitude and the distance, the earthquake database contains basic information about the seismic source including date and time of the event, hypocenter location, faulting mechanism, seismotectonic environment, and others. Detailed data about 1,600 strong-motion stations are also provided (i.e., site characterizations, surface geology, shallow subsurface conditions, the location of the instrument inside the structure's installation place). Furthermore, each acceleration time history has been corrected for the response of the strong-motion instrument itself and filtered out the noise included while it can also be automatically scaled online.

Software and Tools for Ground Motion Selection

Given the above extensive repository of earthquake records and the fact that the most common earthquake record selection procedures involve spectral matching, recent work evolved to develop computational tools for quantifying and/or optimizing spectrum compatibility to a code prescribed or CMS (Youngs et al. 2007). REXEL (Iervolino et al. 2010a, 2011, 2012) was the first, all-in-one, software introduced for this purpose and facilitates the search for suites of waveforms compatible to target spectra that are either user defined or automatically generated according to Eurocode 8 and the recently issued Italian seismic code. An alternative web-based software for earthquake record selection is SeleQ (Dias 2010), offering various filtering options. More recently, the Integrated System for Structural Analysis and Record Selection (ISSARS) software has been developed (Katsanos and Sextos 2013), retrieving dynamically ground motions from the PEER-NGA database, to form suites of records that not only comply with specific criteria but also ensure, through numerical analyses of the structure that

run at the background, a target level of dispersion of structural response quantities.

Accepted Knowledge on Ground Motion Selection for Response History Analysis Purposes

- Structural response is inherently probabilistic in nature due to the variability among ground motions.
- A major challenge in choosing the most appropriate method for ground motion selection and scaling is to understand the purpose of the dynamic analysis for which the ground motions are sought. A major distinction is between design and assessment purposes. Careful selection of methods, intensity measures, and engineering demand parameters is necessary.
- An additional challenge, at least for a design viewpoint, is to keep structural response discrepancy low.
- Numerous GSM methods exist in the literature with distinct advantages and drawbacks. The direct comparison of these methods is not always feasible.
- Most GSM methods adopted in contemporary seismic codes are rather simplified compared to the breadth of the existing methods available in the literature. Still, they require significant effort, deep understanding of the physical problems and the parameters involved as well as specialized computational tools in order to overpass their inherent limitations.

Summary

Linear and nonlinear dynamic analysis of structures is becoming increasingly popular in structural design and assessment practice. Along these lines, the selection and scaling of the appropriate set of earthquake ground motions, required in the framework of dynamic analysis, has become of paramount importance due to the significant sensitivity of structural response to the assumptions made in forming the necessary set of earthquake

records. A large number of ground motion selection and modification (GMSM) methods have been proposed in the literature; still though, the major progress made during the last decade is not yet reflected in modern seismic codes. Along these lines, the present entry aims at briefly presenting, in the simplest possible terms but not simpler than necessary, the objectives and fundamental concepts of GMSM methods along with the current seismic code framework and the computational tools developed to facilitate code-prescribed procedures.

Sensitivity of First-Excursion Probabilities for Nonlinear Stochastic Dynamical Systems

Introduction

Quantification of the performance of structural systems subject to dynamic loading is of paramount interest in several fields of engineering and particularly in the case of earthquake engineering. Knowledge on the performance of a structure during seismic events allows taking design decisions that ensure its serviceability and safety throughout its life. Nonetheless, quantification

of performance is a challenging task as there is always uncertainty on future loadings that affect a structure during its lifetime. Structural reliability has emerged as a discipline that allows accounting for the unavoidable effects of uncertainty over performance. Thus, probability theory is used to describe the uncertainty associated with different relevant parameters that affect performance by means of random variables, random fields, and/or stochastic processes. In this manner, uncertainty is *propagated* from these *input* parameters to the responses of interest such as displacements, accelerations, forces, etc.

A particularly useful way to measure the effects of uncertainty in the dynamic response of structural systems is the so-called first-excursion probability. This probability is widely used in stochastic structural dynamics and measures the chances that one or more structural responses exceed a prescribed threshold level within the duration of a dynamical excitation (Soong and Grigoriu 1993). First-excursion probability estimation is particularly challenging as characterization of uncertain loading usually comprises stochastic processes whose discrete representation can involve hundreds or even thousands of random variables. Similarly, the number of possible failure criteria involved can be extremely large as well, i.e., there can be several responses of interest that must be controlled at a large number of discrete time instants. Hence, several different techniques have been proposed in order to estimate first-excursion probabilities. Among these, methods based on simulation (such as the Monte Carlo method and its more advanced variants) have been shown to be the most appropriate approach to compute these probabilities (Schuëller et al. 2004).

Although first-excursion probability provides a most useful way to rationally account for the effects of uncertainty on structures subject to stochastic loading, it is certainly not the only metric that should be taken into account when designing a system. In fact, it is also of interest analyzing the *sensitivity* of the probability with respect to variations in the properties of the

structural system. For example, determining the variation in probability due to a change in the size of a structural member can provide useful information to increase the safety level or to identify the most influential design parameters. Nonetheless, estimation of the sensitivity of first-excursion probabilities for dynamical systems is a challenging task as it comprises not only taking into account the uncertainty in input parameters but also assessing how performance is affected due to variations in properties of a structure.

This contribution presents an approach for assessing probability sensitivity of systems subject to stochastic excitation with emphasis on structures whose response is nonlinear. The approach combines state-of-the-art simulation strategies with a series of approximation concepts. Salient features of the approach are the capability of considering problems involving a large number of random variables (in the order of thousands), the possibility of estimating sensitivity with respect to several variables simultaneously (scalability), and a high numerical efficiency achieved by integrating an advanced simulation algorithm with local approximations of the functions modeling the structural performance.

Formulation of the Problem

Structural Model

Let $f(t)$ be a scalar representing loading acting over a structure during a time span $t \in [0, T]$. This load is modeled at discrete time instants of analysis $t_k = (k - 1)\Delta t$, $k = 1, \dots, n_T$ where Δt is the time step and n_T is the number of time points considered (clearly, $\Delta t = T/(n_T - 1)$). The loading $f(t)$ is uncertain and is characterized by means of a stochastic process using an appropriate representation (Schuëller 1997), e.g., Karhunen-Loève (KL) expansion, polynomial chaos (PC) expansion, etc. Thus, the loading can be represented as $f(t_k, \mathbf{z})$ where $\mathbf{z}$ is a vector of random variables of dimension n_z whose associated probability density function $f_z(\mathbf{z})$ depends on the characteristics of the stochastic process. Note that depending on the specific situation under

analysis, load could also be represented as a -vector-valued stochastic process (i.e., a vector whose entries are stochastic processes) instead of a scalar. However, in order to simplify the presentation of this contribution and with no loss of generality, the vector-valued case is not explored further.

In addition to the stochastic loading $f(t, z)$, consider a vector $y \in \Omega_y \subset \mathbb{R}^{n_y}$ of dimension n_y , grouping the *design* variables of the structural system. This vector can group those variables that can be altered during the design process (such as cross section of structural members, material properties, etc.). Moreover, consider a classically damped structural system represented by an appropriate model (e.g., a finite element model (Bathe 1996)) comprising a total of n degrees of freedom. Then, the differential equation describing the response of the structure subjected to the stochastic excitation $f(t, z)$ is (see, e.g., Chopra, 1995)

$$\begin{aligned} \mathbf{M}(\mathbf{y})\ddot{\mathbf{x}}(t, \mathbf{y}, \mathbf{z}) + \mathbf{C}(\mathbf{y})\dot{\mathbf{x}}(t, \mathbf{y}, \mathbf{z}) + \mathbf{K}(\mathbf{y})\mathbf{x}(t, \mathbf{y}, \mathbf{z}) \\ + \mathbf{f}_{NL}(\mathbf{y}, \mathbf{x}(t, \mathbf{z}), \dot{\mathbf{x}}(t, \mathbf{y}, \mathbf{z})) = \mathbf{g}\mathbf{f}(t, \mathbf{z}) \end{aligned} \quad (1)$$

where $\mathbf{x}$ is the displacement response vector of dimension n ; $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the mass, damping, and stiffness matrices of dimension $n \times n$; $\mathbf{f}_{NL}(\mathbf{x}, \mathbf{y}(t, \mathbf{y}, \mathbf{z}), \dot{\mathbf{x}}(t, \mathbf{y}, \mathbf{z}))$ is a vector of dimension n representing the effect of nonlinear forces of the structure due to, e.g., special devices for energy dissipation, yielding, nonlinear behavior, etc.; and $\mathbf{g}$ is the vector of dimension n that couples the stochastic excitation $f(t, z)$ with the degrees of freedom of the structure. Note that mass, damping, stiffness, and nonlinear forces are a function of the vector of design variables $\mathbf{y}$.

First-Excursion Probability

The performance of the structural system in view of the stochastic excitation is characterized by means of n_r responses of interest $r_i(t, \mathbf{y}, \mathbf{z})$, $i = 1, \dots, n_r$, $t \in [0, T]$ measuring, e.g., displacements, accelerations, stresses, etc. For example, in applications associated with earthquake

engineering, a response of interest r_i could be the interstory drift displacement, which can be calculated as a linear combination of the displacement vector, i.e., $r_i(t, \mathbf{y}, \mathbf{z}) = \boldsymbol{\gamma}_i^T \mathbf{x}_i(t, \mathbf{y}, \mathbf{z})$, where $\boldsymbol{\gamma}_i$ is a vector of size n whose entries are 0 and 1. For design purposes, the responses of interest r_i , $i = 1, \dots, n_r$ are checked against allowable threshold levels r_i^* , $i = 1, \dots, n_r$. In a deterministic design framework, the objective is verifying that these responses do not exceed their prescribed thresholds in order to avoid undesirable situations (such as loss of serviceability or collapse). However, when uncertainties are explicitly taken into account, the aforementioned condition cannot be always satisfied, i.e., there is the chance that the responses surpass their prescribed thresholds thus leading to an undesirable situation.

In order to account for the effects of uncertainties and potential undesirable performance of a structure during its lifetime, reliability offers the means for quantifying the level of safety associated with a structural system. A criterion widely used for characterizing safety of a structure is the first-excursion probability (see, e.g., Soong and Grigoriu, 1993). This probability measures the chances that uncertain structural responses exceed in magnitude prescribed thresholds within a specified time interval. That is, first-excursion probability measures the chances of occurrence of the following event F (which is termed in the sequence as *failure* event):

$$F = D_N(\mathbf{y}, \mathbf{z}) \geq 1 \quad (2)$$

where $D_N(\mathbf{y}, \mathbf{z})$ is the so-called normalized demand (Au and Beck 2001) and is defined as

$$D_N(\mathbf{y}, \mathbf{z}) = \max_{i=1, \dots, n_r} \left(\max_{t \in [0, T]} \left(\frac{|r_i(t, \mathbf{y}, \mathbf{z})|}{r_i^*} \right) \right) \quad (3)$$

The normalized demand represents the maximum of the quotient between the structural responses of interest and their corresponding threshold levels. Clearly, whenever $D_N(\mathbf{y}, \mathbf{z})$ exceeds 1, there is failure as the response exceeds its maximum acceptable value. In this context, note

the word *failure* is not a synonym of collapse. It is intended to denote unacceptable system performance which can range from partial damage states (e.g., loss of serviceability) to collapse depending on the specific application under study.

The probability of occurrence of the failure event can be defined by means of the following classical probability integral:

$$\begin{aligned} P_F(\mathbf{y}) &= P[D_N(\mathbf{y}, \mathbf{z}) \geq 1] = \int_{D_N(\mathbf{y}, \mathbf{z}) \geq 1} f_z(\mathbf{z}) d\mathbf{z} \\ &= \int_{\mathbf{z} \in \Omega_z} I_F(\mathbf{y}, \mathbf{z}) f_z(\mathbf{z}) d\mathbf{z} \end{aligned} \quad (4)$$

In the above equation, $P[\cdot]$ denotes probability of occurrence of the argument between brackets, $P_F(\mathbf{y})$ represents the probability of failure (i.e., probability of occurrence of the event F), and $I_F(\mathbf{y}, \mathbf{z})$ denotes the indicator function which is equal to 1 in case the normalized demand is equal or larger than 1 and 0 otherwise.

The evaluation of the failure probability integral is a challenging task as it usually involves a high number of dimensions (for applications of practical interest, n_z can be in the order of thousands) and the normalized demand function $D_N(\mathbf{y}, \mathbf{z})$ can be evaluated point-wise only through (numerically demanding) FE analyses. A possible means for evaluating probability integrals is applying simulation methods. Among different available *simulation methods*, Monte Carlo simulation (MCS) (Metropolis and Ulam 1949) is the most general technique. However, MCS is numerically demanding for estimating low failure probabilities (which are typical in engineering applications). In order to circumvent this issue, *advanced simulation techniques* have

been developed, allowing to estimate small failure probabilities at affordable numerical costs (Schuëller et al. 2004).

Sensitivity of First-Excursion Probability

As shown in Eq. 4, the probability of failure is a function of the design variable vector $\mathbf{y}$. Such dependence can be understood as follows: modifications on the design vector do affect the response of the structure and, consequently, also affect the probability of exceeding the prescribed thresholds. In consequence, for decision making and risk analysis, it is important to evaluate the probability of failure $P_F(\mathbf{y})$ and its sensitivity with respect to changes in the design vector $\mathbf{y}$. That is, besides computing the value of the failure probability, it is also of relevance estimating how much the probability changes due to a modification of the design variable vector. A classical measure for sensitivity is calculating the gradient of the quantity of interest. However, within the context of nonlinear dynamics, the estimation of such quantity may not be feasible as the gradient may not exist due to the nonsmooth normalized demand defined in Eq. 3 (see, e.g., Kang et al. 2006). In order to circumvent this difficulty, an approximate representation of the failure probabilities that is differentiable is constructed, and then, the gradient of this approximation is estimated. Details on these approximations are discussed below.

Estimation of First-Excursion Probability Sensitivity

From a mathematical viewpoint, estimating the gradient of the first-excursion probability implies solving the following limit:

$$\frac{\partial P_F(\mathbf{y})}{\partial y_q} = \lim_{\Delta y_q \rightarrow 0} \frac{P_F(\mathbf{y} + \mathbf{v}(q)\Delta y_q) - P_F(\mathbf{y})}{\Delta y_q}, \quad q = 1, \dots, n_y \quad (5)$$

In Eq. 5, $\mathbf{v}(q)$ is a vector of dimension n_y with all entries equal to zero, except by the q -th entry,

which is equal to one. Introducing the definition of failure probability (see Eq. 4) in Eq. 5 yields

$$\frac{\partial P_F(\mathbf{y})}{\partial y_q} = \lim_{\Delta y_q \rightarrow 0} \frac{P_F[D_N(\mathbf{y} + \mathbf{v}(q)\Delta y_q, \mathbf{z}) \geq 1] - P[D_N(\mathbf{y}, \mathbf{z}) \geq 1]}{\Delta y_q}, \quad q = 1, \dots, n_y \quad (6)$$

Note the limit (as well as the partial derivative) in the above equation may not exist as the normalized demand function $D_N(\mathbf{y}, \mathbf{z})$ may be nonsmooth with respect to both the design parameter vector $\mathbf{y}$ and the uncertain variable vector $\mathbf{z}$. In order to avoid this issue and still obtain a sensitivity measure of the first-excursion probability, approximate representations for the normalized demand function and the excursion probability are introduced. These approximations – which were proposed in Jensen et al. (2009) and Valdebenito and Schuëller (2011) – are discussed in the following. The first approximation comprises an approximate representation of the normalized demand function, i.e.,

$$\begin{aligned} D_N(\mathbf{y} + \Delta \mathbf{y}, \mathbf{z}) &\approx \tilde{D}_N(\mathbf{y} + \Delta \mathbf{y}, \mathbf{z}) \\ &= D_N(\mathbf{y}, \mathbf{z}) + \sum_{q=1}^{n_y} a_q \Delta y_q \end{aligned} \quad (7)$$

where $\tilde{D}_N(\mathbf{y}, \mathbf{z})$ is the approximate normalized demand function, $\Delta \mathbf{y}$ is a certain perturbation of

the design variable vector, and $a_q, q = 1, \dots, n_y$ are real, constant coefficients. The procedure to determine these coefficients is described in section “Numerical Implementation.” The second approximation involves an approximate representation of the probability that the normalized demand exceeds a threshold level b , i.e.,

$$P[D_N(\mathbf{y}, \mathbf{z}) \geq b] \approx e^{\psi_0 + \psi_1(b-1)}, \quad b \in [1 - \epsilon, 1 + \epsilon] \quad (8)$$

where ϵ is a small constant and where ψ_0, ψ_1 are real coefficients. The issue of how to calculate them is analyzed in section “Numerical Implementation.” A thorough discussion on the applicability of these two approximations can be found in Jensen et al. (2009) and Valdebenito and Schuëller (2011).

Using the approximations introduced in Eqs. 7 and 8, it can be shown (see Valdebenito and Schuëller (2011)) that the sought gradient can be approximated as follows:

$$\frac{\partial \tilde{P}_F(\mathbf{y})}{\partial y_q} = \lim_{\Delta y_q \rightarrow 0} \frac{P[\tilde{D}_N(\mathbf{y} + \mathbf{v}(q)\Delta y_q, \mathbf{z}) \geq 1] - P[D_N(\mathbf{y}, \mathbf{z}) \geq 1]}{\Delta y_q} \quad (9)$$

$$= \lim_{\Delta y_q \rightarrow 0} \frac{P[D_N(\mathbf{y}, \mathbf{z}) \geq 1] - a_q \Delta y_q - P[D_N(\mathbf{y}, \mathbf{z}) \geq 1]}{\Delta y_q} \quad (10)$$

$$= \lim_{\Delta y_q \rightarrow 0} \frac{e^{\psi_0 - \psi_1 a_q \Delta y_q} - e^{\psi_0}}{\Delta y_q} \quad (11)$$

$$= -\psi_1 a_q e^{\psi_0} \quad (12)$$

$$= -\psi_1 a_q \tilde{P}_F(\mathbf{y}) \quad (13)$$

In the above equations, $\partial \tilde{P}_F(\mathbf{y}) / \partial y_q$ represents the partial derivative of the approximate

representation of the failure probability with respect to $y_q, q = 1, \dots, n_y$ and $\tilde{P}_F(\mathbf{y})$ is the estimate for the failure probability in Eq. 4 which is calculated using an advanced simulation method. Thus, for estimating the gradient of the probability, it is necessary to determine the probability $\tilde{P}_F(\mathbf{y})$ and the coefficients ψ_1 and $a_q, q = 1, \dots, n_y$. A procedure for determining this probability and these coefficients is discussed in the following section.

Numerical Implementation

General Remarks

This section provides details on the procedure to calculate the different coefficients and probability involved in the estimation of the first-excursion probability sensitivity according to the approximate formula proposed in Eq. 13. First, it is explained how excursion probabilities are estimated. Then, the sensitivity of the first-excursion probability with respect to a normalized threshold level is analyzed, and finally, an approximate representation of the normalized demand function is discussed.

First-Excursion Probability Estimations

As already pointed out, estimating a first-excursion probability implies solving the integral in Eq. 4. In this contribution, this probability is evaluated by means of the so-called advanced simulation methods (Schuëller et al. 2004). In particular, in this contribution, subset simulation (SS) (Au and Beck 2001) is applied to estimate first-excursion failure probabilities.

In SS, the failure domain F (see Eq. 2) is defined as a sequence of subsets (or *intermediate* failure events) F_i , $i = 1, \dots, m$ such that $F_1 \supset F_2 \supset \dots \supset F_m = F$. Thus, the failure probability is cast as a product of conditional failure probabilities, i.e.,

$$P_F = P[F_m] = P[F_1] \prod_{i=1}^{m-1} P[F_{i+1}|F_i] \quad (14)$$

where $P[F_{i+1}|F_i]$ is the probability of occurrence of the event F_{i+1} conditioned on the event F_i . In this way, a small failure probability is expressed as the product of larger, conditional probabilities which can be calculated using, e.g., Monte Carlo simulation (MCS). The practical implementation of SS requires an efficient algorithm for generating samples of the uncertain parameters ($\mathbf{z}$) conditioned on an intermediate failure event, such as the modified Metropolis algorithm (Au and Beck 2001). Details on the algorithmic implementation of SS can be found in Au and Beck (2001).

A salient feature of SS is that it *populates* the space of uncertain parameters by means of successive subsets F_i , $i = 1, \dots, m$, each of which is of

a rarer occurrence than the previous one, i.e., $P[F_i] < P[F_{i-1}]$. Hence, a full run of SS does not only provide the probability of occurrence associated with a normalized threshold $b = 1$ (see Eq. 4), but actually for a range of the normalized threshold levels (Au and Beck 2001).

Sensitivity of First-Excursion Probability with Respect to Threshold

The approximation introduced in Eq. 8 allows estimating the probability that the normalized demand function $D_N(\mathbf{y}, \mathbf{z})$ exceeds a prescribed threshold b , i.e., it is sought to estimate the curve relating normalized thresholds b and their corresponding first-excursion probabilities. Note that this curve can be calculated as a byproduct of reliability analysis applying advanced simulation methods such as SS. Thus, the coefficients ψ_0 and ψ_1 can be estimated with no additional numerical efforts once a reliability analysis has been carried out. In fact, when applying SS, the sought coefficients can be calculated with the samples of the normalized demand generated at the last stage of SS. The main idea is generating the curve probability versus normalized threshold in a discrete manner using samples already available. Then, the sought coefficients are calculated in a least square sense considering the analytic approximation of Eq. 8. Details on how to implement this procedure are discussed in Valdebenito and Schuëller (2011).

Approximate Representation of Normalized Demand Function

The approximate representation in Eq. 7 suggests that changes in the normalized demand function $D_N(\mathbf{y}, \mathbf{z})$ due to changes in the design variable vector $\mathbf{y}$ can be explained through a linear relation. Such relation is clearly not captured exactly by such a simple expression due to a number of reasons: higher-order terms involving $\mathbf{y}$ are ignored, no interaction between $\mathbf{y}$ and $\mathbf{z}$ is considered, the nonlinear nature of the normalized demand function (see Eq. 3) is not captured appropriately, etc. However, in case the coefficients a_q , $q = 1, \dots, n_y$ are chosen appropriately, it could be expected that $\tilde{D}_N(\mathbf{y} + \Delta\mathbf{y}, \mathbf{z})$ approximates $D_N(\mathbf{y} + \Delta\mathbf{y}, \mathbf{z})$ sufficiently well. That is, the coefficients a_q represent an *average sensitivity* on how

Sensitivity of First-Excursion Probabilities for Nonlinear Stochastic Dynamical Systems,

Fig. 1 Example – 2-story RC frame structure including nonlinear devices (NLDs)

the design variables affect the normalized demand. Numerical validation (see Jensen et al. 2009; Valdebenito and Schuëller 2011) has shown such an assumption is appropriate within the scope of the problems studied in this contribution.

The procedure applied to calculate the coefficients a_q , $q = 1$, n_y is quite straightforward. Samples of the uncertain variable vector $\mathbf{z}$ are taken from the last stage of SS. It is expected that for these samples the normalized demand function is close to 1. Then, for each of these samples, the value of the normalized demand is reevaluated considering perturbed values of the design variable vector. Then, the sought coefficients are estimated in a least square sense considering the sampled data and the analytic model of Eq. 7. For details on the implementation of this procedure, the reader is referred to Jensen et al. (2009) and Valdebenito and Schuëller (2011).

Example

Description of the Problem

In order to illustrate the application of the procedure for failure probability sensitivity estimation, the following example is considered. It involves a two-story reinforced concrete (RC) frame which includes nonlinear hysteretic devices (NLDs). Figure 1 illustrates the elevation of the model. The frame is excited by a horizontal ground acceleration of 15 [s] duration, which is modeled as a stochastic process. The failure event

takes place whenever displacement of each floor of the building exceeds a prescribed threshold within the duration of the stochastic ground acceleration. The design variables of the problem refer to the dimensions of the columns of the RC frame.

The RC frame possesses a Young's modulus equal to 2×10^{10} [N/m²]. Each of its floors (of mass 1.5×10^5 [kg]) is supported by six columns of square cross section (side length equal to 0.5 [m]) and a height of 3.5 [m]. The beams of the frame are rigid in the axial direction, so each floor can be described by a single horizontal degree of freedom (DOF); thus, the model involves a total of two DOFs. It is assumed that the columns and beams remain linear within the duration of the stochastic ground acceleration and classical modal damping of 5 % for all modes is assumed.

In order to improve the safety of the frame, two hysteretic NLDs are included. The restoring force ($F_{R,i}(\cdot)$) associated with the i -th NLD is described by the following model (Pradlwarter and Schuëller 1993):

$$F_{R,i}(t) = k_d(\Delta_i(t) - q_i^1(t) + q_i^2(t)), \quad i = 1, 2 \quad (15)$$

where $\Delta_i(\cdot)$ is the relative displacement between the $(i, i - 1)$ -th floors, k_d is the stiffness of the NLD, and $q_i^1(\cdot)$ and $q_i^2(\cdot)$ denote the plastic elongations of the NLD, which are governed by the following equations:

$$\dot{q}_i^1(t) = \dot{\Delta}_i(t)H(\dot{\Delta}_i(t)) \left[H(\tau_i(t) - \Delta_p) + H(\tau_i(t) - \Delta_y) \frac{\tau_i(t) - \Delta_y}{\Delta_p - \Delta_y} H(\Delta_p - \tau_i(t)) \right], \quad i = 1, 2 \quad (16)$$

$$\dot{q}_i^2(t) = -\dot{\Delta}_i(t)H(-\dot{\Delta}_i(t)) \left[H(-\tau_i(t) - \Delta_p) + H(-\tau_i(t) - \Delta_y) \frac{-\tau_i(t) - \Delta_y}{\Delta_p - \Delta_y} H(\Delta_p + \tau_i(t)) \right], \quad i = 1, 2 \quad (17)$$

where $\tau_i(t)$ is an auxiliary variable defined as $\tau_i(t) = \Delta_i(t) - q_i^1(t) + q_i^2(t)$, $i = 1, 2$, and Δ_y and Δ_p are the yielding and plastic displacements, respectively. The numerical values considered for the parameters of the NLD are $k_d = 10^8$ [N/m], $\Delta_p = 6 \times 10^{-3}$ [m], and $\Delta_y = 0.8\Delta_p$.

The ground acceleration ($g_A(t)$) is modeled as a filtered white noise of 15 [s] duration. The ground acceleration is calculated as $g_A(t) = \alpha^T \dot{p}(t)$; the vectors α^T and $p(t)$ are defined as

$$\alpha^T = \langle \Omega_1^2, 2\xi_1\Omega_1, -\Omega_2^2, -2\xi_2\Omega_2 \rangle \quad (18)$$

$$\dot{p}(t) = \begin{pmatrix} 0 & 1 & 0 & 0 \\ -\Omega_1^2 & -2\xi_1\Omega_1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ \Omega_1^2 & 2\xi_1\Omega_1 & -\Omega_2^2 & -2\xi_2\Omega_2 \end{pmatrix} p(t) + \begin{pmatrix} 0 \\ \omega(t)e(t) \\ 0 \\ 0 \end{pmatrix} \quad (19)$$

where $\Omega_1 = 15$ [rad/s], $\xi_1 = 0.8$, $\Omega_2 = 0.3$ [rad/s], and $\xi_2 = 0.995$ are the filter parameters; $\omega(t)$ denotes a white noise signal; and $e(t)$ is an envelope function:

$$e(t) = \begin{cases} t^2/16 & 0[s] \leq t < 4[s] \\ 1 & 4[s] \leq t < 10[s] \\ e^{-(t-10)^2} & 10[s] \leq t \leq 15[s] \end{cases} \quad (20)$$

A time discretization step equal to $\Delta t = 0.01$ [s] is used to model the ground acceleration. Thus, the discrete representation of the white noise signal is $\omega(t_k) = \sqrt{2\pi S/\Delta t} z_k$, $k = 1, \dots, 1501$, where $S = 10^{-3}$ [m²/s³] is the spectral density of the white noise and z_k , $k = 1, \dots, 1501$ are independent, identically distributed standard Gaussian variables.

The failure event is formulated as a first-excursion problem during the time of analysis; the structural responses to be controlled are the two interstory drift displacements and the roof

displacement. The threshold values are chosen equal to 0.2 % of the floor height for the interstory drift displacements and 0.1 % of the frame height for the roof displacement. The design variables refer to the cross sections of the columns of the RC frame, more specifically to the second moment of area of the cross section. These cross sections are grouped into two design variables linking the columns of the first and second floor, respectively.

Results

The sensitivity of the first-excursion probabilities is estimated using the approach described previously. In particular, SS is applied considering 2,000 samples of the uncertain ground acceleration at each simulation stage. The resulting first-excursion probability estimate is equal to $\tilde{P}_F = 10^{-3}$. Hence, a total of 6,000 samples of the uncertain variables are required in order to estimate the sought probability. Recall that these samples are also used to estimate the coefficients ψ_0 and ψ_1 . In order to calibrate the approximate model of Eq. 7, 200 perturbed designs are analyzed. Hence, the estimation of the probability sensitivity demands only 200 extra structural analyses. In order to illustrate the variability associated with the approach for estimating first-excursion probability sensitivity, a total of 100 independent runs were generated. The results in terms of the mean of these runs and their corresponding coefficient of variation are shown in Table 1. In addition and in order to validate the results obtained in Table 1, the probability sensitivity is estimated using a central finite difference estimator. In order to ensure the probability

estimates used in the finite difference scheme are sufficiently accurate, the average of 100 independent runs is considered. The results associated with the finite differences are presented in Table 1 as well. It can be observed that the results presented are in good agreement, indicating the approach for sensitivity estimation reported herein provides appropriate results.

Summary

This contribution has presented an approach for sensitivity analysis of first-excursion probabilities associated with nonlinear dynamical systems. The basis of the approach is combining advanced simulation methods for probability estimation with a series of local approximations involving the normalized demand function.

A salient feature of the approach reported herein is that it is numerically efficient. This is achieved as the proposed local approximations take advantage of the results already available from probability estimation.

The results presented in this contribution indicate that the proposed approach for sensitivity is applicable for problems involving a large number of uncertain parameters; results presented elsewhere (see, e.g., Valdebenito and Schuëller 2011) indicate that the approach is also capable of including a considerable number of design variables.

Introduction

The output of a seismic sensor, a seismometer or an accelerometer, is a time-varying voltage, which is related to the ground motion by a differential equation in the time domain or by a transfer function in the frequency domain. This transfer function or response function is characterized by a number of parameters, which are assumed to be constant, at least in the short term.

A seismic sensor will have calibration information given by the manufacturer. These specifications will be used to correct the seismic signal from the sensor to produce the true ground motion. If, e.g., for a given harmonic ground velocity $X(\omega)$, the output from the sensor is $Y(\omega)$, the amplitude response or transfer function $A(\omega)$ is defined as the ratio $A(\omega) = Y(\omega)/X(\omega)$, where ω is the frequency in radian/s. So, if $A(\omega)$ is known, the input (ground motion) can then be calculated as

$$X(\omega) = Y(\omega)/A(\omega) \quad (1)$$

The sensor will, in addition to changing the amplitude of the ground signal, also change the phase of the signal, so an additional function will be needed for the phase response. The phase and amplitude response functions can be combined in one complex function ($A(\omega)$ would then be complex); however, here, for simplicity, they will be treated separately.

The amplitude and phase response functions are usually calculated from the sensor parameters but can also be obtained by direct measurements.

With time, the sensor might degrade or it might develop a fault so there is a need to be able to calibrate the sensor. This means determining the instrument calibration parameters (parametric calibration) or determining $A(\omega)$ directly for each frequency of interest (empirical calibration).

Modern sensors can be very complicated in terms of electronics and mechanical construction so it might not be possible to determine all relevant parameters; however, some parameters can be obtained with simple tests. In this section,

basic parameters will be described, some tests used to obtain them as well as methods for obtaining $A(\omega)$ directly.

Seismic Sensors

Seismic sensors can be divided into two kinds: sensors measuring the ground velocity (velocity sensor or seismometer) and sensors measuring the ground acceleration (accelerometers). A seismometer can be passive, meaning there is no electronic parts or active with an electronic circuit integrated. All accelerometers for seismic recording are active sensors. Piezoelectric accelerometers are passive (although they may have a conditioning circuit built-in) and are widely used for structural vibrations monitoring, but seldom in seismology, due to their poor sensitivity at low frequency and low dynamic range.

Passive Seismometers: A passive seismometer consists of a swinging mass with a coil moving in magnetic field. It is also called an electromagnetic sensor. The swinging system has resonance frequency ω_0 . An example is seen in Fig. 1.

When the mass is moving, the magnetic field will vary in the coil. An output voltage proportional to the velocity of the mass relative to the ground will then be produced. The proportionality constant is called the generator constant G and has the unit V/ms^{-1} . But the relative motion of the mass depends on the frequency of the ground motion. Thus the sensor will not be equally sensitive to ground motion for all frequencies. Qualitatively the response of the sensor can be understood as follows. If the ground moves with a very fast sinusoidal motion, the mass remains stationary in an inertial frame, and thus the ground sinusoidal velocity is measured directly. With the ground moving very slowly, the mass would have time to follow the ground motion, so there would be little relative motion and the gain would be low. At the resonance frequency, the mass could get a new push at the exact right time, so the mass would move with a larger and larger amplitude, only limited by the damping of the motion. The sensor amplitude response $A(\omega)$,

Sensors, Calibration of, Fig. 1 A model of an electro-magnetic sensor. The mass m is also a magnet suspended by a spring k . The coil resistance is R_g , the damping resistor is R , and the voltage output is V_{out} . The mass motion is damped by the current through the coil (fixed to the frame) and the external damping resistor

which is the output voltage of the sensor as a function of the input ground velocity, can be obtained as (e.g., Lay and Wallace 1995)

$$A(\omega) = \frac{G\omega^2}{\sqrt{(\omega_0^2 - \omega^2)^2 + 4h^2\omega^2\omega_0^2}} \quad (2)$$

where h is the damping, ω is the frequency, and ω_0 is the natural frequency of the swinging system. Figure 2 shows examples of $A(\omega)$ with different damping.

It is seen that, as the damping decreases, the gain gets a larger and larger peak at the natural frequency. The flat curve represents a damping of $h = 0.707$ and is the desired value. The damping is achieved by shunting the signal coil with a damping resistor and thereby draining energy out of the swinging system.

Active Sensors: The heart of the active sensor is a device measuring the ground acceleration, the so-called force balanced accelerometer (FBA) (Fig. 3). The FBA has a feedback coil, which can exert a force equal and opposite to the inertia force due to the acceleration. The displacement transducer sends a current to this force coil

through a resistor R in a negative feedback loop. The polarity of the current is such that it opposes any motion of the mass, and it will try to prevent the mass from moving at all with respect to the frame. A small permanent acceleration on the mass will therefore result in a small permanent current, and a large acceleration will need a large current. The current is in fact proportional to the ground acceleration, so the voltage over the resistor gives a direct measure of acceleration. This is how nearly all accelerometers work, and in practice the only constant of importance is the generator constant G in units of V/g, where g is the gravity acceleration.

The FBA principle is now the heart of nearly all modern strong motion and broadband sensors (BB, sensors recording in a large frequency band like 0.01–50 Hz). By connecting an integrating circuit after the output, the sensor can give out a voltage proportional to velocity like for passive sensors. However, due to the mechanical-electrical qualities of the sensor, there is in practice a low frequency limit for the flat velocity response. For lower frequencies, the amplitude response decreases proportional to frequency squared. This means that in practice, a BB sensor will have the equivalent of a free period and a damping, and its amplitude response can be approximated by Eq. 2, although a more exact model of its response should include additional parameters that influence the high-frequency behavior. In practice Eq. 2 must then be multiplied with a function which often represents a filter, like a Butterworth filter that can be represented by a simple function of filter frequency and number of poles of the filter; see Havskov and Alguacil (2010). An estimate for the filter parameters can be obtained by empirical calibration; see later.

The sensor parameters to measure can therefore be summarized as instrument natural frequency, damping, and generator constant. With these parameters, the amplitude response function Eq. 2 can be calculated.

Alternatively the amplitude response function can be determined directly by measuring the output of the sensor with a controlled input.

Sensors, Calibration of, Fig. 2 Amplitude response to ground velocity of a typical passive sensor with a natural frequency of 1 Hz for different damping values

Sensors, Calibration of, Fig. 3 Simplified principle behind the force balanced accelerometer. The displacement transducer normally uses a capacitor C, whose capacitance varies with the displacement of the mass. A current, proportional to the displacement transducer output, will force the mass to remain stationary relative to the frame (Figure from Havskov and Alguacil 2010)

Determining Sensor Parameters

Natural Frequency

The frequency with which the seismometer mass is oscillating depends on the damping; more

damping makes it swing at a lower frequency ω_1 . The relation is (Havskov and Alguacil 2010)

$$\omega_1 = \sqrt{\omega_0^2(1 - h^2)} \tag{3}$$

Sensors, Calibration of, Fig. 4 Free swinging of three typical 1 Hz seismometers with different open-circuit damping h . Traces have been generated synthetically. The decaying extremes (peak amplitudes) are labeled z_1 ,

z_2 , etc. (top trace). On the middle trace, the amplitudes of two maximums following each other are given in an arbitrary scale (Figure modified from Havskov and Alguacil 2010)

The natural frequency is therefore best measured without any external damping. The free period can be determined in several ways depending on the type of sensor.

Passive Sensor: Give the sensor an impulse or a step to make it swing, a small push or tilt will do. For a very few sensors, it is possible to see the mass swing, else the output signal has to be observed on an oscilloscope or recorded. Measure the time of several swings and calculate the average or measure the frequency from the recorded signal. Many short-period sensors (natural frequency higher than 1 Hz) have too high open-circuit damping (damping without a damping resistor) to observe more than a few swings of the signal (Fig. 4), and the signal must be recorded to measure the period.

BB Sensor: The response of a BB sensor is controlled mainly by its internal feedback loop. The user can only measure its “apparent free period”; however, this is difficult since the damping is fixed at 0.7 so there will be almost no swinging (see Fig. 9). Most BB sensors have a calibration input, which can be used to produce

a calibration pulse from which the “apparent free period” and damping can be obtained; see section on calibration pulse later.

If the open-circuit damping is high, say larger than 0.15 (corresponding to about 1 % change in period), the measured free period should be corrected for damping.

Damping

The open-circuit damping h_m is caused by the friction in the mechanical system and can be determined from the signals from the free swinging system as shown in Fig. 4. Using the extreme amplitudes z_1 and z_n where z_1 is extreme 1 and z_n is extreme $n + 1$ (so $n = 1$ for two following extremes (Fig. 4)), the open-circuit damping can be determined as (Havskov and Alguacil 2010)

$$h_m = \frac{\ln(z_1/z_n)}{\sqrt{n^2\pi^2 + \ln^2(z_1/z_n)}} \quad (4)$$

Measuring z_1 and z_2 , h_m can now be determined directly. In Fig. 4, two following maxima ($n = 2$)

Sensors, Calibration of,

Fig. 5 Tilting an accelerometer to determine generator constant. It is assumed that the sensor horizontal direction is toward the east (Figure from Havskov and Alguacil 2010)

have approximate amplitudes 30 and 19, respectively. This gives a damping of

$$h_m = \frac{\ln(30/19)}{\sqrt{2^2\pi^2 + \ln^2(30/19)}} = 0.0725 \quad (5)$$

A sensor in operation should always have a damping resistor connected in order to get the desired total damping of 0.707 so as to get the most flat response. The additional damping caused by the electrical damping is called h_e , and the corresponding total resistance of the coil and damping resistor is R_T . The damping resistor cannot be determined experimentally as above, since with total damping of 0.707, there would be too little overswing. It can be shown (Havskov and Alguacil 2010) that the ratio between two electrical damping constants is inversely related to the ratio of the damping resistances:

$$R_{T2} = R_{T1} \frac{h_{e1}}{h_{e2}} \quad (6)$$

R_{T1} and R_{T2} are two different total damping resistances and h_{e1} and h_{e2} the corresponding damping coefficients caused by the resistances, respectively. In addition comes the open-circuit damping, so, the total damping with R_{T1} is h_1 :

$$h_1 = h_{e1} + h_m \quad (7)$$

and writing Eq. 6 in terms of the total damping gives

$$R_{T2} = R_{T1} \frac{h_{e1}}{h_{e2}} = R_{T1} \frac{h_1 - h_m}{h_2 - h_m} \quad (8)$$

When $h_2 = 0.707$, the corresponding $R_{T2} = R_{0.707}$ is

$$R_{0.707} = R_{T1} \frac{h_1 - h_m}{0.707 - h_m} \quad (9)$$

so the procedure to determine $R_{0.707}$ is:

1. Determine h_m as described above.
2. Connect a damping resistor R_{T1} of “suitable size,” meaning that the overswing is substantially less than when measuring h_m but large enough to get an accurate determination of h_1 .
3. Use Eq. 9 to determine $R_{0.707}$.

For BB sensors or other active sensors, there is no damping resistor, and the damping is preset from the factory. These sensors have a buffered low-impedance voltage output, so an external load resistor would not influence the sensor at all.

Generator Constant

In order to determine the generator constant experimentally, a known input to the sensor must be used or the generator constant must be calculated from other known measurable parameters.

Accelerometer: For a static ground acceleration, an accelerometer has an output proportional to this acceleration. An accelerometer cannot distinguish any difference between an inertial force due to ground acceleration and an equivalent gravity force. By tilting the accelerometer, the effective force on the three components can be determined for different tilt angles and the sensitivity determined; see Fig. 5.

The accelerometer is tilted an angle α . The force in the horizontal direction is now $mg \sin(\alpha)$,

Sensors, Calibration of, Fig. 6 Comparison of signals recorded from two different seismometers with the same recording equipment. The filters and amplifiers are identical and filter out signals below the seismometers natural

frequencies. The ratio of the output amplitudes (right) indicates the ratio of the sensor generator constants (Figure from Havskov and Alguacil 2010)

while in the vertical direction it is $mg\cos(\alpha)$. The voltage output for the vertical component is V_z , and for the horizontal component it is V_h . Considering that in the horizontal position, the output is supposed to be zero and that the vertical force has been *decreased* from mg to $mg\cos(\alpha)$, the generator constant can be calculated as

$$G_z = \frac{-V_z}{g(1 - \cos(\alpha))} \quad \text{and} \quad G_h = \frac{V_h}{g \sin(\alpha)} \quad (10)$$

V_z will be negative since the vertical force is decreased, and V_h will be positive since the force is in the east direction. This method is very simple and can determine the generator constant accurately, but will not give a dynamic calibration. The horizontal components can be tested for symmetry by inclining in the opposite direction. In the case that the instrument output is not zero in the horizontal position, this offset should be adjusted before any measurement is made; alternatively it may be subtracted from the output for each measurement.

Passive Velocity Seismometer: The generator constant can be calculated from

$$G = \sqrt{2m\omega_0 h_e R_T} \quad (11)$$

where m is the mass of the moving mass and h_e is the electrical damping corresponding to the total resistance R_T . In the previous section it has been described how R_T , h_e , and ω_0 can be determined.

All Sensors: A shaking table is a platform that moves with a controlled motion. Setting it up to move with a harmonic motion with maximum amplitude A (velocity or acceleration) at a frequency where the response curve is flat, the output from the sensor will also be a harmonic function with amplitude B . The generator constant is then

$$G = B/A \quad (12)$$

Unfortunately a shaking table is rarely available, so other methods must generally be used.

The ground is always moving so if the motion is known, it is equivalent to having a shaking table moving both horizontally and vertically. The problem is then to determine this motion in order to have an absolute measure. This is done by using a well-calibrated sensor. The experiment then consists of setting up the two sensors close to each other and assuming that they are subject to the same ground motion (Fig. 6). The data is filtered so as to use a frequency band where both sensors are measuring the signal in the flat part of their instrument response function, e.g., from 2 to 5 Hz using a BB sensor as a reference and a 1 Hz sensor to be calibrated.

The generator constant can then be determined as

$$G = G_R B/A \quad (13)$$

where G_R is the generator constant of the reference sensor, A is the amplitude of the reference sensor, and B is the amplitude of the unknown

sensor. The amplitude can be picked for any part of the two seismograms provided that they are identified as the same “swing”; see Fig. 6. It is here assumed that both sensors are of the same type like comparing a velocity sensor to a velocity sensor or an accelerometer to an accelerometer. Note that many accelerometers are not sensitive enough to be able to use this method, so the tilt method should be used.

Calibration of Velocity Sensors by Stepwise Motion: The main idea behind this method is to (1) move the sensor to a known distance (like 1 mm) in its direction of sensitivity, (2) record the signal, and (3) correct the signal for the known displacement frequency response (response function relating sensor output to displacement) to get the displacement. Theoretically, the displacement is now calculated, which can be compared to the actual displacement, from which the generator constant can be calculated. The method is described in detail by Wielandt in chapter “► [MEMS Sensors for Measurement of Structure Seismic Response and Their Application](#)” in NMSOP (Bormann 2002), which claims that the method works well for broadband sensors (accuracy down to 1 %) and even 10 Hz seismometers. Although the method sounds simple, it is not trivial to correct for the instrument response down to DC, particularly for SP instruments.

Another problem is how to move the sensor, horizontally or vertically, at a controlled distance. A simple instrument that has been used for vertical motion is a mechanical balance (Fig. 7). Placing the sensor on the mechanical balance table, the seismometer can be moved at a controlled distance as measured on the balance arm vertical scale. In principle, it is enough to make one displacement, but usually several are made to take average measurements.

A simple portable calibration table which operates on this principle is commercially available from Lennartz Electronic (www.lennartz-electronic.de). It moves the vertical axis a known displacement. It also allows to tilt the sensor a known angle, which is sensed as an apparent step in acceleration along the horizontal axis, thus permitting the calibration of horizontal components as well.

Sensors, Calibration of, Fig. 7 Moving a sensor at a controlled distance vertically with a mechanical balance. The ratio between the motion at x (where we can measure it) and on the balance table can be determined by placing a mass m_1 at x that will balance a mass m_2 on the balance table. The ratio of the two motions is then m_1/m_2 (Figure from Havskov and Alguacil 2010)

It should be noted that some of the triaxial BB seismometers have the three sensors arranged symmetrically, forming an orthogonal frame with its active axes inclined 54.7° with respect to horizontal, so each sensor is sensitive to vertical motions. Their outputs are then electronically combined to generate the conventional two horizontal and one vertical outputs. If the individual sensor outputs are available, they can be calibrated with only the vertical step motion.

Measuring the Complete Response Curve $A(\omega)$

The alternative to obtain the individual sensor parameters and then calculating $A(\omega)$ is to obtain $A(\omega)$ directly. This is an empirical calibration and can only be done by providing a known input to the sensor $X(\omega)$ and measuring the output $Y(\omega)$, from which the response function can be obtained as

$$A(\omega) = Y(\omega)/X(\omega) \quad (14)$$

Shaking Table: Again a shaking table is the simplest way. The shaking table can move

Sensors, Calibration of, Fig. 8 Setup for measuring the instrument response using the calibration input (Figure from Havskov and Alguacil 2010)

vertically and horizontally in a controlled fashion so the ground input is exactly known. All that has to be done is to measure the output, as a function of frequency, and divide by the known input to get the response function. It is not as simple as it sounds. Making a precise shaking table, particularly for horizontal motion, without introducing tilt, is complicated and expensive, so shaking tables are rarely available for the general user and only used in special laboratories.

Sensor Calibration Input: Many sensors have a calibration input. For passive seismometers, this is a calibration coil around the mass, and applying a current to the coil results in a force on the mass. Most active sensors do not have a calibration coil, but an equivalent test can be made when a voltage is applied to the feedback loop to produce a force on the mass. In both cases it is possible to accelerate the moving mass by applying a voltage to the calibration input. By using a sine wave, the sensors experience the equivalent of a ground acceleration, and, by varying the frequency, the complete frequency-dependent amplitude response can be determined, since the input $X(\omega)$ is known and $Y(\omega)$ is measured. This method assumes that the calibration circuit is accurate. An experimental setup is seen in Fig. 8.

A signal generator sends out a sine wave with a constant amplitude V_0 . This voltage is applied to the sensor calibration input and exerts a force on the mass proportional to V_0 . For the velocity sensor with a calibration coil, the amplitude of the force f_i will be

$$f_i = K_c V_0 / R_c \quad (15)$$

where K_c is the calibration coil motor constant (N/A) and R_c is the resistance of the calibration coil. For the active sensor

$$f_i = K_a V_0 \quad (16)$$

where K_a is the calibration input sensitivity (N/V). With a sensor mass of m , the equivalent ground acceleration amplitude is then f_i/m , the equivalent ground velocity is $f_i/m\omega$, and the equivalent ground displacement amplitude is $f_i/m\omega^2$. If the amplitude of the seismometer voltage output is V_s , then the velocity amplitude response (V/ms^{-1}) for this frequency is

$$A(\omega) = \frac{V_s m \omega}{f_i} \quad (17)$$

and similarly for displacement response. By varying the frequency and measuring both input and output signals, a complete response curve can be obtained.

When the calibration coil is used to calibrate a passive sensor, an undesirable effect may be present: a spurious coupling between the calibration coil and the signal coil. This coupling affects mainly the higher frequencies and may be approximately corrected for by subtracting the signal output when the same current is injected with the sensor mass locked (Sauter and Dorman 1986; Steck and Prothero 1989).

From Fig. 8, it is seen that the output signal not only has been changed in amplitude but also has been delayed a little relative to the input signal; in

other words, there has been a phase shift. In this example, the phase shift is positive; see definition in Eq. 18. The complete frequency response of the sensor therefore consists of both the amplitude response function and the phase response function $\Phi(\omega)$. Considering a general input harmonic waveform $x(\omega, t) = X(\omega) \cdot \cos(\omega t)$ at frequency ω , the output can be written as

$$y(\omega, t) = X(\omega) \cdot A(\omega) \cdot \cos(\omega t + \Phi(\omega)) \quad (18)$$

The phase shift is here defined as a quantity being added to the phase as seen above. Thus comparing Fig. 8 and Eq. 18, it is seen that the phase shift is positive.

The phase response function can therefore also be measured using this harmonic drive method. It can similarly be obtained using a shaking table.

Knowing the complete response function $A(\omega)$, it is now possible to get an indication if the response function can be represented by Eq. 2 or there are additional filters to include.

Using the Ground Motion as a Shaking Table: The experiment consists of setting up two sensors close to each other and assuming that they are subject to the same ground motion. If the known and unknown sensors have recorded signals of the ground motion z_1 and z_2 , respectively, and corresponding spectra are $Z_1(\omega)$ and $Z_2(\omega)$, the input ground motion (displacement, velocity or acceleration) is

$$X_1(\omega) = \frac{Z_1(\omega)}{A_1(\omega)} \quad (19)$$

where A_1 is the response function of the known sensor 1. The unknown response function A_2 is then

$$A_2(\omega) = A_1(\omega) \frac{Z_2(\omega)}{Z_1(\omega)} \quad (20)$$

Note that if A_1 is in displacement, then A_2 will also be in displacement and similarly if A_1 is in velocity or acceleration. It is, e.g., possible to use an accelerometer to calibrate a seismometer or

vice versa. Thus, by measuring the signals of the known and unknown sensor, it is in principle simple to determine the response function of the unknown sensor. In order for the method to work, the sensor self-noise must be well below the signal levels generated by the ground motion. That will clearly limit the usefulness of the method at lower frequencies, where, e.g., for a geophone, the output signal level will be low. So, contrary to normal sensor installation, these tests should be made in a high ground noise environment like the top floor of a building, although some care is required to avoid air-coupled acoustic noise, which may affect both sensors in different ways (Pavlis and Vernon 1994).

If the spectra $Z_1(\omega)$ and $Z_2(\omega)$ of the two sensors outputs are contaminated with instrumental noise (a noncausal output), a simple ratio Z_2/Z_1 may yield a biased or unreliable estimate of the response. By using only the correlated part of the signals, i.e., the part due to the common input of both sensors, the ground noise in this case, a more reliable estimate, will be obtained. This may be done by using a known relation between input and output of linear and causal systems: the input-output cross-spectrum is the product of the transfer function and the input power spectrum (see, e.g., Ljung 1999). Consider a linear system whose input is the output of seismometer 1 (Z_1) and its output is the output of seismometer 2 (Z_2). This system would have a transfer function $A_2/A_1 = P_{21}(\omega)/P_{11}(\omega)$, or Z_2/Z_1 if these two spectra were noise-free and generated by the same input. Therefore, a more robust estimation of the unknown response A_2 is obtained using

$$A_2(\omega) = A_1(\omega) \frac{P_{21}(\omega)}{P_{11}(\omega)} \quad (21)$$

where $P_{11}(\omega)$ represents the power spectrum of the output of sensor 1 and $P_{21}(\omega)$ is the cross-spectrum between the outputs of sensors 1 and 2. The advantage of this equation is that, ideally, it cancels out the contributions of uncorrelated components (i.e., self-noise) of the input and output signals. This method has been further

Sensors, Calibration of, Fig. 9 Calibration pulse from a velocity sensor. *Left:* The recorded calibration pulse due to an input step in acceleration. *Right:* The log-log

spectrum of the calibration pulse. The sensor natural frequency ω_0 is indicated. The damping is 0.707 (Figure from Havskov and Alguacil 2010)

improved using three channels of data, resulting in more robust estimate of the relative response function (Sleeman et al. 2006). However, small misalignments between the three sensors may prevent the background noise to be fully canceled out, and a leak of such noise is then evaluated as sensor self-noise. Gerner and Bokelmann (2013) suggest a technique to numerically fix this effect by searching for the optimal alignment.

Calibration Pulse: It is common practice to generate a calibration pulse by applying a step current into the calibration coil of a passive sensor. For a BB sensor an equivalent test can be made when a voltage is applied to the feedback loop to produce a force on the mass. As the applied force is proportional to the coil current or the voltage, this input signal is equivalent to a ground step in acceleration (see also section above). The output pulse can be recorded (Fig. 9), and this pulse can be used in several ways to obtain sensor parameters.

From signal theory (e.g., Scherbaum 2007) it is known that the Fourier transform of the impulse response of a linear system is the frequency response function. However, what is generated here is a step. If the amplitude spectrum of the calibration pulse is $C(\omega)$, the response function will then be $A(\omega) = \omega C(\omega)$. This corresponds to the response function for acceleration since the input was an acceleration step so the velocity response for the velocity sensor is then $\omega^2 C(\omega)$. Thus, multiplying the spectrum in Fig. 9 with ω^2 will give the velocity response for $h = 0.707$ seen in Fig. 2. It is also possible to obtain the approximate natural frequency ω_0 as the frequency where the spectral amplitude (Fig. 9) has decreased from the flat level by a factor

$1/\sqrt{2} = 0.707$ or the frequency for which the low-frequency and high-frequency asymptotes intersect. It is then in principle simple to get the frequency response for the sensor by just doing spectral analysis of the calibration pulse; however, ground and electronic noise might make it inaccurate. In practice the signal-to-noise ratio is improved by summing several calibration pulses with their onsets well aligned. The background noise is decreased in this way, while the signal due to the calibration pulses is increased.

Summary

Calibration of seismic sensor can be done in many ways. The calibration can determine the frequency response of a sensor by determining the sensor parameters natural frequency, damping, and generator constant from which the frequency response can be calculated. The alternative is to experimentally determine the complete frequency response of the sensor using, e.g., a shaking table or the sensor calibration input. In most cases it will be possible for the general user to get a good idea about the response function using one of the methods described in this paper.

Site Response for Seismic Hazard Assessment

Gaetano Elia
School of Civil Engineering and Geosciences,
Newcastle University, Newcastle Upon
Tyne, UK

Introduction

Lessons learned worldwide from historical (e.g., Niigata, Japan, and Alaska in 1964) and recent strong earthquakes (e.g., L'Aquila in 2009, Chile in 2010, Tohoku, Japan, and Christchurch in 2011, among others) have distinguished site amplification and soil liquefaction as two of the main causes of damage to man-made and natural structures during seismic events. As illustrated in Fig. 1, the ground shaking observed at surface during an earthquake depends on the seismic source characteristics and focal mechanism, the

deep wave propagation from the fault to the bedrock, and the local soil conditions. The first two phenomena are commonly studied by seismologists, geologists, and geophysicists, while the third one falls in the geotechnical earthquake engineering field, being strongly related to the mechanical behavior of soils subjected to dynamic loading. The term “site effects” refers to the overall set of modifications of the bedrock motion, in terms of amplitude, frequency content, and duration, during its (almost) vertical propagation through shallow geological deposits. Despite the traveling path of the propagating waves within the surface soils is often less than 100 m, local site conditions can produce significant ground motion amplification, slope instability, excessive building settlements (i.e., subsidence), and liquefaction in loose and saturated granular deposits, thus playing a crucial role in building and infrastructure damage (Fig. 1).

Ground response numerical analyses are, therefore, used by geotechnical engineers to predict the free-field motion, to determine permanent soil deformations (leading to subsidence and liquefaction), and to evaluate the risk of instability of earth structures (e.g., earthquake-induced landslides). They may also include the evaluation of basin and topographic effects on ground motion (e.g., King and Tucker 1984; Bard and Bouchon 1985; Geli et al. 1988; Bard 1994; Ashford et al. 1997; Bouckovalas and Papadimitriou 2005; Semblat et al. 2005; Pagliaroli et al. 2011). In addition, the results of these studies can be incorporated into microzonation and probabilistic seismic hazard analyses (e.g., Tsai 2000; Bazzurro and Cornell 2004; Papaspiliou et al. 2012).

Site response analyses have been traditionally performed using a one-dimensional (1D) frequency-domain numerical scheme based on the equivalent viscoelastic approach. This approach has been extensively adopted in the last 30 years, and it is widely accepted in the engineering practice, although its limitations are well known. Being based on a total stress formulation, it disregards the buildup of excess pore water pressures in the soil deposit. Additionally, the adopted equivalent viscoelastic material properties cannot properly represent the soil

Site Response for Seismic Hazard Assessment, Fig. 1 Wave propagation from seismic source to ground surface and related geotechnical problems (Modified from Lanzo and Silvestri 1999)

behavior under cyclic loading for high seismic intensities at bedrock. Finally, the 1D scheme cannot take into account site effects related to surface and buried complex morphologies, i.e., topographic and valley effects. Time-domain schemes are nowadays available to solve the wave propagation problem in a more realistic way, accounting for the solid–fluid interaction by means of a coupled effective stress formulation. In those schemes, the behavior of the soil can be described using either simple or sophisticated nonlinear soil constitutive models of different level of complexity. In addition, time-domain analyses, usually performed with finite element codes, can also describe two- (2D) and three-dimensional (3D) complex geometries to model topographic and basin effects. Nevertheless, these nonlinear analyses are seldom adopted by nonexpert users because the calibration of advanced soil constitutive models can be challenging and the code usage protocols are often unclear or poorly documented in the literature.

This entry begins with a short overview of available methods for site characterization and evaluation of soil dynamic properties (section “[Soil Dynamic Properties and Measurement Techniques](#)”), factors that are essential for the

assessment of site response effects. Ground response analyses are then discussed in the section “[Ground Response Analysis](#),” describing linear and nonlinear approaches for the study of one-dimensional wave propagation problems in free-field conditions. Soil–structure interaction and earthquake-induced ground failure problems, such as soil liquefaction, landslides, and retaining structure instability, are outside the scope of the entry and, therefore, are not discussed here. A review is given in Kramer (1996), Kramer and Stewart (2004), and Semblat and Pecker (2009). Finally, the section “[Future Challenges](#)” provides an overview of future challenges in the field of geotechnical earthquake engineering.

Soil Dynamic Properties and Measurement Techniques

Soil Dynamic Properties

As schematically indicated by Fig. 1, the propagation of waves from bedrock to ground surface is commonly considered as a vertical process. According to Snell’s law (cf. Richart et al. 1970), in fact, waves traveling from higher-velocity materials into lower-velocity materials

Site Response for Seismic Hazard Assessment,

Fig. 2 Mechanical behavior of a soil element subjected to an irregular simple shear loading history (Modified from Lanzo and Silvestri 1999)

are refracted closer to the normal to the interfaces. Therefore, earthquake waves propagating upward through horizontal layers characterized by lower velocities and densities (such as in typical top soil deposits) are refracted closer to a vertical path. Moreover, saturated soils subjected to earthquake loading behave essentially in undrained conditions, given the rapidity of the seismic action. The volumetric deformations induced by P-waves are, consequently, negligible with respect to the distortional deformations associated with S-waves. For the above reasons, many of the methods of ground response analysis presented in the section “[Ground Response Analysis](#)” simulate the seismic event as a loading process induced by SH-waves only, characterized by a vertical traveling path associated with soil particle motion in the horizontal plane. This phenomenon requires the analysis of the mechanical behavior of soils under simple cyclic shear loading conditions. Considering a generic soil element within the deposit in geostatic conditions (when only the vertical, σ'_{v0} , and the horizontal, σ'_{h0} , effective stresses are applied), the earthquake action induces an additional simple shear stress $\tau(t)$ changing irregularly with time (Fig. 2).

The corresponding stress–strain ($\tau - \gamma$) curve under this cyclic loading history is typically

characterized by state dependency, early irreversibility, nonlinearity, buildup of excess pore pressures, decrease of nominal stiffness, and related hysteretic dissipation (e.g., Sangrey et al. 1969; Hardin and Drnevich 1972; Castro and Christian 1976; Vucetic and Dobry 1991). Under a symmetric cyclic loading condition, the hysteresis loop in the $\tau - \gamma$ plane can be effectively described by two parameters: the shear modulus and the damping ratio. As shown in Fig. 3, the tangent shear modulus $G_{\tan}$ represents the soil stiffness for a specific point of the loop, and it changes continuously throughout the cycle.

An overall indication of the average soil stiffness is, instead, represented by the secant shear modulus $G_{\sec}$, defined as:

$$G_{\sec} = \frac{\tau_c}{\gamma_c} \quad (1)$$

where τ_c and γ_c are the maximum shear stress and shear strain amplitudes, respectively. The area included in the hysteresis loop is a measure of the energy dissipated by the soil during the cycle and is described by the damping ratio D :

$$D = \frac{W_D}{4\pi W_S} = \frac{A_{\text{loop}}}{2\pi G_{\sec} \gamma_c^2} \quad (2)$$

Site Response for Seismic Hazard Assessment, Fig. 3 Evaluation of shear moduli and damping ratio from hysteresis loop (Modified from Kramer 1996)

where W_D is the dissipated energy (equal to the area of the hysteresis loop A_{loop}) and W_S is the maximum strain energy represented by the shaded area in Fig. 3.

Starting from a maximum value, i.e., G_0 or G_{max} , the soil stiffness tends to decrease with increasing shear strains. Its variation with cyclic shear strain amplitude (γ_c) is described graphically by a normalized modulus reduction curve $G/G_0 - \gamma_c$. Conversely, the energy dissipation provided by the soil, increasing with loop amplitude due to plasticity effects, is typically depicted by a $D - \gamma_c$ curve. Therefore, the mechanical characterization of the soil stiffness and damping requires both the evaluation of G and D at very low strains and the way in which the two properties change with cyclic shear strain amplitude. Laboratory tests have shown that soil stiffness and damping are also influenced by other factors, such as mean effective confining pressure, plasticity index (PI), overconsolidation ratio (OCR), and number of imposed cycles (N). In particular, extensive laboratory investigations on the cyclic response of normally consolidated and slightly

overconsolidated reconstituted clays presented by Vucetic and Dobry (1991) indicated that (Fig. 4):

- The values of OCR and effective consolidation stress have almost no effect on the position and shape of G/G_0 and D curves.
- The plasticity index PI is the key factor controlling the dimensionless parameters G/G_0 and D .
- The number of cycles N does affect both the value of G/G_0 (due to the degradation of the shear modulus with N) and the $D - \gamma_c$ curve at high cyclic strains (i.e., after the volumetric threshold).

It should be noted that the modulus reduction and damping curves reported in Fig. 4 for $PI = 0$ are nearly identical to the average curves commonly used for sands (Seed and Idriss 1970). This suggests that the curves shown in Fig. 4 can be used for both fine- and coarse-grained soils. Modulus reduction and damping ratio curves are influenced by the mean effective stress for cohesionless and low-plasticity soils, but this influence decreases with increasing plasticity index, being generally not significant for $PI \geq 30$ (Ishibashi 1992).

Measurement Techniques

The measurement of soil dynamic properties is a crucial task in the solution of any geotechnical earthquake engineering problem. Particularly for the evaluation of local site effects, the characterization of the soil deposit above bedrock in terms of variation of G_0 and D with depth and $G/G_0 - \gamma_c$ and $D - \gamma_c$ curves is essential. A variety of field and laboratory techniques are available, each oriented toward the measurement of low-strain properties and characterized by different advantages and limitations. A complete review of the existing techniques is outside the scope of this entry, and only the most significant ones are discussed in the following.

Low-strain field tests induce seismic waves in the soil and measure the velocities at which these waves propagate. The maximum shear modulus can be computed using the measured shear wave

Site Response for Seismic Hazard Assessment,

Fig. 4 Nonlinear behavior as function of plasticity index in terms of: (a) normalized shear modulus and (b) damping ratio (Vucetic and Dobry 1991)

velocity (V_s) and the soil density (ρ) through the following equation based on the elasticity theory:

$$G_{max} = \rho V_s^2 \quad (3)$$

Shear wave velocities can be measured in situ by several seismic tests, including cross-hole and down-hole, seismic cone penetrometer, suspension logger, SASW (spectral analysis of surface waves), and MASW (multichannel analysis of surface waves). A review of these test methods is given in Woods (1994) and Kramer (1996). Their accuracy can be sensitive to procedural details, soil conditions, and interpretation techniques. Fig. 5 shows the layouts and principles of three established geophysical tests: the continuous surface wave (CSW) method, the down-hole

test, and the cross-hole technique. In the CSW test (Fig. 5a), a mechanical, servo-hydraulic, or electromagnetic vibrator applies a single-frequency sinusoidal force to the ground surface. Rayleigh waves traveling through the soil are detected by a series of geophones (usually two) displaced at a range of distances from the source. By changing the input frequency, a profile of phase velocity against wavelength is obtained, and, consequently, a stiffness profile with depth can be computed. Although less economical than an SASW test, the CSW method has been proved to provide better data, as background noise can be easily recognized and filtered. Likewise the CSW test, the MASW approach uses a multiple of equally spaced receivers (usually 12 to 60) that are deployed on the surface along a survey line.

Each receiver is connected to a common multichannel recording instrument (i.e., a seismograph). This is the most significant difference between the CSW and the MASW techniques, as CSW is usually based on a two-receiver approach. Also the MASW method generally uses an impulsive source, such as a sledgehammer, to produce surface waves, whereas the CSW technique makes use of a frequency-controlled vibrator.

Down-hole and cross-hole tests are alternative low-strain techniques which require one or more borings. In a down-hole test, a vibration source is placed on the ground surface adjacent to a borehole. The arrival of seismic energy is detected at depth either by geophones secured against the borehole sides or by geophones within a seismic CPT (Fig. 5b). The test is repeated changing the depth of the geophones (typically at 1 m intervals) to plot the shear wave travel time as function of depth. The average shear velocity can be computed by knowing the distance between the source and the receiver. The cross-hole test makes use of more than one boring (usually two, less commonly three as this latter option is more expensive): a source is placed in one boring and a receiver is placed at the same depth in each of the other boreholes (Fig. 5c). An impulsive disturbance is applied at the source and the travel time to each receiver is measured. A borehole verticality survey is required in order to calculate the actual distance between the boreholes at each test depth (usually 1 m intervals). The wave propagation velocity is, in fact, computed by knowing the distances between receivers. The use of two sets of receivers (three boreholes) avoids the issue of trigger accuracy, but increases the cost of the test. While CSW and down-hole tests allow to determine the shear modulus for distortion in vertical plane (G_v) as the source produces a vertically polarized horizontally traveling shear wave, the cross-hole technique allows to calculate also the shear modulus in the horizontal plane (G_h) by using horizontally polarized shear wave sources.

The standard penetration test (SPT) and the cone penetration test (CPT), although originally developed for the measurement of soil properties

mobilized at large strains, can be indirectly used to determine shear modulus profiles in situ by using empirical correlations between penetration resistance (N_{SPT}) or tip resistance (q_c) values and G_{max} (a review is given in Kramer 1996). These estimates are affected by high uncertainties and should be used very cautiously, given the scatter in the data on which they are based and the variability in the results obtained by different correlations. Such correlations should be adopted only for preliminary estimates of G_{max} in the framework of simplified approaches.

Finally, standard spectral ratio (SSR) and horizontal-to-vertical spectral ratio (HVSr) methods for the determination of the deposit fundamental frequencies are becoming increasingly popular not only in the research field but also in professional practice (i.e., for microzonation studies). Site amplification factors can, in fact, be inferred, at least in the linear strain range, using the SSR technique described by Field and Jacob (1993). HVSr amplifications obtained experimentally can, instead, be used to validate numerical model results (e.g., SESAME 2004; Lanzo et al. 2011).

In general, field tests have the advantage to describe the dynamic properties of the soil as it is in situ. Laboratory testing methods are, on the contrary, usually performed on relatively small specimens that can be disturbed by the sampling technique and may not be representative of the larger body of soil from which they are retrieved. Nevertheless, cyclic and dynamic laboratory tests are complementary to field methods as they can provide the description of soil nonlinearity over a wide range of shear strains in terms of $G/G_0 - \gamma_c$ and $D - \gamma_c$ curves. Typical low-strain element techniques are the resonant column (RC) and the bender element (BE) tests. A schematic view of the resonant column apparatus is presented in Fig. 6: a solid or hollow cylindrical specimen is subjected to harmonic torsional or axial loading by an electromagnetic loading system. The system usually applies a harmonic load for which the frequency and amplitude can be controlled. The fundamental frequency of the specimen can be identified by gradually increasing the loading frequency. Given the mass polar moment of

Site Response for Seismic Hazard Assessment, Fig. 5 Field seismic tests: (a) continuous surface wave (CSW), (b) down-hole, and (c) cross-hole (Clayton 2011)

inertia of the loading head and the specimen mass and dimensions, the shear modulus of the soil can be calculated, assuming linear elasticity (i.e., using Eq. 3). Repeating the test with increasing loading amplitude, the variation of secant shear modulus with shear strain can also be measured.

Damping can be determined using the half-power bandwidth method or from the logarithmic decrement by placing the sample in free vibration (ASTM 2007). This technique has been modified to allow cyclic torsional shear testing to strain levels above those typically achieved during a

Site Response for Seismic Hazard Assessment, Fig. 6 Schematic drawing of a typical resonant column apparatus: (a) top view and (b) profile view (Kramer 1996)

conventional resonant column test. It is well established that the large strain rates related to the high frequencies applied in an RC test can affect the measured small-strain shear modulus and damping ratio. Dry cohesionless soils usually do not exhibit rate effects, while high strain rates can produce an increase of shear stiffness at small strains in fine-grained plastic soils leading to a G_0 overprediction with respect to cyclic simple shear tests (e.g., Lo Presti et al. 1997; Cavallaro et al. 2003). Moreover, the laboratory results indicate that some energy is always dissipated by the soil, even at very low strains, so that the damping ratio is never equal to zero. This mechanism cannot be justified by plasticity theory, as no hysteretic dissipation of energy associated to the development of plastic deformations takes place at strain levels within the elastic domain. Therefore, the initial damping ratio D_0 observed in resonant column experiments can be probably attributed to material viscous effects and/or the inertia of the resonant column apparatus (e.g., Meng and Rix 2003; Lo Presti et al. 2007).

Another laboratory technique that allows the measurement of the shear wave velocity of a soil sample is the bender element testing method. Bender elements consist of two piezo-ceramic plates bonded together in such a way that application of a voltage causes one plate to expand and the other to contract. This generates seismic waves in

the soil sample in which the device is embedded. At the same time, a lateral disturbance of a bender element produces a voltage, thus allowing the detection of incoming waves. Therefore, BE can be used as both transmitters and receivers of S-waves within a soil sample (typically triaxial). By measuring the time required for the wave to travel from the source to the receiver and knowing the distance between each, the shear wave velocity of the specimen can be measured.

Finally, laboratory tests able to measure the dynamic soil properties at high strain levels have been derived from conventional tests by adding cyclic loading capabilities to the testing apparatus. Examples are represented by cyclic triaxial tests with local strain measurements and cyclic simple shear tests.

Table 1 summarizes the range and applicability of the most common field and laboratory cyclic and dynamic techniques, with particular reference to the induced shear strain level, characteristic frequency, and dynamic soil properties which can be obtained from the tests.

Ground Response Analysis

Analytical solutions have been developed to solve one-dimensional wave propagation problems, assuming that the input motion is harmonic and

Site Response for Seismic Hazard Assessment, Table 1 Range and applicability of field and laboratory dynamic tests (Modified from Vinale et al. 1996)

Site Response for Seismic Hazard Assessment, Fig. 7 Profiles with increasing bedrock acceleration of (a) maximum shear strain, (b) shear modulus, (c) damping

ratio, and (d) maximum acceleration mobilized within the soil deposit (Lanzo and Silvestri 1999)

the soil is a homogeneous elastic or viscoelastic material (e.g., Roesset 1977). They make use of amplification functions to describe the dynamic response of a soil deposit (considered as a single-degree-of-freedom system) in the frequency domain. This approach is limited to the analysis of linear systems, as it relies on the principle of superposition. When the soil deposit is layered, heterogeneous (i.e., G_0 changes with depth), and

nonlinear (i.e., G and D are functions of the shear strain induced by the earthquake), the amplification function is no more constant (as in the analytical solutions) but site specific. The effects of soil nonlinearity on wave propagation are qualitatively illustrated in Fig. 7, where a homogeneous deposit overlying a horizontal bedrock is subjected to an input motion characterized by increasing values of the maximum acceleration ($a_{\text{max},r}$).

Site Response for Seismic Hazard

Assessment, Fig. 8 Peak acceleration on soft soil sites as function of bedrock maximum acceleration (Idriss 1990)

Increasing the peak ground acceleration at bedrock:

- The mobilized shear strain increases (Fig. 7a).
- The shear modulus reduces and the damping ratio increases correspondingly (Fig. 7b, c).
- For low input energy, the peak acceleration along the soil profile increases moving from the bedrock to the ground surface (profiles 1 and 2 in Fig. 7d).
- For high input energy, the peak acceleration along the profile can reduce because the nonlinear behavior reduces the soil shear stiffness, thus preventing from the transmission of high frequencies, while the corresponding increase of damping ratio reduces the displacement and acceleration amplitude peaks (profile 3 in Fig. 7d).

In terms of amplification factor (given as the ratio between the max acceleration at surface to the max acceleration at bedrock), nonlinearity effects can lead to a reduction of the amplification at surface with increasing acceleration levels at bedrock. On the basis of data recorded during Mexico City (1985) and San Francisco Bay area (1989) earthquakes, and of additional ground response analyses, Idriss (1990) related peak accelerations on soft soil deposits to those on rock sites, as reported in Fig. 8. For acceleration levels lower than about 0.4 g, the peak acceleration at soft soil surface is likely to

be higher than on rock. At higher acceleration levels, on the contrary, nonlinearity can prevent from the development of peak accelerations at surface as large as those observed on rock sites.

Local site conditions not only influence the peak acceleration amplitudes but can also strongly affect the frequency content of surface motions. Fig. 9 shows the effects of local soil conditions on the shape of the normalized response spectra computed from ground motions recorded on different sites: for periods above 0.5 s, spectral accelerations for soil sites are higher than those for rock sites. The figure clearly indicates that deep and soft soil deposits enhance the transmission of low frequencies (high periods). The results also show that the use of a single response spectrum shape for all site conditions is not appropriate. This evidence has been incorporated in a large number of seismic codes worldwide which propose the use of different spectral shapes for different subsoil conditions.

Equivalent Linear Approach

Nonlinear soil behavior can be approximated by an equivalent linear characterization of soil dynamic properties. The method makes use of the exact continuum solution of wave propagation in horizontally layered viscoelastic materials subjected to vertically propagating transient motions (e.g., Roesset 1977). It models the nonlinear variation of soil shear modulus and

Site Response for Seismic Hazard Assessment,

Fig. 9 Normalized response spectra (5 % damping) for different local site conditions (Seed et al. 1976)

Site Response for Seismic Hazard Assessment, Fig. 10 Equivalent linear algorithm (Modified from Lanzo and Silvestri 1999)

damping with shear strain through a sequence of linear analyses with iterative update of stiffness and damping parameters. For a given soil layer, G and D are assumed to be constant with time during the shaking. Therefore, an iterative procedure is needed to ensure that the properties used in the linear dynamic analyses are consistent with the level of strain induced in each layer by the input motion.

The iterative procedure, illustrated in Fig. 10, operates as follows:

1. Initial estimates of G and D are made for each layer at low-strain values.
2. These initial values are used in a linear frequency-domain dynamic analysis where the acceleration time history at bedrock is transformed through a fast Fourier transform

(FFT) algorithm and the transfer functions between the bedrock and each layer (H_i in Fig. 10) are computed.

3. The inverse fast Fourier transform (IFFT) algorithm is employed to obtain acceleration, displacement, and shear strain time histories at each layer.
4. The effective shear strain (γ) in each layer is determined from the maximum shear strain ($\gamma_{\max}$) as follows:

$$\gamma = \beta \gamma_{\max} \quad (4)$$

where $\beta = (M - 1)/10$ is usually related to the expected earthquake magnitude M .

5. From this effective shear strain, new equivalent linear values of G and D are chosen for the next iteration.
6. Steps 2–5 are repeated until a convergence criterion is satisfied.

The most widely used computer software for one-dimensional ground response analysis, based on the equivalent linear approach described above, is SHAKE (Schnabel et al. 1972) and its modified version SHAKE91 (Idriss and Sun 1992). For two-dimensional geometries, the equivalent linear approach has been implemented in a number of codes such as FLUSH (Lysmer et al. 1975) and QUAD4M (Hudson et al. 1994), among others. Equivalent linear methods are extensively adopted in engineering practice for their simplicity, flexibility, and low computational requirements. Nevertheless, their limitations are well known. The analysis is performed adopting a total stress approach. This means that excess pore water pressures induced by the earthquake cannot be predicted and the displacements due to consolidation processes cannot be calculated. The model employed to describe the mechanical behavior of soils is viscoelastic. Therefore, the method cannot predict permanent soil displacements or cumulated strains at the end of the analysis. Even though the iteration process allows to approximate nonlinear soil behavior, the approach is still a linear method of analysis. The strain-compatible soil properties are constant throughout the duration of the earthquake. The method is thus not

capable of representing changes in soil stiffness and hysteretic damping during the seismic action.

For problems where strain levels remain low (stiff soil profile and/or relatively weak input motions), the equivalent linear method can produce reasonable estimates of ground response. For high seismic intensities at bedrock, nonlinear time-domain analyses should be preferred as they are likely to provide better results (section “[Verification and Parametric Studies](#)”).

Nonlinear Approach

In recent years, the use of fully coupled effective stress formulations, based on Biot’s theory for solid–fluid interaction (Biot 1941; Zienkiewicz et al. 1999), is becoming increasingly popular as the theoretical basis for the dynamic analysis of geotechnical structures (e.g., Dewoolkar et al. 2001; Elgamal et al. 2002a; Aydingun and Adalier 2003; Dakoulas and Gazetas 2005; Liu and Song 2005; Madabhushi and Zeng 2007; Sica et al. 2008; Alyami et al. 2009; Shahrouar et al. 2010; Elia et al. 2011; Kontoe et al. 2011; Elia and Rouainia 2013, 2014). Specifically for ground response analysis, nonlinear approaches are able to solve the wave propagation problem by direct numerical integration in the time-domain, accounting for the development of plastic deformations and buildup of excess pore water pressures within the soil deposit induced by the earthquake. In those schemes, the mechanical behavior of the soil can be described using either simple or sophisticated nonlinear constitutive models of different level of complexity. In terms of spatial discretization, most numerical approaches are modelling the problem in 1D or 2D plane strain conditions. Nonlinear three-dimensional (3D) ground response analyses are rarely found in the literature, being only performed for critical structures, such as tunnels, bridges, and earth dams (e.g., Elgamal 1992; Stamos and Beskos 1995; Elgamal et al. 2008; Ou 2009; Hatzigeorgiou and Beskos 2010).

A summary of the available computer software, employing equivalent linear and nonlinear approaches to solve the wave propagation problem in one- and two-dimensional conditions, is reported in Table 2.

Verification and Parametric Studies

The effectiveness of the different numerical approaches, briefly described in the previous sections, to simulate the complex wave propagation process has been tested over the last decades using real vertical array data and/or centrifuge test results. In these cases, in fact, the input motion is reasonably well defined, as it is directly recorded on rock or it is imposed during the test. In addition, validation studies have been conducted in several international benchmark projects, such as ESG-IASPEI/IAEE 1992 (Turkey Flat and Ashigara Valley arrays), ESG-IASPEI/IAEE 2006 (Grenoble basin), Turkey Flat 2008, and E2VP 2010 (EuroSeisTest, Greece).

As an example, Borja et al. (1999) presented a verification study using the recordings from accelerometer arrays installed at the Lotung Large-Scale

Seismic Test (LSST) site in Taiwan. The site was established in 1985 to study the dynamic behavior of two scaled-down nuclear plant containment structures constructed by the Electric Power Research Institute (EPRI) and the Taiwan Power Company.

Borja and coworkers studied the ground response at Lotung employing both a standard linear equivalent method (SHAKE) and an advanced nonlinear approach, where a bounding surface soil constitutive model (formulated in terms of total stresses) was implemented into the three-dimensional finite element (FE) code SPECTRA. Fig. 11a, b compares the recorded ground surface accelerations along the EW and NS directions (i.e., FA1-5/EW and FA1-5/NS) with the corresponding predictions obtained through SHAKE. The peak values of both EW and NS accelerations recorded at ground surface

Site Response for Seismic Hazard Assessment,

Fig. 11 Comparison of ground surface accelerations recorded at Lotung (EW and NS components) and predictions by SHAKE and SPECTRA (Borja et al. 1999)

were slightly underpredicted. Moreover, a time shift in the acceleration peak between the recorded and computed NS motions can be observed. On the contrary, Fig. 11c, d shows that peak accelerations were predicted by the nonlinear model within 10–20 % error in both

directions. An excellent match also in terms of zero crossings was obtained using the advanced nonlinear time-domain approach. The advantage of the described approach lies in its capacity to extend the analysis to three dimensions, thus allowing the simultaneous application of the

Site Response for Seismic Hazard Assessment,

Fig. 12 VELACS model 1 recorded and computed acceleration time histories (Elgamal et al. 2002b)

three components of the earthquake (one vertical and two horizontal) at the base of the FE column.

Another example of verification study, this time using centrifuge testing data, is provided by Elgamal et al. (2002b). The authors adopted an advanced plasticity-based constitutive model to simulate the cyclic mobility response mechanism typically observed in medium-dense sands subjected to cyclic loading. The model was implemented into an unnamed fully coupled finite element code to predict the dynamic response observed during different centrifuge tests (VELACS project, Arulanandan and Scott 1993). In particular, Fig. 12 shows the comparison between the computed acceleration time histories and the ones recorded for VELACS model 1 (representing a level site composed of Nevada

sand and subjected to a 2Hz harmonic base excitation). Good agreement was achieved between the computed and recorded responses at different depths within the soil deposit in terms of accelerations, although the numerically predicted settlement due to liquefaction was generally smaller than observations. In addition, the work by Elgamal and coworkers demonstrates how, under level ground conditions, shear strains can be relatively small with minor cyclic mobility effects, while mildly sloping ground may result in large cyclic shear strain accumulation leading to unbounded flow failure. The importance of the dominant excitation frequency on post-liquefaction soil response is also highlighted.

The two examples described above are representative of the state of the art in the field of

nonlinear ground response analysis, but other verification studies are reported by Kramer and Stewart (2004). Although a direct comparison with recorded ground response during seismic actions is invaluable, the performance of advanced numerical approaches can also be usefully evaluated through parametric analyses. These numerical studies can, in fact, provide helpful guidelines to nonexpert users of time-domain nonlinear schemes by clarifying the importance of the different ingredients required to perform sophisticated simulations. One of the most controversial factors affecting FE dynamic simulations is the calibration of the viscous damping, usually needed in nonlinear analyses when the adopted soil constitutive model is unable to provide enough hysteretic energy dissipation through plasticity. Viscous damping is typically introduced in FE codes by means of the Rayleigh formulation, whose damping matrix is defined as follows:

$$[C] = \alpha_R [M] + \beta_R [K] \quad (5)$$

where $[M]$ and $[K]$ are the mass and the stiffness matrix of the system, respectively. The coefficients α_R and β_R are obtained considering the following relationship with the damping ratio D :

$$\begin{Bmatrix} \alpha_R \\ \beta_R \end{Bmatrix} = \frac{2D}{\omega_m + \omega_n} \begin{Bmatrix} \omega_m \omega_n \\ 1 \end{Bmatrix} \quad (6)$$

where ω_m and ω_n are the angular frequencies related to the frequency interval $f_m \div f_n$ over which the viscous damping is equal to or lower than D . The amount of Rayleigh damping to be introduced in an FE dynamic analysis is difficult to quantify a priori, but, at the same time, its magnitude can play a crucial role on the results of the simulations (Woodward and Griffiths 1996). Different possible calibration procedures have been proposed in the literature to identify the interval $f_m \div f_n$. A well-established one (e.g., Hudson et al. 1994) suggests to select f_m as the first natural frequency of the deposit f_I , while f_n is assumed equal to n times f_m , where n is the closest odd integer

larger than the ratio f_p/f_I between the predominant frequency of the input earthquake motion (f_p) and the fundamental frequency of the soil deposit (f_I). This latter assumption was based on the evidence that the higher modes of a shear beam are odd multiples of the fundamental mode of the beam. Recently, Kwok et al. (2007) used linear frequency-domain solutions to provide guidelines on the specification of viscous damping adopted in four 1D nonlinear codes (namely, D-MOD_2, DEEPSOIL, OpenSees, and SUMDES). The idea was to assume the results of 1D linear equivalent analyses as target solutions for the nonlinear approaches, thus guiding the user in the calibration of the viscous damping parameters. The main conclusions of this parametric investigation can be summarized as follows:

- The target damping ratio should be set to the small-strain material damping.
- The two target frequencies should be set, as a first approximation, to the first mode site frequency and five times the site frequency (i.e., $n = 5$).
- More generally, the target frequencies should be established through an iterative process by which linear time-domain and frequency-domain solutions are matched.

Similarly to Kwok et al. (2007), Amorosi et al. (2010) performed a parametric investigation using two different finite element codes (i.e., PLAXIS 2D and SWANDYNE II) and compared the results of 2D FE viscoelastic simulations with 1D linear equivalent solutions (i.e., EERA). In order to provide a useful framework for finite element users, some of the factors potentially influencing the numerical results were critically discussed. In particular, the amount of viscous damping adopted in FE viscoelastic analyses, the spatial and time discretization, and the nature of boundary conditions were examined. The investigation showed that:

- The traditionally adopted procedures for the calibration of the Rayleigh coefficients (e.g., Hudson et al. 1994) can lead to large

overestimation of the peak ground acceleration with respect to the EERA solutions. Therefore, a novel calibration procedure was proposed based on the linear equivalent amplification function and the frequency content of the input motion. It was suggested that the first target frequency (f_m) should be set to the first mode site frequency significantly excited by the seismic motion, while the second (f_n) should be selected equal to the frequency where the amplification function gets lower than one.

- As regards the effect of boundary conditions adopted in the FE simulations, tied nodes at the lateral boundaries of the mesh should be preferred, as they are properly representative of a 1D condition and allow to obtain a perfect match with EERA. When using Lysmer and Kuhlemeyer (1969) boundaries, the 2D mesh should be characterized by a width to height ratio between five and eight to avoid spurious wave reflections at the vertical boundaries.
- In terms of spatial discretization, the FE mesh should always satisfy the condition that the spacing between the nodes, Δl_{node} , must be smaller than approximately one-tenth to one-eighth of the wavelength associated with the maximum frequency component f_{max} of the input wave.
- The time-step algorithm adopted in the FE code can introduce some numerical damping in the integration of the governing equations of motion, and, therefore, the time-stepping coefficients need to be selected carefully in order not to lose accuracy.

Two alternative soil damping formulations for small and large strains have been recently implemented by Phillips and Hashash (2009) in the nonlinear one-dimensional site response analysis code DEEPSOIL. The first one introduces an approach to construct a frequency-independent viscous damping matrix which reduces the overdamping at high frequencies and, therefore, the filtering at those frequencies. A good match with frequency-domain analysis results can be obtained with this new approach, which, nonetheless, requires the calculation of the eigenvalues

and eigenvectors of the matrix $[M]^{-1}[K]$. The second formulation introduces a reduction factor that modifies the extended Masing loading/unloading stress-strain relationship (Masing 1926) to match measured modulus reduction and damping curves simultaneously over a wide range of shear strains. This modified hysteretic model allows to reduce the typically observed overestimation of damping predicted by advanced soil constitutive models for large strains (see next section). The proposed models have been implemented in a total stress nonlinear code and, therefore, cannot predict accumulation of excess pore water pressures during the shaking.

Future Challenges

While during recent years important advances have been made in the field of geotechnical earthquake engineering, some challenges still remain to be addressed.

In situ and laboratory characterization of soil dynamic properties represents a crucial aspect of any seismic design of geotechnical structures. Techniques for more accurate characterization of in situ soil shear wave velocity and damping ratio are required (e.g., Hall and Bodare 2000). Although expensive and time consuming, advanced laboratory cyclic and/or dynamic tests are essential for the correct understanding of soil behavior during seismic excitations and for the proper calibration of sophisticated constitutive assumptions introduced in nonlinear ground response analyses. At the same time, these tests should be interpreted within the framework of plasticity theory, as irreversible deformations in soil samples can develop also for small imposed strains.

With respect to site response analysis, the use of nonlinear time-domain approaches should be encouraged as a viable alternative to the standard linear equivalent method. It can, in fact, better predict soil deformation, degradation of stiffness, and accumulation of excess pore water pressures throughout the shaking. The issue of the accurate prediction of hysteretic damping with advanced soil constitutive models still remains controversial, as these models can significantly

underpredict the damping ratio for small strains and overestimate it in the large strain range. Some adjustments in the mathematical formulation of advanced soil models have been proposed recently (e.g., Phillips and Hashash 2009; Seidalinov and Taiebat 2014) to address this point, but more research work is needed. In general, clear guidance and protocols should be provided to nonexpert users of time-domain codes in order to improve the reliability of nonlinear ground response analysis results.

Another open challenge in the area of seismic risk assessment is related to the selection of appropriate input motions for nonlinear ground response simulations. The correct definition of the design seismic actions, based on seismic hazard and site response analyses, is, indeed, essential to fully implement the performance-based design approach proposed by code prescriptions (e.g., Eurocode 8). The options available to engineers in terms of input acceleration time series are represented by artificial, synthetic, and real accelerograms. Spectrum-compatible artificial records are characterized by excessive number of cycles of strong motion, and consequently they possess unreasonably high-energy content. It is now widely accepted that the use of these artificial records is problematic and not suitable particularly for nonlinear analyses (e.g., Bommer and Acevedo 2004). Synthetic accelerograms generated from seismological source models are highly sensitive to the definition of earthquake source parameters, which involve a significant degree of expert judgment. On the contrary, real earthquake accelerograms represent a more viable option for providing input to dynamic analyses, being more realistic than artificial records and easier to obtain than synthetic accelerograms. In any case, current practice for selecting and scaling ground motions for linear and nonlinear response-history analyses is based largely on engineering judgment. Very few systematic studies provide impartial guidance to geotechnical engineers regarding appropriate methods to use in site-specific applications. The majority of the research has been focused in the last years on structural response more than on site response (e.g., NIST 2011). Practitioners often select

ground motion records based only on distance, site soil conditions, and magnitude of the characteristic event expected to dominate the seismic hazard. However, many other factors, such as directivity of the rupture and presence of basin, affect the ground motion intensity and frequency content, which ultimately govern the nonlinear response and damage in geotechnical and structural systems (e.g., Frankel et al. 2011). Despite this, current practice is not adequately equipped to fully incorporate near-fault directivity, basin, and duration effects in the design process. Methods to implicitly consider inelastic demands by amplifying the design spectra do not provide a reliable basis for representing realistic ground input motions (Kalkan and Kunnath 2006).

More research is still needed to address all these issues, requiring a better integration between the work of geotechnical engineers, seismologists, geologists, and structural engineers. Finally, an ongoing transfer of research knowledge into practice represents a significant requisite to support performance-based earthquake engineering design and quantitative seismic risk assessment.

Summary

Experience from past strong earthquakes worldwide has demonstrated the relevance of local soil conditions on seismic ground response. The changes in amplitude, frequency content, and duration of the seismic motion during its propagation in soil deposits, commonly referred to as site effects, have a crucial impact on buildings and infrastructure response during earthquakes. Numerical methods allow geotechnical engineers to quantify the effects of soil deposits on the wave propagation process from bedrock to ground surface. These methods can be divided into: (i) frequency-domain analyses (using the linear equivalent method) and (ii) time-domain schemes (usually performed with finite element codes). The benefits and limitations of the two approaches are extensively discussed in this entry, together with a short description of the available methods for site

characterization and evaluation of soil dynamic properties. An overview of future challenges in the field of geotechnical earthquake engineering is also presented at the end of the entry.

List of symbols

$a_{\max}$	Earthquake maximum acceleration
A_{loop}	Area of the hysteresis loop
D	Damping ratio
f	Frequency
f_l	Fundamental frequency of the soil deposit
f_p	Predominant frequency of the input earthquake motion
f_r	Resonance frequency
G_{sec}	Secant shear modulus
G_{tan}	Tangent shear modulus
G_0 or $G_{\max}$	Initial shear modulus
M	Earthquake magnitude
N	Number of imposed cycles
N_{SPT}	SPT number
OCR	Overconsolidation ratio
PI	Plasticity index
q_c	CPT test tip resistance
V_R	Rayleigh wave velocity
V_S	Shear wave velocity
W_D	Energy dissipated in one hysteresis loop
W_S	Maximum strain energy in one hysteresis loop
α_R	Rayleigh damping coefficient
β	Ratio of effective shear strain to maximum shear strain
β_R	Rayleigh damping coefficient
γ	Shear strain
γ_c	Cyclic shear strain
ρ	Soil density
ω	Angular frequency

Synonyms

1-D nonlinear seismic site response analysis; 1-D nonlinear site response analysis; One-dimensional (1-D) time domain analysis

Introduction

One-dimensional (1-D) time domain analysis is one of several currently available methods to evaluate the influence of local site conditions on input (i.e., bedrock) ground motions. However, this method is favored by Geotechnical Earthquake Engineers as it takes into account the unique geotechnical characteristic of a given site, including soil nonlinearity and hysteretic behavior and porewater pressure generation and dissipation. It can also be applied for a wide range of shaking intensities, and it is relatively easy to implement in practice as it is coded in commercially available software.

Through back analysis of numerous case histories, the 1-D time domain analysis has been shown to work well when analyzed soil deposits are horizontally layered, there is a significant impedance contrast within the profile, and when material (model) parameters are established through a reasonable site investigation and characterization efforts.

There are many circumstances under which a 1-D time domain site response analysis is performed. Such an analysis is commonly performed in the following situations: (i) when soil conditions cannot be reasonably categorized into one of the standard site conditions, (ii) when empirical site factors for the site are not available (e.g., the International Building Code Site Class F), (iii) when special ground conditions govern the design (e.g., soil liquefaction, seismic settlement and/or lateral spreading, or slope stability), (iv) for any case where the objective is to obtain ground motions considered to be more representative of the local geologic and seismic site conditions than motions obtained from other approaches, and/or (v) when calibration of a more advanced, multidimensional models with or without structural elements is required.

In general, site response analysis methods can be classified based upon the domain in which calculations are performed (frequency domain or time domain), the sophistication of the constitutive model employed (linear, equivalent linear, and/or nonlinear), whether the effects of

porewater pressure generation are neglected or not (total-stress and effective-stress analyses, respectively), and the dimensionality of the space in which the analysis is performed (one-dimensional, 1-D; quasi 2-D, 2-D, and 3-D). Other considerations in classifying site response analysis methods include modeling of cyclic reduction and cyclic degradation in a total-stress mode. This chapter focuses upon time domain nonlinear total- and effective-stress 1-D site response analysis which has significant advantages over its frequency domain linear and equivalent-linear counterparts in areas of very high seismicity (e.g., $\text{PGA} \geq 0.4 \text{ g}$) and/or when the effects of soft and/or potentially liquefiable soils in the profile cannot be ignored.

Theoretical Background

Dynamic Response Model

In 1-D time domain analysis, seismic response of a horizontally layered soil deposit is computed by solving the dynamic equation of motion. The dynamic equation of motion is commonly written as

$$[M] \{\ddot{u}\} + [C] \{\dot{u}\} + [K] \{u\} = -[M] \{\ddot{u}_g\} \quad (1)$$

where $[M]$, $[C]$, and $[K]$ are the mass matrix, viscous damping matrix, and nonlinear stiffness matrix, respectively; $\{u\}$, $\{\dot{u}\}$, and $\{\ddot{u}\}$ are the displacements, velocities, and accelerations of the mass $[M]$ relative to the base; and $\{\ddot{u}_g\}$ is the acceleration of the base.

The stiffness matrix $[K]$ is derived from the nonlinear (and effective-stress) soil constitutive model selected to represent a cyclic response of soil. In principle, all damping in the soil can be captured through the hysteretic loops of the constitutive model used to model cyclic soil behavior. However, most available soil constitutive models cannot properly represent soil damping at low strains. Therefore, it is necessary to add damping through the use of velocity proportional viscous damping, as discussed in detail below.

The dynamic equation of motion can be solved by numerical integration. The numerical integration calls for temporal discretization (i.e., system of coupled equations is discretized temporally), hence the term “solution in time domain.” The dynamic equation is solved by a time-stepping scheme. Examples of time-stepping schemes include Wilson’s theta (θ) algorithm (Clough and Penzien 1993) and several variations of the Newmark’s β algorithms (Newmark 1959).

In order to solve the dynamic equation of motion, it is necessary to properly discretize the domain of interest, which in this case is the 1-D soil column. Two different approaches for discretization of the soil column are available: (i) lumped mass discretization and (ii) finite element discretization.

Figure 1 shows a lumped mass discretization (i.e., lumped mass model) that of a horizontally layered soil deposit. Soil mass (m) is lumped at the layer interfaces (layers 1 through n). In each layer, soil stiffness is represented by a nonlinear spring. In addition to hysteretic damping inherent to a nonlinear spring, a viscous damping coefficient (c) is also part of a model shown in Fig. 1, as schematically represented by dashpots.

The finite element discretization requires solving the dynamic equation of motion (Eq. 1) by means of an explicit time marching integration algorithm. In this type of discretization, mass can be distributed over layer thickness.

The thickness of the layers in both lumped mass and finite element discretization have an impact on calculated site response. The layer thickness determines the maximum and minimum frequency that can be propagated through a soil column. If the layer is too thick, important components of the input ground motion may be filtered, and thus the calculated ground response may be underestimated. If layer thickness is too small, representation of the actual site conditions might be inadequate (e.g., soil lens is modeled as a soil layer).

Nonlinear Constitutive Models with Hysteretic Damping

One-dimensional nonlinear total-stress site response analysis is generally conducted using

Site Response: 1-D Time Domain Analyses, Fig. 1 Lumped mass discretization for 1-D dynamic response model (Matasovic 1993)

relatively simplified constitutive models of soil layers. These models evolved from the early stress–strain relationships of Ramberg and Osgood (1943) and Kondner and Zelasko (1963). The hyperbolic model, introduced by Duncan and Chang (1970) for axial soil behavior, was based upon the basic formulation of the above-cited shear stress and strain behavior models. It was accompanied by sets of generic material properties and hence allowed for an elegant and simple way to capture soil nonlinearity at small axial strains. All three models provided the basis for constitutive models that are presently in use. These include models by Pyke (1979), Matasovic (1993), Matasovic and Vucetic (1993), and Darendeli (2001) which, in addition to better simulation of nonlinear stress–strain behavior, allow for simulation of cyclic loading and reloading in accordance with certain rules. The stress–strain relationship in these models is generally established by: an initial loading curve; a series of rules that describe the backbone curve (see Fig. 2 for definition of backbone curve); and unloading–reloading behavior rules required to establish cyclic loops. The most widely used rules are the Masing rules (Masing 1926) and extended Masing rules

(Pyke 1979; Vucetic 1990). Recently, Phillips and Hashash (2009) developed a set of rules that compensate for one of the most common deficiency of nonlinear models with hysteretic damping – overestimation of damping at large shear strains.

Bounding surface plasticity models may be used to simulate nonlinear stress–strain behavior in one dimension. Example of such models and their application in site response analysis can be found in Borja et al. (2002).

Viscous Damping Models

The viscous damping models are an essential part of nonlinear site response programs. This is because: (i) viscous damping is a necessary input into a linear-elastic solution that is typically an integral part of a time domain site response analysis program; (ii) viscous damping readily increases numerical stability of several numerical schemes used to solve Eq. 1; and (iii) damping calculated by a hyperbolic model at very low strains (strains less than 0.1 %) is very small compared to the values obtained by laboratory measurements. Viscous damping compensates for that difference.

Given the above, most engineers introduce a small amount of viscous damping into site

Site Response: 1-D Time Domain Analyses, Fig. 2 Backbone curve as stress–shear strain relationship for monotonic loading

Site Response: 1-D Time Domain Analyses, Fig. 3 Schematic illustration of viscous damping change with frequency

response analysis. The value of viscous damping introduced is typically small (0.5–5 %).

The most commonly used formulation for evaluation of the viscous damping coefficient (c) is the Rayleigh damping (model). The viscous damping coefficient can be evaluated as

$$c = \alpha_R \mathbf{m} + \beta_R \mathbf{k} \tag{2}$$

where α_R and β_R are the Rayleigh damping coefficients (Rayleigh and Lindsay 1945)

and $\mathbf{m}$ and $\mathbf{k}$ are elements of the mass and stiffness matrices, respectively.

Figure 3 illustrates how Rayleigh damping, expressed through c , changes with frequency. The viscous damping ratio can be brought closer to a constant value of the target damping ratio (ζ_{tar}) by specifying c at only one frequency (e.g., at f_2 in Fig. 3), which is termed the *simplified* Rayleigh damping formulation, and/or at two frequencies (at f_1 and f_2), which is termed the *full* Rayleigh damping formulation.

Kwok et al. (2007) recommended, for most practical applications, use of the *full* Rayleigh damping formulation in nonlinear (total-stress) site response analysis whereby the first frequency is equal to the fundamental frequency of the soil column, while the second frequency is equal to five times the fundamental frequency.

Time Domain Analysis with Porewater Pressure Change

General

The cyclic loading of saturated soils is accompanied by porewater pressure change. This change includes simultaneous porewater pressure generation and dissipation. If the generated porewater pressures are sufficiently large, the soil stiffness and strength are significantly reduced, and ultimately, in some soils, liquefaction can occur.

In nonlinear site response analysis with porewater pressure generation (i.e., in effective-stress analysis), the response of the soil to cyclic loading accounts for the generation of excess porewater pressure (PWP) during cyclic shearing of the soil as well as dissipation of these excess porewater pressures during and after the cyclic loading. The representation of dissipation/redistribution of porewater pressure influences soil stiffness (modulus) and strength (shear stress) during shaking, thus resulting in a more realistic simulation of site response. The PWP dissipation/redistribution is discussed later.

The influence of PWP changes during cyclic loading is incorporated in soil constitutive models in two ways: (i) semiempirical PWP generation models used in combination with total-stress soil models and (ii) advanced effective-stress models whereby the model formulation is in terms of effective stress, and the PWP change is computed as the change between total stresses (or loads) and effective stresses via the soil constitutive model.

Semiempirical Porewater Pressure Generation Models

In this class of porewater pressure generation models, PWP generation in a soil profile is

computed in a semiempirical way. At the beginning of shaking (i.e., at time $t = 0$), stress-strain relationships of the soil are identical to that of the total-stress models since PWP is zero. As shaking progresses, PWP is generated and cyclic degradation (of clay microstructure) starts. Subsequently, the effects of porewater pressure generation and, in some models, of cyclic degradation are included by degradation of soil strength and stiffness. Different models for degradation of soil strength and stiffness are used in some of the models. For example, Matasovic (1993) and Matasovic and Vucetic (1995b) proposed degradation index functions that degrade strength and stiffness of sands at different rates, while the concept of the degradation index (Idriss et al. 1978) is generally used to degrade strength and stiffness of soft clays.

A number of PWP generation models have been developed starting with Martin and Seed (1978) and Martin et al. (1975). A more recent example of the semiempirical porewater pressure model for saturated sand is Dobry et al. (1985) model. This model was developed based upon strain-controlled cyclic direct simple shear and cyclic triaxial testing. The model was later modified by Vucetic (1986) to allow for quasi-two-dimensional shaking and further by Matasovic (1993) to more accurately model porewater pressure-induced degradation of shear modulus and shear stress. The porewater pressure generation models described thus require the use of an equivalent number of cycles to represent earthquake shaking. Polito et al. (2008) introduced an energy-based model (GMP model) for the generation of porewater pressure based on a large number of laboratory tests, which does not require the development of an equivalent number of cycles.

With exception of the modified Dobry et al. (1985) model, there is limited information available to guide the user in selecting the appropriate PWP model parameters.

The effect of cyclic degradation on soil stiffness and strength is illustrated in Fig. 4 for the MKZ constitutive model (Matasovic 1993; Matasovic and Vucetic 1993). The initial hysteresis loop shown in the figure refers to the first cycle of cyclic loading (i.e., at time $t = 0$).

Site Response: 1-D Time Domain Analyses, Fig. 4 Stress-strain behavior modeling illustrating stiffness degradation due to porewater pressure buildup (Matasovic 1993)

The subsequent degraded hysteretic loop refers to any subsequent cycle (i.e., at time t) for which enough porewater pressure has built up to degrade both initial shear modulus G_{mo} and initial shear stress τ_{co} at corresponding shear strain γ_{co} .

An example of a porewater pressure model for clay is the Matasovic and Vucetic (1995a) model. This model was developed based upon the results of cyclic simple shear testing. It should be noted that porewater pressure in clay is of much lower intensity than in sand and that in overconsolidated clay, both positive and negative (suction) porewater pressures may develop (e.g., Matasovic and Vucetic 1992).

Advanced Effective-Stress-Based Models

Another class of soil constitutive models used in site response analysis is effective-stress models. In these models, the formulation of the

constitutive law is developed in effective-stress space, and porewater pressures are computed as the difference between effective stresses and total stresses in the domain of interest. Examples of plasticity-based constitutive models include Roscoe and Schofield (1963), Pestana (1994), and Elgamal et al. (2001). These advanced constitutive models are capable of simulating complex soil behavior under a variety of loading conditions. Key elements of these models include yield surfaces, flow rules, and hardening (or softening) laws. A review of advanced constitutive models with application in site response analysis is provided in Potts and Zdravković (1999).

Generic material parameters for advanced constitutive models are often not available. Evaluation of material parameters for these models requires significant expertise and detailed site-specific soil properties.

Porewater Pressure Dissipation and Redistribution Models

The layers in a soil column have finite, saturated hydraulic conductivities. During ground shaking, even though loading is relatively rapid, it is possible that porewater dissipation and redistribution can occur due to differences in hydraulic gradients and hydraulic conductivities between layers.

An early model for porewater pressure dissipation and redistribution was introduced by Martin and Seed (1978). Input parameters include (effective-stress-dependent) constrained rebound modulus and (saturated) hydraulic conductivity. A porewater pressure dissipation model for composite soil deposits (alternating sand and clay layers) was developed by Matasovic and Vucetic (1995a).

Porewater pressure redistribution occurs and is often modeled in accordance with the principles of Terzaghi's theory of consolidation.

Time Domain Analysis Computer Programs

There are about 25 time domain analysis computer programs that are available globally, either commercially or through direct contact with the author(s). However, only a handful of these programs have a provision to perform an effective-stress analysis, including 2-D and 3-D programs which can be used for analysis of 1-D geometry.

Kwok et al. (2007) performed a comprehensive survey of available time domain analysis computer programs in the United States and found that only five 1-D nonlinear programs were used at the time, including OpenSees (Ragheb 1994) which is primarily used for analysis of 2-D and 3-D problems. Other programs identified by Kwok et al. (2007) include DEEPSOIL (Hashash and Park 2001), D-MOD_2 (Matasovic 2006; subsequently updated with graphical user interface as D-MOD2000), SUMDES (Wang 1990), and

TESS (Pyke 2000), with last three programs also having a provision for effective-stress analysis. The study compared the programs in total-stress mode and found that, when input is properly controlled, most of the software provided similar results.

Matasovic and Hashash (2012) performed a survey of the United States Department of Transportation (DOT) practices. Part of the survey was an inquiry on what site response analysis programs are used, both by DOT-s and their consultants. The survey revealed that the most used program was D-MOD2000 (Matasovic and Ordonez 2007) followed by DEEPSOIL (Hashash et al. 2011). However, D-MOD2000 was the only program cited to have been used in effective-stress mode. Coincidentally, these two programs are the only time domain analysis programs available in United States that have a graphical user interface and the effective-stress analysis provision.

Calibration and Benchmarking Studies

A number of individuals and groups have conducted back-analysis exercises to evaluate site response analysis procedures (and programs) versus measured response to strong ground shaking. Most of these studies include use of recordings from downhole vertical arrays.

Researchers have used a range of inverse analysis techniques that include ad hoc system identification (e.g., Zeghal and Elgamal 1993; Assimaki and Steidl 2007) and evolutionary soil models (e.g., Tsai and Hashash 2007) to calibrate soil constitutive models in site response analysis actual (in situ) soil behavior.

A number of benchmarking exercises have also been conducted to evaluate site response analysis tools. A recent key exercise is the PEER benchmarking exercise for total-stress site response analyses (Kwok et al. 2007). Another interesting benchmarking exercise was the evaluation of site response at Turkey Flat (e.g., Kramer 2009). The interesting outcome of

this exercise is in highlighting the challenges encountered in computing the response at a well-constrained relatively stiff soil site.

Summary

One-dimensional time domain analysis is a powerful tool for evaluation of site response of horizontally layered soil deposits. Compared to other types of 1-D analysis, it has a provision to simulate cyclic soil behavior in a more realistic manner than its frequency domain counterparts, and it can accommodate models for seismically induced porewater pressure buildup. Compared to its 2-D and 3-D counterparts, the advantage of this type of analysis lies in simple constitutive models for which material parameters can be readily evaluated, or generic sets of material parameters are available to practicing engineers. Furthermore, compared to its 2-D and 3-D counterparts, 1-D analysis is far better calibrated and validated. Consequently, consistent with current trends, it is anticipated that the role of 1-D analysis will evolve into calibration of 2-D and 3-D models.

One-dimensional time domain analysis is not perfect. Further calibration and validation of 1-D models are required both in effective-stress mode and at high levels of shaking (>0.4 g). There are also several issues related to the application of this type of analysis in engineering practice and research, as summarized by Hashash et al. (2010). Future trends will certainly address these issues, yet also include improvement of graphical user interfaces that are essential not only for effective use of the programs, but for evaluation and validation of the results.

Introduction

Kanai et al. (1959) discovered from earthquake observations that a horizontal component in site response can be explained by multi-reflection of SH-waves propagating vertically in soil layers. Horizontal displacement of the vertically propagating SH-wave is expressed as

$$u = Af(z - V_s t) + Bf(z + V_s t) \quad (1)$$

where z = vertical coordinate upward positive; t = time; V_s = S-wave velocity; $f()$, $g()$ = an arbitrary functions; and A , B = amplitudes of upward and downward waves, respectively. Site response governed by this equation is largely dependent on the composition of soil layers, S-wave velocities, and soil damping ratios of those layers and their strain-dependent variations. In the following, site response observations in array systems are compared with the SH-wave multi-reflection theory to clarify its applicability in terms of dominant frequencies and spectrum amplifications with special emphasis on soil damping mechanism and strain-dependent soil nonlinearity.

Basic Mechanism on Site Amplification

For a harmonic wave with angular frequency ω and amplitudes A , B , Eq. 1 is replaced by

$$u = Ae^{i(\omega t - kz)} + Be^{-i(\omega t + kz)} \quad (2)$$

Here, k is the wave number expressed as

$$k = \omega/V_s = \omega/(G/\rho)^{1/2} \quad (3)$$

Basic mechanisms of site amplification may be simplified by a two-layer model as illustrated in Fig. 1, where a surface layer with the thickness H overlies a base layer of infinite thickness. Pertinent properties are: ρ_1 , ρ_2 = soil density; V_{s1} , V_{s2} = S-wave velocity; G_1 , G_2 = shear modulus; and D_1 , D_2 = damping ratio of the surface

Site Response: Comparison Between Theory and Observation, Fig. 1 A simplified two-layer model to calculate site amplification

and base layer, respectively. The wave equations in the surface and base layers are expressed as

$$\begin{aligned} u_1 &= A_1 e^{i(\omega t - k_1 z)} + B_1 e^{i(\omega t + k_1 z)} \\ u_2 &= A_2 e^{i(\omega t - k_2 z)} + B_2 e^{i(\omega t + k_2 z)} \end{aligned} \quad (4)$$

where A_1 , B_1 = amplitudes of upward and downward waves in the surface layer and A_2 , B_2 = those in the base layer.

Utilizing the boundary conditions that at $z = 0$, $u_1 = u_2$ and $G_1 \frac{\partial u_1}{\partial z} = G_2 \frac{\partial u_2}{\partial z}$ and at $z = H$, $G_1 \partial u_1 / \partial z = 0$, and also introducing an impedance ratio α as

$$\alpha = \frac{k_1 G_1}{k_2 G_2} = \frac{\rho_1 V_{s1}}{\rho_2 V_{s2}}, \quad (5)$$

the transfer function $(2A_s)/(2A_2)$ is obtained as

$$\frac{2A_s}{2A_2} = \frac{2}{(1 + \alpha)e^{ik_1 H} + (1 - \alpha)e^{-ik_1 H}} \quad (6)$$

Here, $2A_s$ is the wave amplitude to be observed at the ground surface, and $2A_2$ is that at the base layer if it were outcropped and free from the overburden. The site amplification to be used in micro-zonation mapping is determined by Eq. 6.

There are two types of site response monitoring: (a) surface array and (b) downhole array as illustrated in Fig. 2. In the surface array (a), ground motion is monitored at two different

Site Response: Comparison Between Theory and Observation, Fig. 2 Two types of earthquake observation array systems to measure site amplification between ground surface and base layer

surface locations with different geologies, overlying soft layer and outcropping stiff base layer. If the soft layer is underlain by the same base layer and the upward wave in the base layer A_2 is assumed the same at the two places, the site amplification in the soft soil site with respect to outcropping base layer is given by Eq. 6.

In the downhole array (b), surface and downhole seismometers can evaluate the site amplification exactly at the same location, and its transfer function can be formulated as

$$\frac{2A_s}{A_2 + B_2} = \frac{2}{e^{ik_1H} + e^{-ik_1H}} \quad (7)$$

Here, B_2 is the amplitude of the downward wave in the base layer, which is influenced by the dynamic response of the surface layer. In order

to derive the transfer function for micro-zonation $(2A_s)/(2A_2)$, Eq. 7 cannot directly be used, but some modification is necessary to extract the outcropping base motion $2A_2$ from observed base motion $(A_2 + B_2)$.

In a two-layer system, the resonant frequency can be computed by the next equation

$$f = \omega/2\pi = (2n - 1) \frac{V_{s1}}{4H} \quad (8)$$

where n is the order of resonance. The most important is the first-order resonant frequency $n = 1$, and the equation $f_1 = V_{s1}/(4H)$ is named as the 1/4 wavelength formula. In many cases, the site amplification in real site conditions with multilayer systems can be simplified by a

**Site Response:
Comparison Between
Theory and Observation,
Fig. 3** Frequency by $1/4$
wavelength formula f_k
compared to peak
frequency of observed
spectrum ratio f^* for main
shocks of eight strong EQs

two-layer model consisting of a soft surface layer underlain by a stiff base layer. In this case, too, the $1/4$ wavelength formula can be expressed in an extended form as

$$f_j = 1 / \left[4 \sum_{i=1}^j (H_i / V_{si}) \right] \quad (9)$$

Here, j is the number of surface layers involved to create a specific resonant frequency. In Fig. 3, frequencies f_j obtained from the above equation are compared with peak frequencies f^* in the spectrum ratio of observed motions at a number of downhole array sites in Japan during recent strong earthquakes. The figure shows that the value f^* are mostly within 0.8–1.2 times f_k , indicating that the extended $1/4$ wavelength formula Eq. 9 may be useful to roughly estimate the resonant frequency by simplifying actual multilayer soil systems by the two-layer system. Also note in the diagram that Eq. 9 holds for not only the first- but also second- and third-order peak frequencies, which are generated by combinations of base layers of different depths and corresponding overlying layers.

In Fig. 4, two types of transfer functions of the two-layer system in Fig. 1 calculated by Eqs. 6 and

7 are compared in the same diagram. It is apparent from the two equations that the properties of the base layer are included in $(2A_s)/(2A_2)$ in terms of impedance ratio α but not in $2A_s/(A_2 + B_2)$. When $\alpha = \rho_1 V_{s1} / \rho_2 V_{s2} = 0$ in Eq. 6, indicating $\rho_2 V_{s2} \rightarrow \infty$ (rigid base layer), Eqs. 6 and 7 are identical. Hence, in the downhole array transfer function, the base layer is equivalent to a rigid base with the prescribed motion $A_2 + B_2$ when no radiation damping occurs, resulting in infinite amplification in resonant frequencies if there is no soil damping in the surface layer, $D_1=0$. In contrast, $(2A_s)/(2A_2)$ produces a certain finite peak values corresponding to α even for $D_1=0$, because energy radiation into the base layer is possible. It is noteworthy that in a multilayer system, the base layer where the downhole seismometer is installed also serves as the rigid base, whose properties have nothing to do with the downhole array amplification (Schnabel et al. 1972).

Soil Damping Models and Site Amplification

In order to incorporate soil damping in site amplifications, the variables included in Eqs. 6 and 7, k ,

 models for soil damping

V_s , and G , should be replaced by complex wave number k^* , complex S-wave velocity V_s^* , and complex shear modulus G^* , respectively, so that Eq. 3 is modified as

$$k^* = \omega/V_s^* = \omega/(G^*/\rho)^{1/2} \quad (10)$$

Three mechanical models for soil damping can be incorporated in site amplification: (a) Kelvin (Voigt) model, (b) Maxwell model, and (c) nonviscous model as illustrated in Fig. 5, consisting of a spring with shear modulus G and a dashpot with viscosity ζ . For model (c), the dashpot is replaced by a nonviscous

(time independent) dashpot with an imaginary constant iG' . For each model, shear stress τ versus shear strain γ relationship is expressed as

$$\tau = G^* \gamma \quad (11)$$

where G^* is complex shear modulus considering soil damping. The complex shear modulus G^* normalized by G is formulated for each damping models a, b and c using $i = \sqrt{-1}$ as follows (Ishihara 1996):

$$G^*/G = 1 + i(\zeta/G)\omega \quad (12a)$$

Site Response: Comparison Between Theory and Observation, Fig. 6 Variations of normalized shear modulus $|G^*/G|$ and $\tan \delta$ along with normalized angular frequency $(\xi/G)\omega$

$$G^*/G = \frac{i\omega}{1/(\xi/G) + i\omega} \quad (12b)$$

$$G^*/G = 1 + iG'/G \quad (12c)$$

In these equations, the normalized complex shear modulus can be expressed as

$$G^*/G = |G^*/G|e^{i\delta} \quad (13)$$

where δ is the phase lag angle between stress–strain relationships of the models, and $\tan \delta$ is called a loss coefficient. In Fig. 6, the variations of normalized complex shear modulus $|G^*/G|$ and $\tan \delta$ are shown versus dimensionless angular frequency $(\xi/G)\omega$ for models (a) and (b), and constant values are shown for model (c). The damping ratio is correlated with the loss coefficient as follows (Ishihara 1996):

$$D = (\tan \delta)/2 \quad (14)$$

Hence, from Eqs. 12a, b, and c:

$$D = \tan \delta/2 = \omega\xi/(2G) \quad (15a)$$

$$D = \tan \delta/2 = G/(2\omega\xi) \quad (15b)$$

$$D = \tan \delta/2 = G'/(2G) \quad (15c)$$

From Eq. 2, the equation for a wave including soil damping propagating unidirectionally toward $+z$ is written as

$$u = Ae^{i(\omega t - k^*z)} \quad (16)$$

If k^* in this equation is substituted by Eq. 10, and G^* in Eq. 10 is further substituted by Eqs. 12a, b, and c, Eq. 16 can be transformed as follows:

$$u = Ae^{-\beta z}e^{i\omega(t-z/V_s)} \quad (17)$$

Here, β is a positive real number called a wave attenuation coefficient by internal damping, because it determines how the wave attenuates as it propagates by distance z . If δ is small, β is correlated to the damping ratio D as

$$\beta = \omega D/V_s \quad (18)$$

Substituting D in Eq. 15a, b and c into Eq. 18 gives β for the corresponding damping models:

$$\beta = \omega^2\xi/(2\rho V_s^3) \quad (19a)$$

$$\beta = \rho V_s/(2\xi) \quad (19b)$$

$$\beta = \omega G'/(2\rho V_s^3) \quad (19c)$$

Site Response: Comparison Between Theory and Observation, Fig. 7 Transfer functions of a two-layer model using three types of soil damping models: (a) $2A_s/$

$2A_b$ ($\alpha = 0.1$) for surface array and (b) $2A_s/(A_b + B_b)$ for downhole array

In Fig. 7, transfer functions of the two-layer model in Fig. 1 are shown for the three damping models assuming the damping ratios in the surface and base layers $D_1 = 5\%$ and $D_2 = 0\%$, respectively. Figure 7a is for the surface array $(2A_s)/(2A_b)$ with the impedance ratio $\alpha = (\rho_1 V_{s1})/(\rho_2 V_{s2}) = 0.1$, and Fig. 7b is for the downhole array $2A_s/(A_b + B_b)$. The transfer functions are identical in the first peak but obviously differ in higher-order peaks corresponding to the different damping models. In the Kelvin model, the amplification in higher-order peaks tend to reduce more drastically than in the nonviscous model, and in the Maxwell model, it is unchanged at all peaks. These differences arise from the different formulations of β in Eqs. 19a, b, and c with respect to ω . In cyclic loading tests on soil elements, it is widely accepted that soil damping is almost frequency independent (Hardin 1965; Hardin and Drnevich 1972). Hence, in most engineering practice, the soil damping is assumed nonviscous as in Eq. 15c. In this case, the peak amplification of the transfer function becomes lower for higher-order peaks because the wave attenuation coefficient β is proportional to ω as shown in Eq. 19c.

In Figs. 8a–e, some typical Fourier spectrum ratios calculated between surface and base

records at six downhole array sites where PGA exceeds 0.2 g during strong earthquakes are depicted with thin lines in EW and NS directions. For each site, the soil profile with density ρ and S-wave velocity V_s is tabulated in Table 1 together with installation levels of seismometers indicated with arrows. Using the properties in the table, transfer functions for each site, $2A_s/(A_b + B_b)$ for the downhole array and $(2A_s)/(2A_b)$ for the surface array, are calculated and superposed in the diagram with thick curves, where A_b and B_b = amplitudes of upward and downward waves in the base layer. In the calculation, the nonviscous damping model is used as normal engineering practice, and a uniform damping ratio $D = 2.5\%$ is assumed tentatively for all layers. If the observed spectrum ratios are compared with corresponding transfer functions for downhole arrays, $2A_s/(A_b + B_b)$, a fairly well correspondence in peak frequencies can be recognized between the two in most sites despite some minor effect of soil nonlinearity. This indicates the applicability of one-dimensional soil models in these sites to a certain extent.

If $2A_s/(A_b + B_b)$ is compared with $(2A_s)/(2A_b)$ at each site, the difference in the peak values between the two transfer functions is obviously large.

Site Response: Comparison Between Theory and Observation, Fig. 8 Transfer functions of a multilayer system $2A_s/(A_b + B_b)$ compared with $2A_s/2A_b$ and

observed spectrum ratios at six downhole array sites during a strong earthquake

However, the coincidence in peak frequencies is almost perfect in (a) and good in (b) but gets poorer in (c) and (d) and very poor in (e) and (f). The reason may be gleaned by examining the soil profiles. In (a) and (b), the V_s -value at the downhole seismometer is much larger than the upper layers, and the seismometer depth is not so deep from the boundary of clear V_s -contrast. In (c) and (d), the V_s -value at the base layer is not so different from the upper layers, and the seismometer depth is not so deep from a boundary of major V_s -contrast. In (e) and

(f), though the V_s -value at the base layer is much larger than the upper layers, the depth of seismometer is too deep from the upper boundary of clear V_s -contrast to properly detect the response of the upper layers. This observation tells us a significance of choosing appropriate seismometer depth in deploying a downhole array system considering site specific soil profiles.

Another observation may be made on amplification values at individual peaks of observed spectrum ratios compared with the downhole array transfer functions $2A_s/(A_b + B_b)$.

7	9	103	2.4	870

As already mentioned, the damping ratio is tentatively set as 2.5 % in calculating $2A_s/(A_b + B_b)$. At a glance, the peak amplification values of the transfer functions are almost monotonically decreasing with increasing peak frequencies, presumably reflecting the damping characteristics of the non-viscous model used here, as previously explained. In contrast, the peak values of observed spectrum ratios seem to be quite site specific and show no consistent increasing or decreasing trend. This indicates that the soil damping is not perfectly nonviscous (frequency independent) but to some extent frequency dependent (the damping ratio D decreases with increasing frequency f) in a similar manner as the Maxwell model. It is clear that the Kelvin model, for which the peak amplification tends to decrease more drastically with increasing f , has even less applicability than the nonviscous model. Thus, the frequency-independent damping found in laboratory soil tests may not perfectly fit the actual performance of site amplification based on earthquake observations.

One major reason for this deviation may be wave scattering in heterogeneous soils. The wave scattering effect on frequency dependency of damping in elastic waves propagating in heterogeneous earth crust is an important topic in seismology (e.g., Frankel and Clayton 1986; Wu 1982). The effect tends to be more conspicuous with decreasing strain in a stiff rock site. The damping ratio D by wave scattering may be expressed as

$$D = D_r(f/f_r)^{-m} \quad (20)$$

where f_r = a reference frequency, D_r = reference damping ratio, and $D = D_r$ at $f = f_r$. The power constant m is a positive number, and $m = 1$ corresponds to the Maxwell model, as obviously seen in Eq. 15b. In general, the damping ratio may be expressed as the sum of the frequency-independent hysteretic part D_0 and the frequency-dependent part as

$$D = D_0 + D_r(f/f_r)^{-m} \quad (21)$$

Site Response: Comparison Between Theory and Observation, Fig. 9 Fourier spectrum ratios $2A_s/(A_b + B_b)$ observed at a very soft soil site during main shock and aftershocks in directions EW (a) and NS (b)

However, the frequency-dependency of damping is normally ignored in geotechnical engineering practice, because hysteretic nature of soil damping becomes more dominant during strong earthquakes as soil gets softer and strain-dependent nonlinearity becomes more dominant.

Soil Nonlinearity

Seismically induced shear strain γ is calculated from particle velocity $\dot{u}$:

$$\gamma = -\dot{u}/V_s \quad (22)$$

if upward propagating wave is chosen in Eq. 1, for instance. This indicates that the shear strain tends to be greater for strong earthquakes with larger particle velocity amplitudes and in soft soils with smaller V_s -values. Because stress-strain behavior of soil is nonlinear and hence V_s and D are highly strain dependent, the site response during strong earthquakes may greatly differ from that during small earthquakes, particularly in soft soil sites. The soil nonlinearity effect is normally evaluated using the equivalent linear approximation method in engineering practice (Schnabel et al. 1972).

In each of Figs. 9 and 10, Fourier spectrum ratios for a strong main shock are compared with

those for weaker aftershocks in directions EW (a) and NS (b) using earthquake records obtained in the same downhole arrays. As indicated in Table 1, the soil condition for the former site is very soft ($V_s < 100$ m/s at top 18 m), while that of the latter site are relatively stiff ($V_s > 320$ m/s deeper than 4 m). Thick curves for the main shock are obviously different with thin curves for the aftershocks with respect to peak values and peak frequencies. The difference of peak values is greater in Fig. 9 than in Fig. 10 because of the softer soil conditions, and the difference in the same site tends to be greater in higher-order peaks than in the first peak because softer layers near the ground surface tends to contribute more.

Basic effects of soil nonlinearity on site amplification can be examined using the two-layer system shown in Fig. 1. Three levels of induced equivalent strain amplitude are assumed, and corresponding shear modulus degradation G/G_0 and equivalent damping ratio D (nonviscous) are determined based on empirical curves (Fig. 11) often used in engineering practice (Seed and Idriss 1970). Figures 12a and b depict the transfer functions $2A_s/(A_b + B_b)$ for the downhole array and $(2A_s)/(2A_b)$ for the surface array calculated for the three levels of nonlinear soil properties.

Obviously, soil nonlinear properties have great effects on the peak frequencies and the peak amplifications not only in $2A_s/(A_b + B_b)$ as

Site Response: Comparison Between Theory and Observation, Fig. 10 Fourier spectrum ratios $2A_s/(A_b + B_b)$ observed at a stiff soil site during main shock and aftershocks in directions EW (a) and NS (b)

Site Response: Comparison Between Theory and Observation, Fig. 11 Soil nonlinearity curves (G/G_0 - γ , D - γ) used in calculating amplifications in a two-layer system

recognized in actual site amplifications in Figs. 9 and 10 but also in $(2A_s)/(2A_b)$. However, the difference in the peak amplifications due to strain level is less pronounced in $(2A_s)/(2A_b)$ than in $2A_s/(A_b + B_b)$ for the first peak in particular. It is because the radiation damping effect presented by the impedance ratio α affects $(2A_s)/(2A_b)$ in Eq. 6, whereas no effect of α is involved in

$2A_s/(A_b + B_b)$ as indicated in Eq. 7. Under the paramount effect of radiation damping associated with α , the difference in the amplification $(2A_s)/(2A_b)$ due to strain-dependent nonlinear properties becomes less conspicuous. Furthermore, the impedance ratio, $\alpha = \rho_1 V_{s1}/\rho_2 V_{s2}$, which becomes smaller with degraded modulus or degraded S-wave velocity V_{s1} in the surface layer, tends to give larger amplification compensating the effect of increased damping ratio in the surface layer during strong earthquakes. Thus, the difference in soil nonlinearity between the main shock and aftershocks seems to have smaller influence on the amplification in $(2A_s)/(2A_b)$ than in $2A_s/(A_b + B_b)$ as indicated from the comparison of Fig. 12a, b.

The Fourier spectrum ratio corresponding to the transfer function $(2A_s)/(2A_b)$ cannot be obtained directly from downhole array records, but the peak value can be calculated from $2A_s/(A_b + B_b)$. Figure 13 shows an example how this calculation is carried out. First, a transfer function $2A_s/(A_b + B_b)$ is calculated at a downhole array site based on the multi-reflection theory. Among soil properties needed, the S-wave velocities of individual layers are given by in situ logging tests if strain-dependent soil nonlinearity is not so significant, and soil densities are judged from previous experiences.

downhole array and (b)
 $2A_s/2A_b$ for surface array in
different induced strain
levels

The damping ratio D is tentatively assumed 2.5 % in all layers and also postulated to be nonviscous or frequency independent.

Then, the calculated transfer function $2A_s/(A_b + B_b)$ is compared with the corresponding spectrum ratio obtained from downhole array records. If a peak in the transfer function can be found at about the same frequency in the spectrum ratio of recorded motions, it is identified as the corresponding peak, and the damping ratio assumed as $D = 2.5\%$ previously is modified to have the same peak value, by using the equation $D = Q_1/Q_2 \times 2.5(\%)$, where Q_1 is the peak value of the calculated transfer function and Q_2 is that of spectrum ratio based on the actual records as indicated in Fig. 13. Not only the first peak but also the higher-order peaks are

compared in this manner if possible, and the values of D in the two directions, EW and NS, are averaged for individual peaks. Then, the transfer function $(2A_s)/(2A_b)$ is computed using the modified damping ratio D based on the same multilayer system. In this way, the peak amplifications for $(2A_s)/(2A_b)$ between surface and base, to be used in seismic zonation study for surface soil resting on the common base layer, can be obtained using the downhole array records.

In Fig. 14, the peak amplification values in the first peak of the spectrum ratios are compared between small aftershocks (in the horizontal axis) where shaking is relatively smaller ($\text{PGA} \leq 0.1 \text{ g}$) and main shock (in the vertical axis) with $\text{PGA} \approx 0.1 \sim 2.4 \text{ g}$, based on vertical array records during strong earthquakes and

Fig. 14 Comparison of spectrum peak amplifications between aftershocks and main shocks of downhole arrays $2A_s/(A_b + B_b)$ and surface arrays in $2A_s/2A_b$

associated aftershocks recorded at many vertical array sites in Japan (Kokusho and Sato 2008; Kokusho 2013). The triangular symbols for downhole arrays $2A_s/(A_b + B_b)$ are dispersed in a wide range, and the majority is plotted around or below the diagonal line (main shock = aftershock), indicating that during strong shaking the site amplification in terms of $2A_s/(A_b + B_b)$

possibly reduces due to soil nonlinearity. In contrast, the solid circular symbols corresponding to $(2A_s)/(2A_b)$ in surface arrays, though the amplification values are small, concentrate near the diagonal line, indicating that the effect of soil nonlinearity is less dominant in the first peak site amplification, as demonstrated in Fig. 12 by using a simplified two-layer model.

Thus, the soil nonlinearity affects the site amplification considerably with respect to peak frequency and peak amplification. However, for the amplification of the first peaks in the surface array, the nonlinear effect is obviously minor. This may simplify the seismic zonation procedure considering strong shaking.

Summary

1. Two types of site amplification monitoring can be defined and implemented in earthquake observations, surface array and downhole array. For micro-zonation mapping, the amplification for the surface array is needed.
2. For reproduction of site amplification observed in the field, it is possible to simplify a complicated multilayer system to a two-layer system composed of a surface layer of a certain thickness underlain by a base layer of infinite thickness. Resonant frequencies of the multilayer system can roughly be evaluated using the $1/4$ wavelength formula.
3. In the downhole array, the installation level of the downhole seismometer serves as a rigid boundary, and soil properties below have nothing to do with the amplification of the ground surface with respect to the base motion.
4. Among three soil damping models, Kelvin, Maxwell, and nonviscous, the nonviscous model is normally used for site amplification evaluation in engineering practice. In this case, the peak amplification of the transfer function becomes lower for higher-frequency peaks because the wave attenuation coefficient β is proportional to the frequency.
5. There are evidences from earthquake observations to suspect that some degree of frequency-dependent damping similar to Maxwell damping due to a wave-scattering mechanism exists in the field. However, it is normally ignored in geotechnical engineering, because hysteretic (nonviscous) nature of soil damping becomes more dominant during strong earthquakes as soil gets softer and more strain-dependent nonlinear.

6. Site amplification observations show that soil nonlinearity affects the site amplification considerably with respect to peak frequency and peak amplification. However, for the amplification of the first peak in the surface array, the nonlinear effect is obviously minor, which may simplify the seismic zonation procedure even for strong earthquakes.

Introduction

The rapidly evolving social media platforms, with an estimated 1.9 billion users worldwide, offer a myriad of communication benefits and risks in the context of a disaster. Social media generally refers to internet-based technologies that enable people to interact and share resources and information using either text or multimedia applications (Lindsay 2011; Dabner 2011). Advances in mobile devices allow access to anyone who has the ability to connect online (Abbasi et al. 2012). For example, the microblogging platform Twitter allows followers to track what an account holder is doing and thinking in real time within the confines of 140 characters (Kaigo 2012). Tweets can be sent from a variety of platforms ranging from cell phones to computers. Other examples of social media platforms today are Facebook, YouTube, Qzone, Pinterest, Instagram, and Flickr. This entry describes how social media, in particular Twitter, can be used for a variety of applications before, during, and after an earthquake, both inside and outside the area of impact. These include detection, warnings, connecting to survivors, situational awareness, notifying responders of where help is needed, and galvanizing humanitarian aid. Importantly, the increasing participation of “citizen seismologists” via social media is filling the information gap with field observations

immediately after an earthquake (Young et al. 2013) for both first responders and survivors. In fact, social media, in particular Twitter, may be the only immediate source of data from locations with limited sensors or other scientific instruments. Obviously, not all earthquakes are reported on social media as many events are in remote areas or undersea and in countries with limited social media access or the magnitude is too small to be felt. A unique benefit of social media is that it is user generated – disaster agencies, seismologists, and other parties do not have to motivate citizens to tweet – they will do it anyway, potentially by the thousands in a significant earthquake. The challenge is how to transform the rapidly spreading flood of real-time information, some of it inaccurate, into reliable, useful, and valuable data. Part of the solution is to train Twitter users to tweet messages that can be more easily analyzed both manually and automatically using a crisis-specific syntax (Starbird and Stamberger 2010). This approach, among others discussed in this entry, will help guide disaster response, galvanize ongoing humanitarian efforts, and add value to the expanding body of earthquake sciences gathered since the development of the modern seismograph in the late 1800s.

Sourcing Information in Disasters

People facing a disaster seldom act on one source of information. Hunting for firsthand local information, they will “channel swap” across the traditional media, go online to news websites and social media, and contact family and friends. Without proof from a variety of trusted sources, people will believe there is no immediate threat or that the situation does not apply to them. The delay in taking action – known as milling – can increase the risk of death or injury from a hazard before steps are taken for self-protection. The milling effect is increased if warnings are vague and conflicting across various channels or the credibility of the source is in doubt. Under these circumstances, social media becomes a double-edged sword. The speed of social media can reduce the decision-making lag time while, at

the same time, increasing confusion and uncertainty if the information is wrong or conflicting. It is generally accepted that trust in social media information remains well below that of traditional media. The 2014 Edelman Trust Barometer found that 47 % of people trusted social media sources, while 65 % trusted the traditional media. In practice this was reflected in the 2011 Japan earthquake. Although most people turned to social media as their most reliable source of information, one third described the “lack of trust in formation as the greatest problem associated with social media use in the disaster” (Perry et al. 2012, p. 15). For disaster agencies, the challenge of earning trust and building credibility and relationships can be overcome by actively engaging online before the disaster. As noted by the US-based Centers for Disease Control and Prevention (CDC): “Organisations need to be regular users of social media before the crisis. If not, social media users will go to other sources and groups with whom they already have relationships for information” (2012, p. 268). Engaging with social media before a disaster can also build preparedness and education for survival. For example, more than 1.3 million people in New Zealand took part in the “ShakeOut” earthquake drill in 2012, driven by a social media campaign. Many organizations took the drill realistically. For example, a hospital in the country’s North Island shut off its power and water for 24 h to simulate the impact of an earthquake. Portable cooking, lighting, and other equipment maintained hospital services (Civil Defence Emergency Management 2012). Similar events are held in other countries to prepare communities for an earthquake. Although disaster agencies are using social media to educate communities and disseminate information, they have been historically more reluctant to rely on social media data in their incident command systems. The reasons include fears about misinformation (Williams et al. 2012), the speed and spread of the information which makes validation difficult (Gowing 2009), and a lack of understanding about how they can make use of social media (Duffy 2012; Palen 2008). For example, Tapia et al. (2013) argue that a major issue for

disaster agencies is how social media data can be effectively incorporated into time-critical decision-making processes. As Tapia et al. (2013, p. 770) note, “while data quality continues to be a barrier, what is far more important to organizational use is the serving of this data at the appropriate time, in the appropriate form to the appropriate person and the appropriate level of confidence.”

Online Support on the Ground

Driven by developing mobile technology, social media is taking on an increasing role in connecting people in disasters. Part of the reason is that people reach out to both their “offline” and “online” communities during a crisis or disaster (Dutta-Bergman 2006). In other words, they parallel their physical world with their virtual world to garner “social support and gather information, and vice versa.” In turn, on a much wider scale, this online convergence builds and strengthens community resilience through “people power” (Duffy 2012). A bank of social capital is developed by the exchange of information “during difficult times” to build relationships between people (Kaigo 2012). Therefore, social media in disaster impact areas is frequently driven by the community to share knowledge and as a form of empowerment toward recovery. The CDC (2012) notes that the public uses social media on a greater scale in the hours after a disaster than official agencies. Williams et al. (2012), who have produced a practical guide to community-based social media in disasters based on lessons from a series of tornadoes and floods in the United States, found that post-disaster social media was generated and driven by citizens rather than emergency agencies. In most cases, community-managed social media was the primary source of information for those impacted by the disaster. For example, a University of Missouri Extension Facebook site – Branson Tornado Info – attracted 14,000 followers within 12 h of a tornado in February 2012. One victim posted: “For the first few days after the storm, this Facebook page was our main source of

Social Media Benefits and Risks in Earthquake Events, Table 1 The expanding role of social media in earthquake events

2008 Sichuan (China) earthquake	The first alert of the severity of the earthquake was reported on Twitter (Moore 2008; Cellan-Jones 2008)
2010 Haiti earthquake	First major earthquake in the age of social media. The purpose-built Ushahidi crisis map became an emergency reporting system to locate people texting for help. Social media-generated significant humanitarian aid (Meier 2012; MacLeod 2010)
2011 Christchurch (NZ) earthquake	Social media became “the Church or meeting hall” for people to support each other and share information (Mathewson 2012)
2011 Japan earthquake and tsunami	Social media platforms, particularly Facebook, Twitter, and Japan’s own social media site Mixi, provided information and connected families when telephone communication was damaged or became congested (Wallop 2011)
2011 Turkey earthquake	Facebook was used to coordinate donations and aid requests. People trapped in rubble tweeted for help (Turgut 2011)
2013 Ya’an (China) earthquake	Social media platforms become a place for mourning when people turned their profile photographs to gray in remembrance of the victims (Hui 2013)

information. Volunteers here answered our questions about where to go to get help, what resources were available and what we needed to do next” (Williams et al. 2012, p. 18). In the context of earthquakes, social media has played an important and increasingly sophisticated role, as the following Table 1 demonstrates:

Twitter Faster than Earthquakes

It is well documented that the real-time speed and user-input microblogging capability of Twitter make it one of the most useful social media tools for disaster management agencies to gain a rapid snapshot of the earthquake aftermath and

the level of response and resources that may be required. Earthquake alerts are now within the scope of Twitter. Crooks et al. (2013) found that the velocity of Twitter can be used as a warning system in large-scale events. Tweets and re-tweets spread from the epicenter faster than the physical effects to distant locations. For example, tweets about the 2011 Virginia earthquake were read in New York 30 s before it was felt there, “showing that information moves faster through networks than the earthquakes themselves” (Perry et al. 2012, p. 6). Automatic earthquake warnings sourced from Twitter data are being developed using algorithms to analyze keywords, the number of words, and their context (Sakaki et al. 2010). Importantly, Tweets can include locations, which is fundamental in sensing earthquake events (Sakaki et al. 2010). Another real-time online method of detecting earthquakes in a general location is to trace the IP addresses of visitors to earthquake information websites. For example, surges in visitor traffic to the European-Mediterranean Seismological Centre from people wanting information about what they had felt can provide a snapshot within 2 min into the location and potential damage from an earthquake (Bossu et al. 2011).

Greater Situational Awareness

Tweets within the first minutes of an earthquake are mostly generated from around the epicenter and provide potentially useful situational awareness for both emergency responders, seismologists, and, importantly, survivors. In the 2011 Christchurch, New Zealand, earthquake, the first tweet was within 30 s, the first photo was within 4 min, and the first video was uploaded to YouTube in 40 min. It is widely accepted that information such as this supplements, rather than replaces, data sourced from scientific instruments. As Earle et al. (2011, p 709) note: “The qualitative descriptions contained in the tweets are available at the same time as the seismically-derived earthquake parameters and sometimes provide a responding seismologist with a quick indication of the severity of the earthquake

effects.” Although Twitter’s 140 characters may be limiting, the narratives often produce a consensus on the intensity of the earthquake because “citizens tend to report very similar experiences” (Young et al. 2013, p. 19). Hashtags are quickly formulated to spread information. For example, within minutes of the 2011 Christchurch, New Zealand, earthquake, the hashtags #eqnz and #chch helped to share images and videos of the damage (Edmond 2013). Within 2 min of a tremor in Victoria, Australia, more than 100 tweets were posted, giving an indication of strength and reports of minor damage (Anderson 2012). In the 2011 Japan earthquake, Twitter was more effective in providing information in devastated areas than traditional media and websites (Kaigo 2012). It has led the Japanese authorities to consider making social media networks part of the country’s emergency call system (Dugan 2012). Scanning other social media platforms can also strengthen situational awareness. There are a myriad of social media platforms that can convey video, photographs, audio, and written accounts of the earthquake event. For example, the following chart outlines key benefits of Twitter, YouTube, Facebook, and blogs (Table 2).

Social Media Clutter, Misinformation, and Rumors

Social media is flooded with information in a disaster event. For example, an estimated 2.3 million tweets mentioned Haiti or the Red Cross in the 24 h following the 2010 Haiti earthquake. In Japan, more than 2000 tweets were posted every second of the day following the 2011 earthquake and tsunami (Meier 2013). Significant numbers of tweets are re-tweeted, adding to the social media “clutter” and potential spread of misinformation in the aftermath of a disaster. To make sense of the situation and to gather reliable data, a number of social mapping and analysis projects are under development. They include machine-learning approaches for classifying and extracting “informative” Twitter messages to augment situational awareness (Imran et al. 2013)

Social Media Benefits and Risks in Earthquake Events, Table 2 The benefits of various social media platforms for communicating during a disaster

Twitter (140 characters)	Instant messaging One-to-many receivers (followers) Monitoring first impressions of the shaking in real time Issuing warnings and alerts rapidly Integrating mass or interpersonal communication Initiating situational awareness from the field Channels to dispel rumors and correct information Interactive mapping Rapid updating of traditional media Alternative method of seeking aid for survivors Linking to more detailed information on other platforms Ability to “snowball” information by re-tweeting
YouTube (and others)	Broadcasting live vision from a location Providing a channel to group videos Upload vision/audio for traditional and online media consumption Facilitating updates
Facebook	Offers two-way communication Connecting people inside and outside the disaster area Providing more information than Twitter Immediate updates Delivering vision/audio/images Linking to other agencies and sources of information Accessible to anyone with an email address
Blogs	Rapid updates Allows discussion Space for more information Linking to other agencies and sources of information Providing opportunities to share stories and experiences

and volunteers, such as micromappers.com, to quickly filter social media data during a disaster using apps to tag tweets and photographs. Advances in technology are providing dividends. Another project, the Artificial Intelligence for Disaster Response, reports that 40–80 % of tweets containing disaster information can be detected automatically, with an 80–90 %

accuracy rate on whether the tweet was from an eyewitness. To obtain more structured firsthand accounts from social media users, crowdsourcing approaches are utilized by dedicated not-for-profit and government-based earthquake reporting and information sites. For example, the US Geological Survey actively seeks contributions through its “Did You Feel It” project by “asking people where they were, what they observed and what they experienced during the earthquake” (Young et al. 2013, p. 2). Earthquake-Report.com, which describes itself as the “best independent earthquake reporting site in the world,” utilizes multiple social media platforms to share firsthand accounts of earthquakes in real time along with merging data from scientific sources. Crowdsourcing questions from the impact area include location, scale of intensity, and a brief description of the experience, including damage.

Squashing Viral Rumors and False Information

People power – termed the Wikipedia effect – is a self-correcting social media. Many of the rumors and misinformation in a disaster are identified and corrected by social media users. Traditional journalists, unable to compete with the speed of social media, have assumed the mantle of “fact-checkers” to validate information. For example, fake information and images distributed on Twitter during Hurricane Sandy in 2012 were quickly ousted by other social media users and traditional media outlets. Although traditional media outlets have published inaccurate information sourced from social media, it is often quickly corrected. Twitter and Facebook were used extensively by the Queensland Police Service during the South East Queensland, Australia, floods in 2011 to identify rumors and respond with factual information. Those platforms became an important resource for traditional media. As Bruns et al. (2012, p. 8) observed: “Additionally, @QPSMedia also played a crucial role in enabling affected locals and more distant onlookers to begin the difficult process of making

sense and coming to terms with these events, even while they were still unfolding.”

Psychological Support for Survivors

Social media plays a key role in the earthquake recovery phase. Unlike the limitations of the one-way traditional media model, social media’s two-way interaction helps rebuild communities and bring together families, friends, and neighbors. Importantly, social media provides “psychological first aid” where people “reported feeling a sense of connectedness and usefulness, felt supported by others and felt encouraged by the help and support being given to people” (Taylor et al. 2012, p. 25). In the weeks and months following the 2011 Christchurch earthquake, Dabner (2011) found that online discussion provided support and information, with one participant describing it as a lifeline “that helped her (and therefore her children) cope with aftershocks by realizing normally (sic) would eventually return” (2011, p. 10). Due to the level of destruction, the role of churches was resumed through social media, with one researcher observing: “Social media was really a way for people to feel like they weren’t being forgotten or like they were part of a larger community. As far as someone sitting at home alone at 10 pm, they were not able to go out for a cuppa. That’s where social media really kicked in” (Chapman-Smith 2012).

Summary

Social media continues to rapidly evolve as a useful tool in earthquake communication. Developing technology will increase the accuracy of information from “citizen seismologists” to enhance situational awareness, improve warnings, coordinate aid and recovery, and galvanize humanitarian relief efforts. Impacted communities will increasingly turn to social media as a way to communicate lifesaving information, gather support, and empower each other in the recovery process.

Soil-Structure Interaction

Christos Vrettos
Division of Soil Mechanics and Foundation
Engineering, Technical University of
Kaiserslautern, Kaiserslautern, Germany

Synonyms

Dynamic soil-structure interaction; Seismic soil-structure interaction; SSI

Introduction

Seismic waves propagating through the soil impinge upon structures founded on the soil surface or embedded into it. Displacements are then produced both in the structure and in the soil. The mutual dependency of the displacements is called soil-structure interaction, abbreviated as SSI. Consequently, the motion occurring at the base of the structure is different compared to the free-field motion (motion in the absence of the

structure). Soil-structure interaction characteristics depend on several factors:

- Intensity, wavelength, and angle of incidence of the seismic waves
- Soil stratigraphy
- Stiffness and hysteretic damping of the particular soil layers
- Geometry and rigidity of the foundation
- Embedment depth of the structure
- Inertia characteristics, slenderness, and natural vibration period (eigenperiod) of the superstructure
- Presence of nearby structures

Various effects are associated to this phenomenon:

- A building founded on compliant ground has different vibrational characteristics, for example, higher natural period compared to the same building on rigid base (solid rock). The softer the soil, the larger the difference.
- A part of the vibrational energy emanating from the compliant structure foundation is transmitted into the surrounding soil through wave radiation in the unbounded soil medium and hysteretic energy dissipation. Such effects do not occur in a rigidly supported structure.
- Due to the compliance of the foundation, the motion at the foundation base contains rocking and torsional components in addition to the translational components.

The mechanisms governing soil-structure interaction can be divided into two distinct interactions: inertial and kinematic interaction.

Kinematic interaction is the deviation of the soil response from the free-field motion due to the resistance of the stiffer foundation to conform to the distortions of the soil imposed by the traveling seismic waves. It is commonly expressed in terms of frequency-dependent transfer functions relating the disturbed motion at the interface foundation/soil to the free-field motion.

Inertial interaction arises as the structure responds to the soil motion induced by kinematic interaction at the foundation level. Inertial forces

are developed in the structure being transmitted to the compliant soil. Frequency-dependent impedance functions are used to represent the stiffness of the foundation/soil system and the associated radiation damping.

The relative impact of each contribution is a function of the characteristics of the incoming waves, the foundation geometry and rigidity, and the soil conditions.

The analysis is particularly challenging due to the semi-infinite extent of the soil medium, the nonlinearity of the soil behavior, the inherent variability of the soil stratigraphy, and the dependency of the response on frequency. Several procedures of different degrees of complexity have been proposed during the past five decades. A historical overview is given by Kausel (2010). The book by Wolf (1985) provides a rigorous and comprehensive treatment of the topic including applications to seismic problems.

Even with the computational facilities available today, such analyses are associated with a major effort, both for modeling the soil-structure system and carrying out the calculation. In particular during the early design stage, parametric studies are necessary in order to assess the influence of the various parameters and optimize the system for purposes of cost estimation. This necessitates the application of simplified methods that capture the essential features of the system response. The next sections provide a brief overview with emphasis on such simplified methods.

Soil-Foundation-Structure Analysis Models

Two general approaches are commonly used for the analysis of soil-structure interaction problems.

Direct Approach

The soil and the structure are treated together in a combined analysis by modeling them using finite elements or finite differences in two or three dimensions. This offers the advantage that inelastic behavior, particularly for the soil, can be taken

into account by the step-by-step numerical integration of the equations of motion within a time-domain algorithm. A drawback is the necessity to specify the input motion at the base of the model, where it is not known a priori. Since the design seismic motion is usually given at the free surface or at outcropping rock, a deconvolution is necessary to obtain the compatible bedrock motion. Often the bedrock is located at large depths thus prohibiting the modeling of the entire soil layer, and some artificial boundary is defined at a shallower depth. The deconvolution then involves an iterative procedure. For convenience, the deconvolution is often carried out using algorithms that are based on 1D vertical shear wave propagation, thus requiring an adjustment of the model parameters in order to achieve compatible solutions between 1D and 2D analyses. Attention is further required in the selection of appropriate boundary conditions at the side boundaries of the discretized domain to avoid spurious reflections that would contaminate the results. The composite soil-structure model is finally subjected to the previously determined base rock motion, and the evolution in time of displacement and stresses is computed.

Substructure Approach

The underlying calculation method comprises three steps. At first the seismic motion acting at the foundation level is determined assuming a rigid but massless foundation. This is referred to as foundation input motion (FIM), and for an embedded structure, it will include both translational and rotational components. In the second step, the complex-valued frequency-dependent impedances for the foundation/soil system are determined. The real part of the impedance function represents a linear spring and the imaginary part, a viscous dashpot accounting for the energy radiation into the soil medium. Finally, the structure supported by the frequency-dependent springs and dashpots is subjected to the foundation input motion computed in the first analysis step.

While impedance functions are sufficient for rigid foundations, distributed springs and dashpots placed around the foundation are used for

nonrigid embedded foundations when the distribution of sectional forces is sought. In this case, due to the vertical variation of ground motion, the imposed differential ground displacements vary over the height of the basement walls.

The validity of this approach – often called superposition theorem – is shown by Kausel and Roesset (1974). The main advantage of the method is that each step can be handled independently and with different algorithms. Further, it allows an insight into the contributions from each analysis step and is particularly suitable for parametric studies.

The application of the principle of superposition requires linear behavior. Inelastic behavior is implemented using equivalent linearization by selecting soil modulus and radiation damping to correspond to the likely effective strain level the soil will experience under the specific loading. This is achieved by means of an iterative procedure. Superposition is shown to be a reasonable approximation even when inertia forces produce large strains in the vicinity of the foundation, since shear strains due to kinematic interaction effects are usually significant in deeper soil regions.

Inertial Interaction

Shallow Foundations

The illustration of the concepts is made on the basis of a simple structure-soil system being composed by a linear structure of height h , mass m , lateral stiffness k , and damping ratio β_{str} that is connected to a rigid foundation of radius r resting on the surface of a homogeneous elastic half-space. The half-space is used to represent the unbounded soil medium and is characterized by its shear modulus G , Poisson's ratio ν , and mass density ρ . Mass and moment of inertia of the foundation are neglected for simplification. The compliance of the soil is modeled by two frequency-dependent springs placed underneath the rigid foundation: a horizontal translation spring of stiffness K_x and a rotational spring of stiffness K_θ . Energy dissipation in the soil due to friction within the material (hysteretic damping)

and wave radiation in the unbounded medium is modeled by a pair of frequency-dependent dashpots with coefficients C_x and C_θ attached parallel to the respective springs. This model may be viewed as a single- or multistory building after an appropriate reduction of the degrees of freedom.

Springs and dashpots for each degree of freedom j can be condensed to complex-valued impedances that are expressed in two equivalent forms:

$$\tilde{K} = K_j + i\omega C_j = K_j(1 + i2\beta_j) \quad (1)$$

where ω is the circular frequency of the excitation, i is the imaginary unit, and β_j is a damping coefficient that is related to the viscous dashpot coefficient of a simple oscillator by

$$\beta_j(\omega) = \frac{\text{Im}(\tilde{K}_j)}{2\text{Re}(\tilde{K}_j)} = \frac{\omega C_j}{2K_j} \quad (2)$$

The use of β_j has the advantage that at resonance of the compliant system β_j corresponds to the percentage of critical damping.

The undamped natural vibration period of the structure in its fixed-base condition is

$$T = 2\pi\sqrt{\frac{k}{m}} \quad (3)$$

For the case of a compliant base, it can be shown that the respective natural period is (Veletsos and Meek 1974)

$$\tilde{T} = T\sqrt{1 + \frac{k}{K_x} + \frac{kh^2}{K_\theta}} \quad (4)$$

Hence, the period of the flexibly supported structure is higher than that on rigid base. Since the spring stiffnesses are in general frequency dependent, an iterative procedure is necessary to evaluate the period $\tilde{T}$. A reasonable approximation consists in using the spring values corresponding to the fixed-base natural period, and even simpler is to use the static values of the springs.

Soil-Structure Interaction, Fig. 1 Effects of soil-structure interaction: (a) elongation of natural period in dependency on the ratio of structure-to-soil stiffness $\bar{s}$; (b) increase in effective damping in dependency on the natural period ratio $\tilde{T}/T$. Curves are for mass ratio $\bar{m} = 0.15$

and different values of the slenderness ratio $\bar{h}$. Poisson's ratio $\nu = 0.45$ (Adapted from Veletsos (1977). In: Hall WJ (ed) Structural and geotechnical mechanics, 1st edn, © 1977. Reprinted by permission of Pearson, Inc., Upper Saddle River, NJ)

The dimensionless parameters controlling the period lengthening are

$$\text{Stiffness ratio structure-to-soil } \bar{s} = \frac{h}{T v_s} \quad (5)$$

$$\text{Slenderness ratio } \bar{h} = \frac{h}{r} \quad (6)$$

$$\text{Mass ratio } \bar{m} = \frac{m}{\rho \pi r^2 h} \quad (7)$$

with

$$v_s = \sqrt{G/\rho} \quad (8)$$

denoting the shear wave velocity in the soil.

The stiffness ratio will be larger for stiff structural systems such as shear walls and smaller for flexible systems such as moment frames. For soil and weathered rock sites, this term is typically smaller than 0.1 for flexible systems such as moment frames and between approximately 0.1

and 0.5 for stiff systems such as shear wall and braced frame structures. The period lengthening variation with the stiffness ratio is shown in Fig. 1a for typical values of the parameters involved.

For the overall effective damping ratio of the system, several approaches have been proposed in the literature differing in the degree of approximation involved. Usually products of damping ratios are neglected as higher-order terms. The most widespread among these solutions – that also entered design codes – is that derived by Veletsos and Meek (1974). Assuming structural damping of viscous nature, the overall effective damping becomes

$$\tilde{\beta} = \beta_0 + \frac{\beta_{\text{str}}}{(\tilde{T}/T)^3} \quad (9)$$

where β_0 represents the contribution from the soil-structure interaction – being referred to as foundation damping – that includes both material

and radiation damping (Veletsos 1977). The respective expression is written here in the more general form

$$\beta_0 = \left(\frac{T}{\tilde{T}} \right)^3 \left| k \frac{\tilde{T}}{T} \left(\frac{\beta_x}{\tilde{K}_x} + \frac{\beta_\theta}{\tilde{K}_\theta} h^2 \right) \right| \quad (10)$$

From Eq. 9 it is evident that the effectiveness of the structural damping is reduced by soil-structure interaction as the period ratio $\tilde{T}/T$ increases. This may lead to a decrease in overall damping unless this reduction is compensated by the increase in the foundation damping. In practice, effective damping is taken higher than the structural damping, the value 5 % used in the development of design provisions being considered as a lower bound. Figure 1b shows the significant increase of the foundation damping with decreasing slenderness ratio h/r : rocking motion that is characterized by small radiation damping dominates the response of slender structures, whereas for squat structures the prevailing motion is horizontal translation that radiates energy into the soil more efficiently.

Observations based on data from instrumented buildings confirmed the analytical findings. For the majority of structures, the stiffness ratio h/Tv_s will be less than 0.5 and the mass ratio will range between 0.1 and 0.2 with a typical average of 0.15 (Stewart et al. 2003). The case studies analyzed revealed that the governing parameter for inertial interaction is the stiffness ratio and that these effects can be neglected for values less than 0.1.

Impedances for Shallow Foundations

Frequency-dependent springs and dashpots for shallow foundations have been determined in the last decades by several authors for different geometries and soil stratigraphies. In most cases radiation damping is expressed in terms of the dashpot coefficient C_j , as given in Eq. 1. The stiffness K_j at zero frequency is referred to as the static foundation stiffness and is denoted by K_j^0 . The effects of frequency on the spring values for the particular vibrational mode j are then given by stiffness modifiers such that

$$K_j = K_j^0 k_j \quad (11)$$

Exact closed-form solutions are available only for perfectly rigid circular foundations and relaxed boundary conditions at the soil-foundation interface, i.e., normal stresses are neglected for swaying and shear stresses for rocking. These solutions are

Horizontal translation

$$K_x^0 = \frac{8}{2 - \nu} Gr \quad (12)$$

Rocking

$$K_\theta^0 = \frac{8}{3(1 - \nu)} Gr^3 \quad (13)$$

These expressions may be used for square foundations – and also for rectangular foundations with aspect ratio less than 3 – by replacing the radius by an equivalent value that yields the same footprint area for swaying and equal moments of inertia for rocking.

A review of available solutions for foundation impedances is presented by Pais and Kausel (1988) and Gazetas (1991) and the update by Mylonakis et al. (2006). Approximate expressions and graphs are compiled for various configurations and for all six modes of vibration. They include static values for rectangular foundations, stiffness modifiers, and expressions for the radiation damping.

We restrict here the presentation of results to swaying and rocking motion for rectangular foundations with footprint area $2a \times 2b$ with $a \geq b$ with the x -axis running parallel to the longer foundation side. The subscripts θ_x and θ_y in the impedances indicate rotation around the x - and y -axis, respectively. The weak coupling between translational and rocking mode is neglected. The frequency dependency is captured by the dimensionless parameter

$$a_0 = \frac{\omega b}{v_s} \quad (14)$$

and the foundation aspect ratio is denoted by

$$\ell = \frac{a}{b} \geq 1 \quad (15)$$

The approximate expressions obtained by Pais and Kausel (1988) are displayed in the following.

Surface Foundations

The static solutions are:

$$\text{Swaying } K_x^0 = \frac{Gb}{2-v} [6.8\ell^{0.65} + 2.4] \quad (16)$$

$$\text{Swaying } K_y^0 = \frac{Gb}{2-v} [6.8\ell^{0.65} + 0.8\ell + 1.6] \quad (17)$$

$$\text{Rocking } K_{\theta_x}^0 = \frac{Gb^3}{1-v} [3.2\ell + 0.8] \quad (18)$$

$$\text{Rocking } K_{\theta_y}^0 = \frac{Gb^3}{1-v} [3.73\ell^{2.4} + 0.27] \quad (19)$$

The frequency-dependent stiffness modifiers are:

$$\text{Swaying } k_x = 1 \quad (20)$$

$$\text{Swaying } k_y = 1 \quad (21)$$

$$\text{Rocking } k_{\theta_x} = 1 - \left[\frac{0.55a_0^2}{0.6 + \frac{1.4}{\ell^3} + a_0^2} \right] \quad (22)$$

$$\text{Rocking } k_{\theta_y} = 1 - \left[\frac{(0.55 + 0.01\sqrt{\ell})a_0^2}{2.4 - \frac{0.4}{\ell^3} + a_0^2} \right] \quad (23)$$

The viscous damping coefficients accounting for radiation damping as determined from the dashpot coefficients using Eq. 2 are:

$$\text{Swaying } \beta_x = \left[\frac{4\ell}{K_x^0/Gb} \right] \left[\frac{a_0}{2k_x} \right] \quad (24)$$

$$\text{Swaying } \beta_y = \left[\frac{4\ell}{K_y^0/Gb} \right] \left[\frac{a_0}{2k_y} \right] \quad (25)$$

$$\text{Rocking } \beta_{\theta_x} = \left[\frac{(4/3)\bar{v}\ell a_0^2}{(K_{\theta_x}^0/Gb^3) \left[\left(2.2 - \frac{0.4}{\ell^3} \right) + a_0^2 \right]} \right] \left[\frac{a_0}{2k_{\theta_x}} \right] \quad (26)$$

$$\text{Rocking } \beta_{\theta_y} = \left[\frac{(4/3)\bar{v}\ell^3 a_0^2}{(K_{\theta_y}^0/Gb^3) \left[\left(\frac{1.8}{1 + 1.75(\ell - 1)} \right) + a_0^2 \right]} \right] \left[\frac{a_0}{2k_{\theta_y}} \right] \quad (27)$$

where

$$\bar{v} = \sqrt{2(1-v)/(1-2v)} \quad \bar{v} \leq 2.5 \quad (28)$$

is the ratio of compressional wave velocity to shear wave velocity in the soil.

It should be mentioned that the exact curves for the stiffness modifiers and the damping factors have in general a smooth wavy form, and the expressions given above consist approximations to these curves.

Key features of the system behavior are:

Dynamic modifiers for translational stiffness are almost unity independent of the foundation aspect ratio, whereas rocking modifiers are significantly reduced with frequency in a very weak dependency on the foundation aspect ratio.

Radiation damping for the horizontal translational mode is only modestly influenced by the direction of vibration or the foundation aspect ratio. For rocking on the other hand, the damping is strongly affected by the aspect ratio and the direction of vibration, increasing with the foundation aspect ratio. At low frequencies damping in rocking motion is smaller compared to that in horizontal translation due to interference phenomena; it only overweighs translational damping at higher frequencies and for elongated foundations when excited in the direction of the longer foundation side. Hence, translational foundation movement may often be predominant with respect to radiation damping.

Embedded Foundations

The references cited above contain also information for embedded foundations. Embedment increases static foundation stiffness. According to the review by Pais and Kausel (1988), dynamic stiffness modifiers remain largely unaffected. The dynamic analyses for obtaining such impedances usually assume a perfect contact between the soil and the basement walls, a situation that seldom occurs in reality. This yields higher damping values as observed from the actual response of buildings. A practical, conservative approach consists in considering the embedment effects only for the static stiffness and applying the dynamic modifiers of surface foundations. Alternatively, one may use the formulae given by Gazetas (1991) and by Mylonakis et al. (2006) that consider an effective height of the contact zone along the perimeter of the embedded foundation.

Soil Layering

Impedance functions for multilayered soils can only be determined with specialized software that is not easily accessible to practicing engineers. Available algorithms are mostly based on finite element procedures incorporating efficient consistent boundaries for the proper energy radiation at the domain boundaries.

A particular case constitutes a soil layer of finite depth on rock where a cutoff frequency exists, below which there is no radiation damping. The respective formulae given in the above references may be used for a two-layer system when the shear wave velocity in the top layer is less than half of that of the underlying stratum. Impedances for square foundations on uniform or nonuniform soil layer overlying a half-space are tabulated by Wong and Luco (1985).

Parameters for Soil Behavior

The expressions given above assume linear elastic or viscoelastic soil behavior. However, for moderate or strong seismic excitations, the nonlinearity of the soil must be taken into account. Hence, the values of the shear modulus entering the equations for the SSI effects must be adjusted to reflect the strain level in the ground

associated with the stipulated design ground motion. In critical projects seismic site response analyses are carried out with the soil properties being determined from special dynamic laboratory tests on undisturbed samples. First-order estimates for the strain-compatible values are given in some code provisions. Typical values as recommended by Eurocode 8, Part 5 (CEN 2004), are tabulated below in terms of their small-strain amplitude values G_0 and v_{s0} in dependency on the effective ground acceleration defined as the spectral acceleration at the plateau of the response spectrum divided by 2.5. Guide values for the hysteretic soil damping are also given.

The small-strain values of the soil shear modulus or the shear wave velocity may be determined by a variety of methods, the choice depending on the variability of the soil conditions, available knowledge on the material behavior, and the importance of the structure. These methods include: (i) empirical relationships in terms of the SPT blow count or of the tip resistance of the CPT tests, (ii) geophysical field methods based on wave propagation, and (iii) dynamic laboratory tests. An overview of the testing procedures and available design equations is summarized by Kramer (1996).

	Effective spectral ground acceleration [g]		
	0.10	0.20	0.30
G/G_0	0.80 (± 0.10)	0.50 (± 0.20)	0.36 (± 0.20)
v_s/v_{s0}	0.90 (± 0.07)	0.70 (± 0.15)	0.60 (± 0.15)
Damping ratio	0.03	0.06	0.10

Adaption in Design Codes and Implication for the Design

The implications of inertial SSI for design are illustrated in Fig. 2 with reference to the acceleration response spectrum used for evaluating seismic base shear forces in buildings. Idealized envelope spectra in modern codes initially increase with period, attaining a plateau value, and start decreasing monotonically after a certain period that is in the order of 0.4 to 1.0 s.

Soil-Structure

Interaction, Fig. 2 Effect of natural period elongation and foundation damping on a typical acceleration design spectrum (Adapted from Stewart et al. (2003) by permission of the Earthquake Engineering Research Institute)

**Soil-Structure**

Interaction, Fig. 3 Ratio of spectral acceleration to peak ground acceleration for 5 % structural damping for some severe earthquakes with long-period components compared to that of a typical code for soft soil (Adapted from Gazetas and Mylonakis (1998) by permission of the American Society of Civil Engineers)

For buildings with periods larger than about 0.5 s, consideration of period elongation and flexible base damping will lead to a reduction of the base shear demand. Hence, in most cases, SSI effects are neglected in the frame of conservative design.

However, there are various seismic environments with recorded response spectra exhibiting

their peak at periods greater than 1.0 s. Spectra from some prominent records are contrasted to a typical design spectrum for soil in Fig. 3. SSI phenomena in these earthquakes had detrimental effects as revealed by analyses linking site conditions and building natural periods to observed damage. In the 1985 Mexico City earthquake, for example, due to SSI effects, the natural period of

10–12 story buildings founded on soft clay was altered from about 1.0–1.5 s to nearly 2.0 s, thus coinciding with the peak of the response spectrum at the particular site. The associated phenomena are elucidated among others by Gazetas and Mylonakis (1998).

Hence, proper assessment of both the anticipated seismic input and the prevailing soil conditions is an indispensable prerequisite in any SSI analysis. In modern seismic codes the site characterization for deep soil deposits is based almost exclusively on the near-surface region of the soil (often the top 30 m), disregarding the depth of the underlying rock. The representative average shear wave velocity to this depth in this deposit is used as parameter for the classification; cf. Dobry et al. (2000).

Pile Foundations

Single Pile

Consider a pile horizontally loaded at its head at the ground surface. The deformed shape of the pile extends down to a so-called active (or effective) length below which it becomes negligible. This length depends on the pile diameter, the elastic modulus of the soil, the ratio of pile modulus to soil modulus, and the fixity conditions. Expressions for static and dynamic loading are given by Gazetas (1991). For static loads this length is of the order of 10–20 pile diameters, while for dynamic loading this length will be greater due to the wave propagation. With respect to flexural response, the pile can be modeled without significant error as an infinite-long beam when its length is greater than the active length. Two models are commonly used for the analysis: elastic continuum theory or Winkler spring models (Pender 1993).

Following the same principles as for shallow foundations, the horizontally loaded soil-pile system may be represented by three impedances corresponding to swaying, rocking, and cross-swaying-rocking. Consideration of the latter is necessary since the reference level is located at the pile head and the resultant of the reactions acts at a specific depth thus inducing a bending moment at the pile head. Expressions synthesized

from results by various authors are summarized by Gazetas (1991). The static stiffnesses are expressed in terms of the pile diameter d and Young's moduli of the soil and the pile E and E_p , respectively:

$$\text{Swaying } K_x^0 = dE \left(\frac{E_p}{E} \right)^{0.21} \quad (29)$$

$$\text{Rocking } K_\theta^0 = 0.15d^3E \left(\frac{E_p}{E} \right)^{0.75} \quad (30)$$

$$\text{Cross-swaying-rocking } K_{x\theta}^0 = -0.22d^2E \left(\frac{E_p}{E} \right)^{0.50} \quad (31)$$

The dynamic modifiers are approximately equal to unity:

$$k_x = k_\theta = k_{x\theta} \approx 1 \quad (32)$$

The expressions for the radiation damping β_j as defined by Eq. 2 are given in dependency on the dimensionless frequency

$$a_0 = \frac{\omega d/2}{v_s} \quad (33)$$

as follows:

$$\text{Swaying } \beta_x = 0.35 a_0 \left(\frac{E_p}{E} \right)^{0.17} \quad (34)$$

$$\text{Rocking } \beta_\theta = 0.11 a_0 \left(\frac{E_p}{E} \right)^{0.20} \quad (35)$$

$$\text{Cross-swaying-rocking } \beta_{x\theta} = 0.27 a_0 \left(\frac{E_p}{E} \right)^{0.18} \quad (36)$$

Pile Groups

Building foundations are always constructed as groups of piles. In evaluating the dynamic stiffness of a pile group, the interactions between the piles must be taken into consideration, just like in the case of static loading. However, the cross-interaction of individual piles is strongly

dependent on frequency, thus precluding description by simple explicit formulae. The rigorous solution methods available are based on the thin-layer method (Kaynia and Kausel 1982; Waas and Hartmann 1984). Fortunately, a remarkable simple solution procedure was discovered by Dobry and Gazetas (1988) that is straightforward to implement, thus facilitating the assessment of the associated SSI effects with a very good accuracy. The respective interaction coefficients between the piles are given in terms of pile spacing, excitation frequency, and the wave velocity through the soil between the piles. The values for the overall stiffness and damping of the pile group are then assembled using the respective values of the single piles and these interaction factors.

Kinematic Interaction

Shallow Foundations

Kinematic interaction is induced by the presence of a stiff foundation that forces the foundation motions to deviate from the free-field motions. The associated phenomena are due to (i) base-slab averaging of inclined or incoherent seismic waves, and (ii) embedment of the foundation.

Base-Slab Averaging

Seismic waves impinging at directions other than vertical arrive at different points along the foundation at different times giving rise to the so-called wave passage effects. The apparent propagation velocity of the waves is in the order of 1.5–3.5 km/s and is controlled by the wave propagation in the underlying rock. In addition to this, ground motion is in most cases inherently incoherent resulting from inhomogeneities along the travel path from the source to the site.

Studies conducted hitherto mainly address the wave passage problem that is amenable to analytical treatment. They show that the slab due to its stiffness and flexural rigidity averages the free-field displacement pattern by reducing the translational motions and at the same time introducing rotational motions. The latter include rocking in the presence of inclined SV-, P-, or

Rayleigh waves, and torsion in the presence of SH- or Love waves. The torsion of symmetrical buildings observed in earthquakes is a consequence of obliquely incident seismic waves. Further, the modification of the seismic motion depends on the frequency content of the seismic motion with high-frequency components being filtered out by the slab when the respective apparent wavelength is shorter than an effective length of the foundation slab (the diameter for circular foundations).

Kinematic interaction effects are expressed in terms of transfer functions relating the amplitude of the foundation input motion to that of the free-field motion. The system considered consists of a rectangular foundation with area $2a \times 2b$, $a \geq b$ that is subjected to harmonic SH waves of circular frequency ω with particle motion in the direction of the x -axis impinging on the foundation at an angle α_v with the vertical and propagating along the positive y -axis. The transfer functions derived by Veletsos et al. (1997) include both coherent and incoherent seismic motions. They are given in dependency on the dimensionless parameter

$$\tilde{a}_0 = \frac{\omega b_e}{v_s} \sqrt{\kappa^2 + \sin^2 \alpha_v \left(\frac{b}{b_e}\right)^2} \quad (37)$$

where $b_e = \sqrt{ab}$ is the half-side length of an equivalent square foundation, v_s is the shear wave velocity, and κ is a ground motion incoherence parameter. The curves shown in Fig. 4 represent the two limiting cases with $\kappa = 0$ and $\alpha_v = 0$, respectively. The transfer functions for torsional motions are referred to the foundation edge being the product of foundation half-width b and rotational angular distortion.

Lateral transfer functions are for both types of wave motion only very weak dependent on the aspect ratio a/b suggesting that the governing parameter is the foundation area. The induced torsional component, however, is very sensitive both to the aspect ratio and the type of wave motion.

Recent observations on buildings indicate that the apparent value of κ (denoted by κ_a) is nearly

Soil-Structure Interaction, Fig. 4 Amplitude of transfer functions between free-field and foundation input motion for rectangular foundations subjected to obliquely incident shear waves: (a) vertically incident, incoherent

waves; (b) non-vertically incident, coherent waves. The *solid lines* are for the horizontal motion and the *dashed lines* for the induced torsional component. Curves computed from expressions in Veletsos et al. (1997)

proportional to the small-strain shear wave velocity v_s yielding roughly $\kappa_a = 0.2$ at a typical value $v_s = 250$ m/s, Kim and Stewart (2003).

Foundation Embedment

Embedment effects result from the scattering of incoming waves. Rocking motions develop due to nonuniformly distributed tractions against the side walls. Assessment is made by means of transfer functions relating the base-slab translational and rocking motions to the free-field motions. An accurate numerical solution for cylindrical foundations subjected to coherent shear wave motions is provided by Day (1977). The embedment depth e is normalized with respect to the radius of the foundation r , and the frequency dependency is captured by the dimensionless parameter $a_0 = \omega r / v_s$. Figure 5 shows typical patterns for vertically propagating waves.

Piles

Piles embedded in a soil stratum respond to incident vertical shear waves in dependence on their flexural rigidity in relation to the stiffness of the surrounding soil. The incoming wave field is modified, the displacement at the pile head differs from that of the free field, and pile-head rotation is induced. The displacement reduction depends on the ratio of pile modulus to soil modulus, the

slenderness of the pile, and the frequency of excitation with high-frequency components being filtered out especially by relatively short, rigid piles.

Analyses of kinematic interaction that include variable stratigraphy are carried out mostly by using the Winkler spring model. The ends of the springs and dashpots that capture SSI effects are connected to the free field where the soil response is imposed. The latter is computed independently. The accuracy of this simplified approach depends on the selection of the springs and dashpots that are obtained adopting physically justified approximations (Pender 1993).

Attention deserves the bending moment induced in the pile during the passage of seismic waves. The maximum value occurs, as expected, at soil layer interfaces, strongly increasing with the contrast in shear wave velocity between the bottom and top layer (Nikolaou et al. 2001).

The numerical study by Fan et al. (1991) using the continuum model by Kaynia and Kausel (1982) for pile groups excited by vertically propagating shear waves provides graphs showing the effects of pile rigidity relative to that of the soil, pile slenderness, pile spacing, number of piles, and pile-head fixity conditions. An idealized general shape of the frequency dependence of the kinematic response is defined in terms of a

Soil-Structure Interaction,

Fig. 5 Amplitude of transfer functions between free-field and foundation input motion for cylindrical, embedded foundation subjected to vertically incident coherent shear waves for different normalized embedment depths. (a) horizontal translation; (b) rocking component (Redrawn from Day (1977))

displacement factor relating the pile-head displacement to that of the free field. This factor is approximately unity at low frequencies with the pile closely following the ground movement; in the medium frequency range, it decreases with frequency and beyond a distinct frequency fluctuates around a constant value of 0.2–0.4. The difficulty consists in defining the transition frequencies for the particular system layout.

It must be realized though that there is no simple means for evaluating kinematic interaction for pile groups. In noncritical situations, however, this difficulty may be circumvented by neglecting kinematic interaction. This is justified by findings that kinematic effects for pile groups are similar to those for individual piles, in particular for horizontal translation and to a lesser extent for torsional and rocking vibration modes.

Concluding Remarks

Despite its inherent complexity, the theory of linear soil-structure interaction and the implications in structural performance are now well understood. Refinements, optimization, and validation studies are subjects of ongoing research. The variability in the stratigraphy of soil deposits, the nonlinearity of the soil behavior, the frequency dependency of the response, and the limited availability of specialized software for the analysis make the proper assessment of the SSI effects still a difficult task, requiring physical insight when applying such concepts. It should be self-evident that the effective implementation in an integrated structural design asks for a close collaboration between structural and geotechnical engineers.

Summary

The main effects of soil-structure interaction on the seismic response of structures founded on compliant ground are presented. The modeling concepts to capture the associated modification of the building natural period and the energy dissipation due to radiation damping are highlighted by reference to relatively simple structures. Both kinematic and inertial actions are treated. Available expressions for the dynamic impedance functions are summarized both for shallow foundations and piles. A brief account is given of the implications in seismic design provisions for buildings.

Source Characterization for Earthquake Early Warning

Aldo Zollo, Gaetano Festa, Antonio Emolo and Simona Colombelli

Department of Physics, University of Naples Federico II, Federico II – AMRA S.c.ar.l, Napoli, Italy

Synonyms

Earthquake early warning; Earthquake ground motion; Earthquake source observation; Real-time location; Real-time magnitude

Introduction

Earthquake Early Warning Systems (EEWS) are real-time, seismic monitoring infrastructures that are able to provide a rapid notification of the potential damaging effects of an impending earthquake. This objective is achieved through the fast telemetry and processing of data from dense instrument arrays deployed in the source region of the event of concern (regional EEWS) or surrounding/at the target infrastructure (front-detection or site-specific EEWS).

A regional EEWS is based on a dense sensor network covering a portion or the entire area that is threatened by earthquakes. The relevant source parameters (event location and magnitude) are estimated from the early portion of recorded signals (initial P-waves) and are used to predict, with a quantified confidence, a ground-motion intensity measure at a distant site where a target structure of interest is located. Site-specific (or on-site) EEWS consist of a single sensor or an array of sensors deployed in the proximity of the target structure that is to be alerted and whose measurements of amplitude and predominant period on the initial P-wave motion are used to predict the ensuing peak ground motion (mainly related to the arrival of S- and surface waves) at the same site. Front-detection EEWS is essentially a variant of the on-site approach, where a

barrier-shaped, accelerometric network is deployed between the source region and the target site to be protected. The alert is issued when two or more nodes of the array record a ground acceleration amplitude larger than a default threshold value. For typical regional distances, the peak acceleration at the barrier nodes is expected to be associated with the S-wave train, so that the distance between the network and the target is set to maximize the lead time (i.e., the time available for warning before the arrival of strong ground shaking at the target sites), which is, in this case, the travel time of S-waves from the barrier to the target site.

EEWS have experienced a very rapid improvement and a wide diffusion in many active seismic regions of the world in the last three decades (Fig. 1). They are operating in Japan, Taiwan, Mexico, and California. Many other systems are under development and testing in other regions of the world such as in Italy, Turkey, Romania, and China. Most of these existing EEWS essentially operate in the two different configurations described above, i.e., regional and on-site, depending on the source-to-site distance and on the geometry of the considered network with respect to the source area. The “front-detection” EEWS such as the barrier-type, Seismic Alert System (Espinosa-Aranda et al. 2011) for Mexico City can be particularly advantageous when the only potential seismic sources are at some distance from the strategic target to be protected.

The regional EEWS approach is based on the detection of the initial P-wave signal at a number of near-source stations, typically 4 to 6. Several methodologies have been proposed for the real-time estimation of the earthquake location and magnitude and are now implemented in the EW algorithms, such as ElarmS (Allen et al. 2009), Virtual Seismologist (Cua et al. 2009), and PRESTo (Satriano et al. 2010) presently running in California, Switzerland, and Southern Italy, respectively. In the framework of EU REAKT (Strategies and Tools for Real-time Earthquake Risk Reduction, FP7:ENV2011.1.3.1-1) and international collaboration projects, testing of PRESTo early warning platform is performed in

Source Characterization for Earthquake Early Warning, Fig. 1 The map shows the distribution of Earthquake Early Warning Systems around the world, with a color indicating the status of the system. In *purple*, the

operative systems, which are providing warnings to public users. In *black*, the systems which are currently under real-time testing. *Gray* color is finally used for those countries where feasibility studies are currently being doing

Romania, Greece, Turkey, Spain, and South Korea. The real-time magnitude estimation is generally inferred from the measurement of peak displacement amplitude and/or the predominant period measured in the first few seconds of the recorded P-signal, typically 3–4 s. Although the saturation of the P-wave parameters has been observed for $M > 6.5$ –7 earthquakes, several methodologies making use of longer time windows of the P-wave and/or the S-wave to update magnitude estimates have been shown to be efficient in minimizing the problem of magnitude underestimation (Colombelli et al. 2012b). The source location and magnitude estimations, which are continuously updated by adding new station data, as the P-wave front propagates through the regional EW network, are then used to predict the severity of ground shaking at sites far away from the source, by using regional-specific, ground-motion prediction equations.

The on-site early warning approaches are generally aimed at estimating the expected peak ground shaking, associated with S- and surface waves, directly from the recorded early P-wave signal. This is achieved through the use of empirical regressions between measurements

performed on the initial P-wave signal and the final peak ground motion. Wu and Kanamori (2005) first showed that the maximum amplitude of a high-pass filtered vertical displacement, measured on the initial 3 s of the P-wave (named P_d), can be used to estimate the peak ground velocity (PGV) at the same site, through a power-law relationship. The main advantage is that this relationship does not require an independent estimate of the magnitude as for regional EEWs. Although initially observed for near-source records (distances < 30 km), further analyses on independent datasets have confirmed that $\log PGV$ vs. $\log P_d$ scaling is still valid at relatively large distances (distances < 300 km) (Zollo et al. 2010; Colombelli et al. 2012a). Most of the currently operating on-site EEWs are threshold-based, alert methodologies: the alert is issued as the measured initial P-wave peak amplitude overcomes a given threshold which is arbitrarily set according to the predicted S-wave peak ground-motion amplitude. Since small magnitude earthquakes may have very large amplitudes driven by high-frequency spikes, such a basic threshold system can produce frequent false alarms. A more robust approach is to combine

the P-wave peak (which scales with distance and magnitude) and P-wave predominant period (which scales with the magnitude), into a single proxy to be used for on-site warning (Wu and Kanamori 2005). Following this idea, Zollo et al. (2010) and Colombelli et al. (2012a) have proposed a threshold-based EW method based on the real-time measurement of the period (τ_c) and peak displacement (P_d) parameters at stations located at increasing distances from the earthquake epicenter. The measured values of early warning parameters are compared to threshold values, which are set for a given minimum magnitude and instrumental intensity. At each recording site an alert level is assigned based on a decisional table with four levels defined upon threshold values of the parameters P_d and τ_c . Given a real-time, evolutionary estimation of earthquake location from first P arrivals, the method also furnishes an estimation of the extent of potential damage zone as inferred from continuously updated averages of the period parameter and from mapping of the alert levels determined at the near-source accelerometer stations.

P-wave-based, regional, and on-site EW methods can be integrated in a unique alert system (as actually done, e.g., in the new version of PRESTo, e.g., PRESTo Plus, Zollo et al. 2014), which can be used in the very first seconds after a moderate-to-large earthquake to determine the earthquake location and magnitude and to map the most probable damaged zone, using data from receivers located at increasing distances from the source.

Methodologies for regional earthquake early warning assume a point-source model of the earthquake source and isotropic wave amplitude attenuation. These assumptions may be inadequate to describe the earthquake source of large earthquakes and wave amplitude attenuation effects, and they can introduce significant biases in the real-time estimation of earthquake location and magnitude. This issue is critically related to the EEWS performances in terms of expected lead time and of uncertainties in predicting the peak ground motion at the site of interest. Within this context, new developments have been

proposed, such as the strategy of expanding the P-wave time window for the real-time signal processing, the 2D mapping of the potential damage zone, and the use of continuous GPS measurements and methodologies to estimate fault rupture extent in real time by classifying stations into near source and far source. These innovative aspects of early warning will be discussed in the present review, with a specific focus on methods for rapid and reliable source characterization for early warning applications.

Methodology

Point-Source Characterization for an Earthquake Early Warning System

In EEWS the strong motion is generally synthesized by a single parameter (in most cases the peak ground velocity, PGV , the peak ground acceleration, PGA , or the peak ground displacement, PGD , Fig. 2), which can be directly related to the damage that a building or an infrastructure may undergo because of the earthquake. Two possible approaches can be explored for the prediction/estimation of ground-motion parameters at a given site.

A first possibility is to relate the ground shaking to simplified macroscopic description of the source, yielding ground-motion prediction equations. In such a case, indicating with PGX the selected ground-motion parameter, the simplest attenuation relationship relates the logarithm of PGX with the earthquake-to-site distance R and the magnitude M :

$$\log PGX = f(M, R) \quad (1)$$

By definition of magnitude, a linear function of M is in most cases adequate to describe the influence of the earthquake size on the ground motion. The distance effect is instead accounted for by two terms describing the decay of the amplitude owing to geometrical spreading and inelastic processes within the upper crust. Nevertheless, more complex ground-motion prediction equations may be used containing high-order terms, focal depth dependence, and site effects. It is worth to

Source Characterization for Earthquake Early Warning, Fig. 2 Schematic illustration of early warning parameters. From *top to bottom*, an example of the vertical component of acceleration, velocity, displacement, and integral of squared velocity (IV2) signals. The ground-motion parameters PGA, PGV, and PGD are measured as the absolute maximum along the signal, using acceleration, velocity, and displacement records, respectively.

The *gray small box* shows a zoom on the first few seconds of P-wave on velocity (*top*) and displacement (*bottom*) records. The initial peak displacement (P_d) is measured as the absolute maximum of displacement waveform on the early portion of P-wave (typically 2–4 s) while the period parameter τ_c is measured from the ratio between initial displacement and velocity waveforms in the same time window

note that while magnitude is an ensemble measure for earthquake size, the definition of the distance requires a specific metric, which is sensitive to the ratio between the source-to-site distance and the earthquake size. At distances significantly larger than the source size, a point-source approximation for the earthquake can be generally assumed, and R refers to the epicentral or the hypocentral distance. In the near-source range, instead, finite-fault effects may be relevant and a different metric for the distance could be required. Anyhow, whatever choice of attenuation relationships and distance metrics are done, the ground-motion prediction requires the knowledge of earthquake location and size. This model

is used by regional early warning systems, for which the characterization of the source is performed by a network installed in the source vicinity.

A complementary approach is based on empirical relationships between a ground-motion parameter P_y measured in the early portion of the P-wave train and the final PGX . This is physically grounded on the first-order approximation that $\log P_y$ has the same magnitude and distance dependence of $\log PGX$, being differences concentrated only on static and possibly frequency-dependent effects. In such a case, estimation of source parameters is hidden in the common dependence and the uncertainty may be

significantly reduced by avoiding the estimation of magnitude and distance. Additionally, this approach does not require a seismic network to constrain the source parameters and can be efficiently used for single stations. Such a model is the one implemented in on-site early warning systems.

Finally both models can be combined together, with source parameters estimated by a regional network and ground motion locally verified at a specific site.

Real-Time Location

A main concern for any early warning system is the reliable estimation of earthquake hypocenter in real time. Recently, Satriano et al. (2008) have developed an evolutionary approach aimed at constraining the earthquake location, which starts when the first station is triggered by the seismic event and is updated as time passes. This technique is based on the equal differential time (EDT) formulation and provides a probabilistic density function for the earthquake location in a three-dimensional space accounting, at each time step, for information from both triggered and not-yet-triggered stations. In particular, with a single, initial, recorded arrival time, the hypocenter has to belong to the Voronoi cell containing the triggered station, which is created using the travel times to the not-yet-triggered stations. As more and more stations identify the seismic event, the location is constrained in the volume defined by the intersection of the Voronoi cells for the remaining not-yet-triggered stations and the EDT surfaces evaluated for all pairs of already-triggered stations.

Let us consider a seismic network (Fig. 3a) with N operational recording stations $S_1, \dots, S_N$ and a gridded volume V containing both the network and the earthquake source. Preliminarily, we computed the travel times from each grid point (i, j, k) in the volume V to each station of the network. If the earthquake hypocenter is at the node (i^*, j^*, k^*) of the searching grid, the classical EDT formulation prescribes that the difference between the theoretical travel times ttt_m and ttt_n from the event source to two stations S_m and S_n of the network is exactly equal to the difference

between the observed arrival times ot_m and ot_n at the same stations, since they share the same earthquake origin time:

$$(ttt_m - ttt_n)_{i^*, j^*, k^*} = ot_m - ot_n, \quad \text{with } m \neq n \quad (2)$$

If a homogeneous velocity model is assumed, the previous equation defines a 3D hyperbolic surface whose symmetry axis passes through the two stations. With N_T triggered stations, we obtain $N_T(N_T - 1)/2$ surfaces and the hypocenter is then located at the region crossed by the maximum number of EDT surfaces.

This description is modified in the evolutionary approach introduced by Satriano et al. (2008) in which, at each time step, EDTs are evaluated not only for pairs of triggered stations but also for those pairs where only one station has already triggered. This means that when the first station, let us say S_n , is triggered by the earthquake at the time t_n , it is immediately possible to limit the hypocentral position (Fig. 3b) from the EDT surfaces defined considering that any operational but not-yet-triggered receiver S_l will identify the seismic arrival at a later time t_l (with $t_l \geq t_n$) such that

$$(ttt_l - ttt_n)_{i^*, j^*, k^*} \geq 0, \quad \text{with } l \neq n \quad (3)$$

The equality in the previous equation corresponds to the set of points in the volume of interest for which the travel time at the first station is equal to the travel time at any remaining, not-yet-triggered, receivers (conditional EDT). As a consequence, the inequality delimitates the region in the volume V , bounded by the conditional EDT, that must contain the earthquake hypocenter. In the case of a homogeneous propagation medium, the region bounded at the time t_n by the conditional EDTs evaluated for all the stations corresponds to the Voronoi cell for the receiver S_n . As the time goes on, the source volume is bounded by the system of equations

$$(ttt_l - ttt_n)_{i^*, j^*, k^*} \geq t_{\text{cur}} - t_n, \quad \text{with } l \neq n \quad (4)$$

Source Characterization for Earthquake Early Warning, Fig. 3 Sketch of the evolutionary earthquake location approach. For simplicity of the presentation, it is shown only a plane view of the epicentral location. (a) The Voronoi cells associated with each station (operational and not) of the network are a priori known. (b) As the first station triggers, it is possible to identify a volume that is bounded by the conditional EDT surface on which the travel time for the first receiver is equal to the travel times for each not-yet-triggered station. This volume is likely to contain the true earthquake location. (c) As the time passes, further information from station that

has not yet triggered is gained and the EDT surface bends around the first triggered station. As a consequence, the source volume decreases. (d) As the second station triggers, a true EDT surface is defined. The intersection between this surface and the conditional EDT surfaces limits the likely source volume whose dimension is continuing to decrease. (e) Two more true EDT surfaces become available when the third station triggers, thus better constraining the earthquake location. (f) As more and more stations trigger, the earthquake location converges to the standard EDT solution which is based on true EDT only (After Satriano et al. (2008))

provided that, at the current time t_{cur} , only the station S_n has triggered at the previous time t_n . As t_{cur} increases, the hypocentral volume becomes smaller since the conditional EDT surfaces fold around the station S_n (Fig. 3c).

It is possible to prescribe a probability density function (pdf) for the hypocentral volume associated with each inequality in the previous equations and for each grid point. We assign a value $p_{n,l}(i, j, k) = 1$ if the inequality is satisfied and a value $p_{n,l}(i, j, k) = 0$ if it is not. Summing up over all the stations, we obtain, for each grid point, a non-normalized PDF $P(i, j, k)$ whose maximum value is $(N-1)$ for those grid points for which all inequalities in the equation are satisfied.

When the second station (and, as the time progresses, further receivers) triggers, the equation is evaluated for all the possible pairs of triggered and not-yet-triggered stations. Then, true EDT surfaces are defined for each pair (n, m) of triggered stations computing, for each grid point, the quantity

$$q_{n,m}(i, j, k) = \exp \left\{ \frac{[(ttt_n - ttt_m)_{i,j,k} - (ot_n - ot_m)]^2}{2\sigma^2} \right\},$$

with $n \neq m$

(5)

where the expression in square brackets corresponds to the standard EDT and σ represents the uncertainty associated with the arrival time picking and travel-time computation. The quantity $q_{n,m}(i, j, k)$ varies between 0 and 1. We then sum the $q_{n,m}$'s with the updated $p_{n,l}$'s to obtain a new $P(i, j, k)$ which now has a maximum value equal to

$$P_{\text{max}} = (N - N_T)N_T - \frac{N_T(N_T - 1)}{2} \quad (6)$$

being N_T the number of triggered stations. Once we have evaluated P , we can define the function

$$Q(i, j, k) = \left(\frac{P(i, j, k)}{P_{\text{max}}} \right)^N \quad (7)$$

which varies in the range $[0, 1]$ and represents the PDF for hypocentral location at the grid cell (i, j, k) .

As the time increases and more and more stations trigger, the number of not-yet-triggered stations becomes smaller and smaller, and the earthquake location converges toward the hypocenter which would be obtained through the standard EDT approach using data from all operational stations of the network (Figs. 3d–f). Tests performed on both synthetic and real data have shown that when a dense seismic network (i.e., with a mean station spacing of about 10 km) is deployed around the fault zone, a location accuracy is achieved within 1–3 s after the first arrival detection.

Real-Time Magnitude Estimation and Earthquake Rupture

Magnitude estimation for early warning applications is based on empirical relationships relating the earthquake size with parameters measured in the early portion of the P- and S-wave trains. These parameters are generally associated to the low-frequency content of the data, which is sensitive to the seismic moment, and can be related to the maximum amplitude, the dominant frequency, or the energy released by the event. Associated proxies are peak values, predominant period and integrated measurements, respectively. Several authors showed that the initial portion of recorded P-waves carries information about the event magnitude, both through its frequency content and amplitude (Allen and Kanamori 2003; Kanamori 2005; Zollo et al. 2006; Wu and Zhao 2006; Böse et al. 2007; Wu and Kanamori 2008). A review of the common used parameters is detailed in the next section; here we want to note that peak and energy estimates are dependent on the source-to-site distance, while predominant period is pretty insensitive to the epicentral location (Allen and Kanamori 2003). In all cases, when dealing with dense regional networks surrounding the fault that generated the earthquake, location is generally available before or at the same time the first estimates of magnitude are performed. Therefore, it is not a

disadvantage to use distance-dependent parameters as compared to distance-independent ones. All of the parameters are estimated from measures in the early portion of the signal: with the goal of issuing an early warning for earthquakes with magnitude larger than 5.5, the time scale in which performing the measurements is few seconds (2–4 s generally).

The definition of a time window t_0 for the measurements corresponds to image a specific area on the fault plane, delimited by the corresponding isochrone. It is defined as the set of points whose radiation arrives at a given station at the same time t_0 . Hence, the portion of the fault enlightened by the first few seconds of signal depends both on the relative location of the station as compared to the fault and on the phase, either P or S. Specifically, for the same time window, S-waves image a larger area on the fault, because their speed is closer to the rupture speed as compared to the P-waves, and the regions explored by the different stations do not overlap as much as P-waves. We then expect that inclusion of early portion of S-waves may significantly constrain the estimation of the earthquake magnitude, as compared to the only use of P-waves. This approach is possible for close stations (with epicentral distances smaller than 30 km) for which the analysis of S-waves does not significantly affect the lead time for early warning. Additionally, isochrone mapping enhances that few seconds of P/S-waves correspond to an earthquake size of magnitude 6–6.5. This indicates that the early portion of the signal captures almost the whole rupture process up to this magnitude, while effective prediction is possible beyond that limit. Using a kinematic description of the rupture, we can argue that early warning parameters up to magnitude 6–6.5 change because both the ruptured area and the total average slip increase. Beyond that threshold, these parameters image almost the same portion of fault and any change with magnitude is only ascribed to any increase of the average slip in that region.

From this consideration we can retain that scaling of early warning parameters may be different for different magnitude ranges, and a

two-slope behavior is expected around the deterministic threshold. Hence, the use of a single relationship for a broad magnitude range should be statistically checked to avoid under/over estimations of the magnitude at the limits of the investigated range. Additionally, if any scaling occurs for events with magnitude larger than 6, this indicates a different initiation process for earthquakes that reach different sizes. Specifically, since the scaling of parameters is observed up to magnitude 7.5, this implies that when we look at the earthquake rupture on a given space scale characteristic of a magnitude 6.0 event, we can probabilistically forecast if this rupture will soon stop or it will grow up to a larger space scale. Beyond that limit, standard regression laws saturate and a different approach is required to capture the earthquake size for very big-size events. As a final comment, since the parameters have a different sensitivity to the slip increase, the uncertainty associated to the magnitude estimation may change. Generally, peak parameters are more sensitive to slip changes, the slope of the scaling is larger, and the uncertainty in the magnitude estimation is smaller as compared to predominant period estimations.

We now discuss a real-time approach for magnitude estimation based on a probabilistic evolutionary approach (Lancieri and Zollo 2008). This approach generalizes standard averages coming from single-station estimates of magnitude and can include also a priori probability density functions for magnitude characterization. As discussed before, we assume a linear scaling between the logarithm of the early warning parameter Py and the final magnitude

$$\log Py^{\text{theo}} = A + BM + C(R/R_0) \quad (8)$$

where C is a function of the distance R and R_0 a reference distance. Coefficients are generally different for P- and S-waves. For low-frequency estimators that depend on the distance, the predominant effect comes from geometrical spreading and we can assume $C(R) = K \log R$. After defining the duration of the window for P- and S-waves, the computation of Py is performed by isolating the corresponding time windows after

the P- and S-wave arrivals. P-wave arrival is automatically picked, while S-wave arrival is computed using a theoretical travel-time database derived by a 1D or 3D velocity model suitable for the area of investigation. Since S-wave estimates are significantly different from P-wave estimates, we need to be sure that the selected P-wave window is not contaminated by the following S-wave, to avoid any bias in the magnitude estimation. If the S-wave arrival is expected in the P-wave window, that P-wave measurement is discarded. For a single P_y measurement at a given station and for a given phase, the magnitude can be estimated using the Bayes theorem:

$$P(M|P_y) = \frac{P(P_y|M)P_a(M)}{\int_M P(P_y|M)P_a(M)} \quad (9)$$

In the above formula the probability $P_a(M)$ represents the a priori probability on the magnitude, the probability $P(P_y|M)$ comes from the regression relationship, and, assuming a Gaussian distribution for $\log(P_y)$, this writes

$$P(P_y|M) = \frac{1}{\sqrt{2\pi}\sigma} \exp \left[-\frac{1}{2\sigma^2} (\log P_y - \log P_y^{\text{theo}})^2 \right] \quad (10)$$

(σ is the standard deviation of the fit). Finally the denominator is a normalization factor. This approach can be directly plugged into a real-time evolutionary magnitude estimation where the probability is updated as new information comes from additional stations or phases. Without any information, we assume an a priori magnitude distribution coming from the long-term earthquake catalog inspection (generally a Gutenberg-Richter distribution). To build up an evolutionary scheme, assuming to have computed the probability density function for the magnitude after $n-1$ measurements of P_y , this function is then used as the a priori distribution for the n th measurement. It is worth to note that this scheme allows accounting for magnitude saturation. In this case the probability

distribution $P(P_y|M)$ is assumed uniform beyond the magnitude saturation threshold.

Parameters for Magnitude Estimation

In the context of real-time applications, different amplitude and period parameters have been proposed to get independent estimates of the earthquake size. We present here an overview of the parameters used by the different systems for the magnitude estimation.

Following an original idea of Nakamura (1988), Allen and Kanamori (2003) first proposed the use of a period parameter, measured on the first few seconds of P-wave signal, to infer the size of the ongoing earthquake. The predominant period is measured on the vertical component of velocity record and is defined as

$$T_i^p = 2\pi \sqrt{X_i/D_i} \quad (11)$$

where

$$X_i = \alpha X_{i-1} + x_i^2 \quad (12)$$

$$D_i = \alpha D_{i-1} + \left(\frac{dx}{dt} \right)_i^2 \quad (13)$$

where T_i^p is the predominant period at the i th sample, x_i is the recorded ground velocity, X_i is the smoothed squared ground velocity, D_i is the smoothed squared velocity derivative, and α is a smoothing constant. They showed that an empirical log-linear correlation exists between the event magnitude and the maximum of T_i^p (named $T_{i \text{ max}}^p$) within 2–4 s after the P-wave arrival. Using a dataset of Californian earthquakes, they derived two linear relations between $T_{i \text{ max}}^p$ and magnitude, for small earthquakes (in the magnitude range 3–5) and for larger earthquakes (magnitude range 5–7.3). In particular, for the upper magnitude class they found a log-linear relationship of the form:

$$M = 7.0 \log(T_{i \text{ max}}^p) + 5.9 \quad (14)$$

Source Characterization for Earthquake Early Warning, Fig. 4 Empirical scaling relationships between early warning parameters and magnitude. (a) The average period as a function of magnitude (After Zollo et al. (2010)); (b) the initial peak displacement as a

function of magnitude (After Lancieri and Zollo (2008)); (c) the correlation between P_d and PGV (After Zollo et al. (2010)); and (d) the scaling of the integral of squared velocity (IV2) with magnitude (After Festa et al. (2008))

A similar period parameter has been proposed by Kanamori (2005), who defined the average period (τ_c) of the first seconds of P-wave signal as

$$\tau_c = 2\pi \sqrt{\frac{\int_0^{\tau_0} u^2(t) dt}{\int_0^{\tau_0} v^2(t) dt}} \quad (15)$$

where u and v are displacement and velocity, respectively; the integrals are computed over a time window $(0, \tau_0)$ starting from the P-wave arrival and τ_0 is generally set at 3 s.

Using a database of Taiwan, Japan, and Italy earthquakes (magnitude range $4 < M < 8.3$), Zollo et al. (2010) determined the relationship between average period and magnitude (Fig. 4a). By measuring τ_c in seconds, they found

$$\log(\tau_c) = 0.21(\pm 0.01)M - 1.19(\pm 0.08) \quad (16)$$

Both period parameters ($T_{i \max}^p$ and τ_c) are empirically related to the event magnitude but are pretty independent of the distance.

An alternative estimate of the earthquake size can be obtained using amplitude parameters. Zollo et al. (2006) showed that the low-pass filtered, peak displacement amplitude of initial P- and S-wave seismic signals correlates with the earthquake magnitude (Fig. 4b). The P- and the S-peak amplitudes are measured in a short time window (2–4 s) after the arrival times of P- and S-waves, respectively. The initial peak amplitude can be measured on the single vertical component or on the modulus of the displacement vector, as proposed by Lancieri and Zollo 2008. In both cases the functional dependence of the peak amplitude follows the more general relationship, including also the dependence on the distance (Eq. 8), with the reference distance $R_0 = 10$ km. Hereinafter, we will adopt the initial P-peak amplitude of the vertical component and will refer to it as P_d .

Finally, Festa et al. (2008) investigated the scaling of the early-radiated energy, with the final size of the event. The radiated energy can be inferred from the squared velocity integral (IV2), which is measured on the initial portion of P- and S-wave signals and is defined as follows:

$$IV2_c = \int_{t_c}^{t_c + \Delta t_c} v_c^2(t) dt \quad (17)$$

where the subscript c refers to the P- or S-phase, t_c is the corresponding first arrival, and v_c is the particle velocity measured on the seismograms. Moreover Δt_c is the length of the signal along which the analysis is performed. They found an evident log-linear scaling of IV2 with magnitude for both P- and S-wave data, up to $M = 5.8$ (Fig. 4c). Beyond this value, the early energy increases less with respect to the final magnitude. Thus, they suggested that early-radiated energy can be used to discriminate whether the event has a magnitude larger or smaller than 5.8, and only in the latter case it allows for real-time magnitude

estimation. For larger magnitudes a saturation effect of IV2 prevents from a correct evaluation of the event size. The saturation effect disappears when the velocity integral is evaluated along the whole signal duration, showing a robust log-linear correlation up to larger magnitudes (~ 7).

In addition to the event magnitude, another relevant and complementary piece of information to be provided in real time is the estimate of the expected ground shaking at target sites. This latter represents an important aspect of the practical implementation of an EEWS and is crucial for the decision-making processes and the prompt activation of security actions and emergency procedures. With this aim, an empirical correlation between the initial peak displacement (P_d) and the final observed peak ground velocity (PGV) can be used. Analyzing a database of earthquake records from Japan, Taiwan, and Italy (2009 Mw 6.3 L'Aquila mainshock and aftershocks) and considering a maximum recorded distance of 60 km, Zollo et al. (2010) obtained the following regression relation (Fig. 4d):

$$\log(PGV) = 0.73(\pm 0.01)\log(P_d) + 1.30(\pm 0.02) \quad (18)$$

where PGV is in cm/s and P_d is in centimeters.

Amplitude and period parameters thus provide complementary information about the ongoing earthquake, being them related to the expected ground shaking at recording sites and to the earthquake magnitude, respectively. With this in mind, Wu and Kanamori (2008) proposed an original, on-site alert-level scheme, based on the combination of measured P_d and τ_c parameters. The idea is to rapidly distinguish the case of a small/large and close/faraway event from the observed values of P_d and τ_c at each recording site. Following this idea, Zollo et al. (2010) proposed a threshold-based approach to EEWS which is aimed at the setup of local alert levels based on a decision table. The key element of the method is the real-time, simultaneous measurement of initial peak displacement (P_d) and period parameter (τ_c) in a 3 s window after the first P-arrival time and on the use of the initial peak displacement as a proxy for the PGV .

Source Characterization for Earthquake Early Warning, Fig. 5 Alert levels and threshold values for observed early warning parameters (After Zollo et al. (2010)). (a) P_d versus τ_c diagram showing the chosen threshold values and the regions delimiting the different alert levels. Level 3 = damage expected nearby and far away from the station; level 2 = damage expected only nearby the station; level 1 = damage expected only far away from the station; level 0 = no expected damage (After Zollo et al. (2010)). (b) Conceptual scheme for the potential damage zone definition. Measured and predicted Pd

values over the area are interpolated and the PDZ is obtained by delimiting the $P_d = 0.2$ isoline. (c) Example of potential damage zone resulting from the interpolation of measured and predicted P_d values. Gray triangles represent the stations triggered by the earthquake, while red and blue triangles show the alert level recorded at each station, as soon as 3 s of signal after the P-picking are available. The color transition from light blue to red delimits the potential damage, PDZ (After Colombelli et al. (2012a))

From the analysis of strong-motion data of Japan, Taiwan, and Italy, Zollo et al. (2010) calibrated the threshold values, for the definition of four alert levels (0, 1, 2, 3) (Fig. 5a). The threshold values have been established according to the P_d vs. PGV and to the τ_c vs. M empirical relationships (Fig. 4a, d). The threshold values correspond to a minimum magnitude $M = 6$ and to an instrumental intensity $I_{MM} = 7$, assuming that the peak ground velocity provides the instrumental intensity through the relationship of Wald et al. (1999). The alert-level scheme can be

interpreted in terms of potential damaging effects nearby the recording station and far away from it. For example, following the scheme of Fig. 5a, the maximum alert level (level 3, i.e., $\tau_c \geq 0.6$ s and $P_d \geq 0.2$ cm) corresponds to an earthquake with predicted magnitude $M > 6$ and with an expected instrumental intensity (at the site) $I_{MM} \geq 7$. This means that the earthquake is likely to have a large size and to be located close to the recording site and a high level of damage is therefore expected either nearby or far away from the recording station. On the contrary, in

case of a recorded alert level equal to 0 ($\tau_c < 0.6$ s and $P_d < 0.2$ cm), the event is likely to be small and far from the site, thus no damage is expected either close or far away from the station. The application of this method to a series of large Japanese events ($M > 6$) (Colombelli et al. 2012a) confirmed that the threshold-based approach is a robust strategy to rapidly predict the expected damage at recording sites, showing a very good matching between the real-time assigned local alert levels and the final, observed peak ground velocity, carried by the later arrival of S-waves.

Extended Source Approach

Expansion of the P-Wave Time Window for Large Magnitude Events

There are no concerns, in fact, on the effectiveness of EEWS for the real-time characterization of small and moderate events, for which the fracture process is concluded within a few seconds. Anyhow, regression relationships between peak displacement, predominant period, and other integrated parameters based on 2–4 s of P-wave saturate beyond a magnitude threshold that can be estimated into the range 7–7.5. This saturation is owed to the limited window range that images a too small portion of the fault plane. When an earthquake extends for hundreds of kilometers on the fault, its dynamics is expected to be controlled by large asperities that the rupture can meet during its propagation also far away from the hypocenter. Another aspect to be carefully checked is the filter used to get a reliable low-frequency signal. Generally the high-pass cutoff frequency is 0.075 Hz that is comparable with the corner frequency of an M 7 event. This means that up to magnitude 7, the cutoff filter still includes the ensemble radiation emitted by the fault while for larger magnitudes the selected frequency range extracts only the constructive interference coming from specific regions of the fault. Investigation of large magnitude events hence requires a progressive extension of the P-wave time window, with update of early warning parameters at individual stations. Since at fixed time close stations experienced a large time

window when compared to farther stations, an efficient procedure should manage in real time both the increasing of the time window at single stations and different time windows, when combining information coming from different stations.

The analysis of strong-motion data of the recent Mw 9.0, 2011 Tohoku-Oki mega-thrust earthquake confirmed the necessity of considering larger time windows to overcome the problem of parameter saturation. Colombelli et al. (2012b) proposed an evolutionary approach to early warning, in which amplitude and period parameters (P_d and τ_c , respectively) are measured in progressively increasing P-wave time windows. The real-time measurements are no more done within a fixed portion of signal but starting from the P-wave arrival and expanding the time window up to the arrival of the S-waves at each recording site. With such an approach, the standard methodologies and the empirical regression relationships can be extended to very large earthquakes, provided that appropriate time windows are selected for the measurements. With this approach data from different stations require a specific weight depending on the available P-wave time window (PTW). Specifically, a weight proportional to the square of PTW was shown to provide a good compromise between the window length and the number of stations. As shown in Fig. 6a, that peak displacement increases with PTW, indicating a final level of 8.5. Final underestimation may be related in this case to the regression relationship, validated for smaller magnitude events and shorter distances, to the cutoff frequency, or to the specific dynamics of the event, which exhibited a frequency-dependent radiation (Fig. 6b). On the other hand, predominant period does not monotonically increase with larger time window, indicating that its use in real time could be sensitive to the specific event to be analyzed.

Real-Time Estimation of Fault Rupture Extent Using Strong-Motion Data

Even if we improve the magnitude estimation for very large earthquakes, distance metrics might be inadequate, mostly for targets that are close to the causative fault but far from the epicenter. In such a

Source Characterization for Earthquake Early Warning, Fig. 6 Real-time evolution of average values of peak displacement (P_d) (a) and predominant period (τ_c) (b) as a function of the P-wave time window used. Error bars are computed as the standard deviation associated to each value; the gray number close to each point represents the number of stations used for each considered time window.

Both parameters exhibit saturation when a 25–30 s PTW is used; the saturation level is shown by the *gray-dashed lines*. For each plot, the corresponding magnitude scale is also represented; this has been derived based on the coefficients of Eq. 1 and on the τ_c vs. M relationship determined by Zollo et al. (2010) (After Colombelli et al. (2012b))

case ground-motion prediction could be significantly underestimated. To this end, Yamada et al. (2007) proposed a method to classify recording stations in near- and far-source distance. If a dense seismic network is available, this subdivision can be used to infer information about the fault geometry. Analyzing strong-motion data from past events, the authors found that the combination of vertical acceleration and horizontal velocity produces the best performance for stations classification. Their discriminant is given by

$$F_i = 6.046 \log Z a_i + 7.885 \log H v_i - 27.091 \quad (19)$$

where $Z a_i$ and $H v_i$ represent the peak acceleration on the vertical component (in cm/s^2) and the

square root of the sum of the squares of the peak velocity on the horizontal components, recorded at the i th station, respectively. Thus, the quantity

$$P_i = \frac{1}{1 + e^{-F_i}} \quad (20)$$

provides the probability that the i th station is in the near- or far-source region. Specifically, the recording site is classified as a near-source station if the probability is greater than 1/2.

For real-time application, peak values used for recording site classification are computed from incoming data every 10 s for each station and then used in the discriminant function. As example, in Fig. 7 the procedure is applied to the case of

Source Characterization for Earthquake Early Warning, Fig. 7 Snapshots showing the recording stations identified as near-source sites in the case of the 1999 M7.0 Chi-Chi (Taiwan) earthquake. The *star* marks the earthquake epicenter. *Circles* represent the

recording stations. *White zones* correspond to the source area and *rectangle s* identify the surface projection of the causative faults. The darker is the marker, the higher is the probability that the corresponding site is located in near source (After Yamada et al. (2007))

the 1999, M7.0, Chi-Chi (Taiwan) earthquake. As time goes on, the near-fault stations identify quite well the fault extent.

In a recent paper, Yamada (2014) proposed an improved version of this discriminant. This approach identifies the fault rupture geometry by classifying stations into near-source and far-away source and provides reasonably good estimates of the extent of the near-source area.

Potential Damaged Zone

As for the point-source analysis, on-site approaches can be used to predict finite source effects, such as directivity and azimuthal changes on the ground motion directly analyzing the early motion at the single sites, without explicitly estimating any source parameters. The idea is to use the threshold-based approach to compute threshold levels at single stations and to interpolate the

levels to define the potential damage zone associated with the earthquake (Kanamori 2005; Zollo et al. 2010).

At a single site, the real-time measure of the P-wave parameters (P_d and τ_c) thus provide a rough but rapid alert notification, although no information is given about the accurate earthquake size and location. Considering that the same measure can be performed at different nodes of a dense array of stations, deployed nearby and far away from the earthquake epicenter, the mapping of the recorded maximum alert levels (3 or 2) provides a preliminary estimation of the extent of the potential damage zone (PDZ), i.e., the area where the damages are expected to be equal or greater to those predicted by the level VII according to the instrumental intensity scale.

The same authors proposed that a rough but very rapid estimation of the PDZ extent can also be made from the updated averages of the period parameter τ_c which is recorded at strong-motion sites in the near-source region. Fixing the parameter P_d at its threshold value and using the progressively updated estimations of the period parameter, the empirical equation

$$\log P_d = A + B \log \tau_c + C \log R \quad (21)$$

(R is the hypocentral distance; A, B, C are determined by the regression analysis) can be used to determine the radius of the area within which the strong ground motion is expected to produce an instrumental intensity $I_{MM} > 7$. The off-line application of the method showed a very consistent match between the rapidly predicted (within a few sec from the first recorded P-wave) and observed damage zone, the latter being mapped from detailed macroseismic surveys a few days after the event. A more refined technique for the real-time mapping of the PDZ has been proposed by Colombelli et al. (2012a), who tested the method on data from ten $M > 6$ Japanese earthquakes occurred in the period 2000–2009 and recorded at the K-Net/Kik-Net Japan accelerometric arrays. The method is based on the recursive use of the ground-motion prediction equation for P_d (Eq. 21), with real-time, updated estimate of the earthquake location and

characteristic period τ_c . The area covered by stations is divided into cells, using a prefixed spatial grid, which is needed to fill the gaps where stations are not available. At those stations where the first 3 s of signal after the P-picking are available, an alert level is locally assigned, based on P_d and τ_c measurements. At the same time, the event location is obtained by using the available P-picks and a real-time location method. Furthermore, the expected P_d value can be predicted at each node of the grid, through Eq. 21 and the τ_c averaged over the available measurements at the considered time step. Measured and predicted P_d values are thus interpolated; the area within which the highest level of damage is expected can be delimited by the isoline corresponding to $P_d = P_d^{th} = 0.2$ cm.

The predicted PGV values at stations and at grid nodes can be computed using the equation relating $\log(PGV)$ and $\log(P_d)$ (Eq. 1 in Zollo et al. 2010) and finally converted into an instrumental intensity measure using the relationship of Wald et al. (1999). An interpolation is performed between all intensity values to produce a real-time, continuously updated, intensity map (Fig. 5b,c). This procedure is repeated every time step (typically 1 s); as the waves propagate within the area and trigger other stations, the event location is refined by using P-pickings, average τ_c value is updated, and more data are used for the interpolation procedure. The studied cases for Japan earthquakes displayed a very good matching between the rapidly predicted earthquake potential damage zone inferred from initial P-peak displacement amplitudes and the instrumental intensity map, the latter being mapped after the event, using peak ground velocity and/or acceleration, or from field macroseismic surveys. The performance of the method has been evaluated by defining *successful*, *missed*, and *false alarms* in terms of observed versus predicted instrumental intensities for all the analyzed events and by counting their relative percentage. A very high percentage (88 %) of alert levels has been correctly assigned, and most of maximum alert levels correspond to the area within which the highest level of damage has been observed.

Source Characterization for Earthquake Early Warning, Fig. 8 (a) Example of snapshot of the GPS-based strategy for the Mw 9.0, 2011 Tohoku-Oki earthquake. The background color represents the predicted intensity distribution using the final magnitude value and the distance from the finite fault. The purple color scale shows the slip distribution on the seven-patch slip model. The total length estimate (L) is also plotted as vectors on the fault plane. Black vectors represent the observed horizontal offset while white vectors show the static displacement resulting from the inversion algorithm. (b) Magnitude estimate as a function of time from the origin time. The magnitude is obtained by using the static displacement

Summary

An approach that may be more robust is the inversion for the final slip on the fault plane, which allows consideration of the contributions from the entire fault plane and may provide a more realistic estimate of both size and potential damage of the ongoing event.

One way to recover the slip distribution on the fault plane is to use the permanent ground deformation, which is directly related to the earthquake magnitude. The static component of ground motion could, in principle, be obtained using dynamic range, accelerometric sensors, which are able to record unsaturated signals in a broad range of frequencies (0 ÷ 100 Hz). Accelerometric records are integrated twice to

provided by GPS data using the near-field, point source approximation (dark blue solid line) and resulting from the slip inversion (small blue squares). For comparison, the evolution of magnitude estimate provided by the JMA early warning system is also shown as a dotted gray line, and the continuous gray line represents the real moment magnitude value. (c) Warning timeline for the Tohoku-Oki earthquake showing when the GPS information is available with respect to the time at which the strongest shaking occurs in the Sendai and Tokyo regions and with respect to the JMA warnings. After Colombelli et al (2013)

obtain displacement time series. Unfortunately, for near-field records, this operation may introduce artificial effects and long-period drifts (Boore et al. 2002), which are usually removed by applying a high-pass filter. The application of the filter, while removing the artificial distortions, reduces the low-frequency content of the recorded waveforms, resulting in the complete loss of the low-frequency energy radiated by the source and of the static offset, which is the most relevant piece of information for a large earthquake.

GPS stations are able to provide a direct and evolutionary measurement of the permanent ground deformation, i.e., of the resulting co-seismic displacement after the dynamic vibration has finished. With the increasing diffusion of

high-rate 1 Hz GPS stations, the seismological community has begun looking at GPS data as a valid complement to the high-frequency information provided by seismic data.

Once the permanent static offset is extracted from GPS displacement time series, a real-time static slip inversion scheme can be used to infer the slip distribution on the fault plane for both the rapid determination of the event size and for the near-real-time estimation of the rupture area (Fig. 8). Many authors have recently started applying GPS data to EEW (Allen and Ziv 2011; Crowell et al. 2012; Wright et al. 2012; Ohta et al. 2012; Colombelli et al. 2013); they showed that 1 Hz GPS data provide a rapid and remarkably robust magnitude estimate and can be used for the real-time estimation of the rupture area, which, in turns, would allow for an improved prediction of the earthquake damaging potential.

Another possibility would be a fast kinematic inversion of the rupture process, searching for the fault geometry, the focal mechanism, and the slip distribution on the fault plane. A first approach was proposed by Dreger et al. (2005), who combined preliminary information on location and magnitude with scaling laws for source size to determine both the focal mechanism and a kinematic rupture model from inversion of strong-motion integrated displacement waveforms. The approach revealed useful for estimating the ground shaking in the near-fault domain for the 2003, M 6.5, San Simeon, California, earthquake. Nevertheless, computational times were estimated however of the order of minutes, making the results available in near real time but not in real time.

Introduction

Assessing the integrity of the structures in real time is a very important topic for which many methods have been developed in the last decades. Today, structural health monitoring (SHM) is gaining more and more attention: in the case of bridges, the maximum loads tend to increase (increase of the vehicle weights), while most of the structures are coming to the end of their theoretical lifetime. In addition, exceptional events such as collisions or earthquakes can cause more severe and fast deteriorations. Optimal maintenance calls for an early detection of small damage in structures, as it is well known that limited and frequent repairs are much less costly than major repairs or total rebuilding after

collapse. Current monitoring practice consists in scheduled maintenances including visual inspections, ultrasounds, eddy current, magnetic field, or radiography techniques (Hellier 2003). All these experimental methods require however that the vicinity of the flaw is known and that the proximity to be inspected is accessible. Moreover, these local inspections are labor intensive and therefore very expensive. A major problem is that traditional monitoring is noncontinuous which means that if a critical damage occurs between two inspections, it might lead to catastrophic structural failure. One of the most relevant examples is the I-35W Mississippi River Bridge case (Rofidal 2007): this bridge collapsed in August 2007 killing 13 people and injuring 145, despite annual inspection.

A general trend for new structures and bridges is a lighter and more slender design, which tends to increase the levels of vibrations under ambient excitation. While these levels of vibrations need to be controlled as they could be detrimental to the lifetime of the structure, they can also be used for the continuous monitoring of the structure without disruption or decrease of functionality. The basic idea is that the occurrence of damage alters the structural parameters which in turn affect the vibration characteristics. Vibration SHM of civil engineering structures relies on ambient vibrations, as artificial excitation of such large structures is often unpractical.

Based on this basic concept, many vibration-based SHM techniques have been developed in the last decades using mainly eigenfrequencies, damping ratios, or mode shapes (Doebling et al. 1998). The reason of this popularity is the ease of measuring modal parameters or frequency responses on real structures thanks to recent advances in sensors and sensing systems and in the development of efficient operational modal analysis techniques (Reynders and De Roeck 2008; Reynders et al. 2012). Such advances are so important that more and more very large bridges are instrumented with larger and larger sensor networks. China has been the driving force in this direction with the massive instrumentation of bridges in the Hong Kong area, the largest one

being the Stonecutters Bridge with more than 1,500 sensors among which are 58 accelerometers and 853 dynamic and static strain sensors (Ni et al. 2012). In Europe, the Messina bridge project, designed to be the largest cable-stayed bridge in the world would include a very large monitoring system with more than 3,000 sensors (De Neumann et al. 2011).

These technological advances have opened the way to real-time automated SHM of bridges. A major problem related to the use of such very large sensor networks is to find adequate techniques to post-process the data: intelligent methods are needed in order to take advantage of the enormous amount of information provided by these large networks. In fact, operational modal analysis is not yet fit for automated modal analysis using very large sensor networks.

With that perspective, rather than identifying online the full set of modal properties of the structure, an alternative is to condense the measured data while keeping the information about the potential damage occurring in the structure. The technology presented in this entry is spatial filtering, which consists in using a linear combiner to condense the information from very large networks of sensors into one or just a few “virtual sensors.” Such virtual sensors can be designed in order to react strongly to damage while being insensitive to environmental changes or even to react to a damage occurring in a specific location along the bridge.

Rytter (Rytter 1993) has proposed a hierarchical decomposition of the SHM process in four levels, which has been widely accepted in the SHM literature: detection (level 1), localization (level 2), quantification (level 3) of the damage, and prediction of the remaining service life of the damaged structure (level 4). As the level of SHM increases, the knowledge about the damage increases and, usually, the complexity of the method increases as well. The method based on spatial filtering can deal with levels 1 and 2 by comparing data measured in the current unknown state with data measured from the structure assumed to be undamaged.

The general scheme of the method is shown in Fig. 1. It is divided in three parts: (i) the

Spatial Filtering for Structural Health Monitoring, Fig. 1 General scheme of vibration-based SHM

measurement of raw time-domain data, including data reduction, (ii) the transformation of the data into information using feature extraction, and (iii) the diagnostics of the structural health based on the monitored features.

The first section of this entry deals with measurement of raw time-domain data and details the spatial filtering technique for data reduction. The second section is devoted to feature extraction, and the third section deals with the diagnostics, both for damage detection and localization. The last section presents an experimental illustration of the SHM technique on a 3.78 m long steel I-beam tested in the laboratory.

Measurement of Raw Time-Domain Data

The first building block of the SHM system is the sensor network. As stated earlier, a current trend is to implement very large sensor networks on large civil engineering structures. In such cases, it is often necessary to perform data reduction in order to decrease the power consumption and the bandwidth needed to transmit the data and to facilitate the data storage and post-processing. For SHM applications, an optimal reduction is one that significantly reduces the amount of data while keeping most of the information about the damage. The technique presented in this entry for data reduction is spatial filtering.

Spatial and Modal Filtering

Consider a structure excited with an ambient force $f(t)$ equipped with a network of n sensors whose time-domain output is denoted by $y_k(t)$ as shown in Fig. 2. The dynamic time-domain response at each sensor can be decomposed into a sum of contributions of the N mode shapes excited by the ambient force:

$$y_k(t) = \sum_{i=1}^N a_i(t) \phi_{ki} \quad (1)$$

where $a_i(t)$ is the modal amplitude of mode i and ϕ_{ki} is the projection of mode shape i on sensor k . The application of spatial filtering with coefficients α_k leads to a single sensor output $g(t)$:

$$g(t) = \sum_{k=1}^n \alpha_k y_k(t) = \sum_{i=1}^N \sum_{k=1}^n \alpha_k \phi_{ki} a_i(t) \quad (2)$$

The general scheme of spatial filtering can be used for different purposes. A first idea is to condense the information into the modal coordinates of the undamaged structure, which allows to reduce the data $y_k(t)$ from a very large network of n sensors to a limited set of $a_i(t)$ time series from N modal sensors. This idea is motivated by the fact that the vibration of structures typically involves only a few mode shapes which are excited in a given frequency band of interest.

To design a modal filter, the vector of the linear combiner α_k must be orthogonal to all the modes of the structure in a frequency band of interest, except mode l :

$$\sum_{k=1}^n \alpha_k \phi_{ki} = \delta_{li} \quad (3)$$

Equation 2 then reduces to

$$g(t) = a_l(t) \quad (4)$$

Equation 3 can be written in a matrix form:

$$[C]^T \{\alpha\} = e_l, \quad (5)$$

Spatial Filtering for Structural Health Monitoring,

Fig. 2 Principle of spatial filtering on a network of n sensors

where $\{\alpha\} = \{\alpha_1 \dots \alpha_n\}^T$ and $e_l = \{0 \ 0 \dots 1 \dots 0 \ 0\}^T$ (all components set to 0 except the l th component) and $[C]$ is a matrix whose columns correspond to the N mode shapes projected on the n sensors of the array. Equation 5 can be solved only if there are at least as many sensors as there are mode shapes ($n \geq N$). In this case, matrix $[C]$ is rectangular and the system of equations is overdetermined (several solutions exist which satisfy Eq. 5). The minimum norm solution is usually adopted by computing the pseudo-inverse (regularized with singular value decomposition) of $[C]^T$ (Deraemaeker et al. 2008).

The modal filter can be tuned to any of the N mode shapes in the frequency band of interest. In the frequency domain, the FRF of the modal filter tuned on mode l is given by

$$G(\omega) = \frac{b_l}{(\omega_l^2 - \omega^2 + 2j\xi_l\omega_l\omega)}, \quad (6)$$

where b_l depends on the excitation level and position. It corresponds to the FRF of a single degree of freedom system which presents a single peak at frequency ω_l .

Using modal filtering, the amount of data from a large network of n sensors can be significantly reduced to just a few modal filters. Such modal filters are virtual sensors which measure the amplitude of vibration of each mode separately. Typically, for a bridge excited by the ambience, only a few (up to ten) mode shapes are relevant, and the information can be drastically reduced. The computation of the linear combiner coefficients α_k is based on Eq. 5 which requires the knowledge of matrix $[C]$. This matrix should be built using experimentally identified mode shapes in order to avoid the need for

Spatial Filtering for Structural Health Monitoring, Fig. 3 Effect of a structural change on the modal filter tuned on mode l (Deraemaeker et al. 2008)

a numerical model of the structure to be monitored. This can be achieved thanks to operational modal analysis, using, for instance, stochastic subspace-based methods (Reynders and De Roeck 2008).

Effect of Damage on Modal Filters

Suppose now that damage initiates in the structure. This damage will alter the stiffness matrix, affecting the eigenfrequencies and mode shapes of the structure. The change of mode shapes will be reflected in matrix $[C]^T$ so that Eq. 5 will now be violated. In other terms, the damage will alter the mode shapes, and the coefficients of the linear combiner will not be tuned anymore. This will result in the reappearance of the filtered peaks, as illustrated in Fig. 3. This is the central idea of vibration-based SHM based on modal filters, as detailed in Deraemaeker et al. (2008).

Spatial Filtering for Structural Health Monitoring,

Fig. 4 Example of I_{Peak} values for an increasing peak

From Data to Information

The raw time-domain output of modal filters is not exploitable as such, as the changes in the time-domain response due to damage will be very small. The transformation in the frequency domain is an important step which allows to enhance these small changes by focusing on the frequency bands away from the main peak where the filtered peaks will reappear. In the case of ambient vibrations, the input force is not known, and the power spectral density (PSD) $S_{gg}(\omega)$ of $g(t)$ should be computed. This quantity is directly related to the amplitude of the FRF $G(\omega)$ as follows (Ewins 1984):

$$S_{gg}(\omega) = |G(\omega)|^2 S_{ff}(\omega) \quad (7)$$

This equation shows that if peaks are filtered in the FRF $G(\omega)$, they will be filtered in $S_{gg}(\omega)$ as well. When damage occurs, the reappearance of spurious peaks should be monitored based on the power spectral density of the output of the modal filter $S_{gg}(\omega)$.

Feature Extraction

Because the spurious peaks are expected to appear around the initial eigenfrequencies of the structure, the strategy consists in extracting one feature in each frequency band around them. Let $s(\omega)$ be the frequency dependent amplitude in the frequency range (ω_a, ω_b) (Fig. 4). For ambient vibrations, $s(\omega)$ is the PSD $S_{gg}(\omega)$.

The frequency band is typically defined by $\omega_a = 0.95\omega_i$ and $\omega_b = 1.05\omega_i$, where ω_i is the angular eigenfrequency. A peak indicator is then computed in this frequency interval:

$$I_{Peak} = \frac{2\sqrt{3RVF}}{\omega_b - \omega_a}, \quad (8)$$

where RVF is the root variance frequency defined by

$$RVF = \sqrt{\frac{\int_{\omega_a}^{\omega_b} (\omega - FC)^2 s(\omega) d\omega}{\int_{\omega_a}^{\omega_b} s(\omega) d\omega}}, \quad (9)$$

and FC is the frequency center defined by

$$FC = \frac{\int_{\omega_a}^{\omega_b} \omega s(\omega) d\omega}{\int_{\omega_a}^{\omega_b} s(\omega) d\omega} \quad (10)$$

Theoretically, I_{Peak} is equal to 1 if $s(\omega)$ is constant and decreases when the peak grows. Figure 4 gives an example of I_{Peak} values computed between ω_a and ω_b when a spurious peak grows around ω_i . The advantage of that feature is that it is very sensitive to the peak growth but not to the level of the excitation force, which is particularly needed for ambient vibrations. More details on the peak indicator computation can be found in Deraemaeker and Worden (2010).

Spatial Filtering for Structural Health Monitoring, Fig. 5 A typical control chart

Diagnostics

The last building block of the SHM system is the diagnostics. It consists in assessing, based on the monitored features (here the peak indicators) whether the structure is healthy or damaged, and possibly in giving indication on the location of damage.

Statistical Analysis of the Features

When the excitations are random, the peak indicators behave like random variables. They will therefore follow a statistical distribution which can be inferred from several undamaged samples. Many tools have been developed to detect a change in that statistical distribution such as outlier analysis or hypothesis testing. In this contribution, control charts (Montgomery 2009; Ryan 2000) are presented. This tool of statistical quality control plots the features or quantities representative of their statistical distribution as a function of the samples. Different univariate or multivariate control charts exist but all these control charts are based on the same principle which is summarized in Fig. 5.

In phase I, a set of samples are collected and analyzed to infer statistical characteristics of the process when it is assumed to be in control (i.e., when the structure is undamaged). The aim of this step is to compute the control limits (upper control limit UCL and/or lower control limits LCL) between which the feature should be included if

the process stays in control. Those limits are governed by the statistical distribution $f(x)$ of the quality characteristic and the probability $1 - \gamma$ that any in-control sample will fall inside the control limits. There are control limits that can be computed to detect a shift of the mean value of the process or a shift of the variance of the process.

Once a set of reliable control charts has been established (phase I), the process is under monitoring (phase II). The process state is unknown (it might be in or out of control), and if a sample falls outside the control limits previously computed, it is considered as an abnormal value, and a warning is triggered. Phase I fixes the probability of type I (false alarms) and type II (missing alarms) errors. Because the control limit values are based on the number of samples in the in-control set of data, the statistical distribution $f(x)$, and the γ value, the statistical analysis must be done very carefully.

Typically, one can find two families of control charts in the literature: the univariate control charts and the multivariate control charts. The first family will be used if there is only one feature to be monitored, while the second one is used when several features are monitored at the same time. In the present application, this means that if one checks the appearance of only one spurious peak around one given natural frequency, the univariate control chart will be applied on that feature, while a multivariate

control chart will be used if one checks the spurious peaks around several eigenfrequencies in each modal filter. Finally, there are two categories of control charts in each family: the Shewhart control chart and the time-weighted control charts. The first category monitors each sample independently while the second category considers the previous samples to monitor the current sample, which allows to detect smaller shifts. It has been found that the best results are obtained when the Shewart control charts are applied, because the time weighted control charts increased too much the number of type I errors. For this reason, only the univariate and the Hotelling T^2 control charts are presented.

Individual control chart Consider that only one feature x following a normal distribution is monitored (e.g., one I_{peak} value in each modal filter). The individual control chart will monitor that individual feature x . The control limits are

$$\begin{aligned} \text{Upper Control Limit: } UCL &= \bar{x} + 3 \frac{\overline{MR}}{d_2} \\ \text{Lower Control Limit: } LCL &= \bar{x} - 3 \frac{\overline{MR}}{d_2} \end{aligned} \quad (11)$$

If the number of samples in phase I is n , then

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i, \quad (12)$$

$$\overline{MR} = \frac{1}{n} \sum_{i=2}^n |x_i - x_{i-1}|, \quad (13)$$

and $d_2 = 1.128$. In fact, $\frac{\overline{MR}}{d_2}$ is an estimate of the standard deviation σ of x assumed to follow a normal distribution in phase I. Equation 11 is therefore based on a choice of $\gamma = 0.027$. The individual control chart is designed to detect a shift of $\bar{x}$.

Hotelling T^2 control chart If two or more features are monitored at the same time, monitoring these two quantities independently by applying two or more univariate control charts can be very misleading, especially if those features are correlated. On the opposite, the Hotelling T^2 control chart is designed for the monitoring of

several features simultaneously. Consider p features following a p -normal distribution. The Hotelling T^2 control chart monitors the Mahalanobis distance T^2 :

$$T^2 = (x - \bar{x})^T \Sigma^{-1} (x - \bar{x}), \quad (14)$$

where Σ is the $p \times p$ estimated covariance matrix of features, x is the current $p \times 1$ feature vector, and $\bar{x}$ is the $p \times 1$ vector of estimated mean values of x vectors (only the undamaged samples are considered to obtain Σ and $\bar{x}$). Since the Mahalanobis distance is always positive, only the upper control limit UCL based on an F distribution is considered:

$$UCL = \frac{p(m+1)(m-1)}{(m^2 - mp)} F_{\gamma, p, m-p}, \quad (15)$$

where p is the number of variables, m is the number of samples in the set of data in phase I, and γ is such that there is a probability of $1 - \gamma$ that any in-control sample will fall between the control limits. Like the individual control chart, the Hotelling T^2 control chart detects a change of $\bar{x}$.

Damage Detection and Localization

When condensing all the sensors into a single virtual modal sensor as shown in Fig. 2, the statistical analysis can only give an indication on the deviation from the normal condition on the structure as a whole, leading to damage detection. The methodology can be extended to damage localization: consider now that the n sensors installed on the structure are grouped in several smaller sensor networks, each consisting of m sensors. Modal filters can be built for each of these local sensor networks resulting in independent *local modal filters* (Fig. 6).

If the local network l contains sensors $y_{1,l}, \dots, y_{m,l}$, the output of its modal filter tuned to mode l is given by

$$g_l(t) = \sum_{k=1}^m \alpha_{k,l} y_{k,l}(t), \quad (16)$$

Spatial Filtering for Structural Health Monitoring, Fig. 6 Principle of damage localization using local modal filters

where the $\alpha_{k,I}$ coefficients are computed in order to satisfy the following condition:

$$\sum_{k=1}^m \alpha_{k,I} \phi_{(k,I)i} = \delta_{li}, \quad (17)$$

where $\phi_{(k,I)i}$ is the k th ($k = 1, \dots, m$) component of the i th mode shape projected on the I th local sensor network. If a damage occurs under spatial filter I and if the sensor responses are locally sensitive to damage, the mode shape will only be altered in that spatial filter. As a result, only the spatial filter I will have spurious peaks, indicating the location of the damage.

The efficiency of the approach relies therefore on a very strong assumption: damage in a local filter will cause a local change of the mode shape which is limited to the very close vicinity of the damage location. The fulfillment of this requirement depends on the type of measured quantity which is considered. Two different approaches coexist in the literature: in Mendrok and Uhl (2010), accelerometers are used, while in Tondreau and Deraemaeker (2013), dynamic strain sensors are used. These two approaches have been compared in Tondreau and Deraemaeker (2011), showing that the method based on strain sensors has a higher sensitivity to damage and better

localization capabilities. This highlights the importance of the choice of the type of sensor which is part of the first building block of the SHM system. Applications of spatial filtering techniques have been limited so far to accelerometers or dynamic strain sensors.

Illustrative Example

Description of the Case Study

The experimental application consists in a 3.78 m long steel I-beam which is bolted on two big concrete cubes. The structure is excited with a Modal 110 electrodynamic shaker from MB Dynamics, and a network of 20 $13 \text{ mm} \times 170 \text{ mm} \times 50 \mu\text{m}$ low-cost PVDF sensors have been fixed with double-coated tape, providing a continuous measurement of the dynamic strains along the beam between sensors 1 and 20. A National Instrument PXIe-1082 data acquisition system is used to measure the sensor responses with a sampling frequency of 6,400 Hz, as well as to generate a band-limited white noise between 0 and 500 Hz (not measured) which drives the shaker. Figure 7 shows the experimental setup as well as the definition of the PVDF sensors (accelerometers installed for preliminary tests can also be seen, but are not used in the present study).

Test setup.

Artist front view: definition of the PVDF sensors.

Spatial Filtering for Structural Health Monitoring, Fig. 7 Experimental setup: 3.78 m steel I-beam equipped with 20 dynamic strain sensors (PVDF) for damage localization

The damage is introduced by fixing a very small steel stiffener (35 mm × 65 mm × 17 mm) directly against one of the PVDF sensors (Fig. 7a) in order to induce a local change of stiffness at that position. It has been checked that such a local change of stiffness induces a local change of strain similar to what happens with damage. The network of 20 sensors is split in five local filters of five sensors, with a small overlap: (i) [1:5], (ii) [4:8], (iii) [8:12], (iv) [12:16], and (v) [16:20]. The damage scenarios are described in Table 1. For the undamaged case, the measurement is performed 350 times in order to infer the statistical properties of the peak indicators. For each damaged case, 50 measurements are performed. Each measurement is referred to as a statistical sample.

The modal filters tuned on the two first bending mode shapes of the beam at 64 and 230 Hz are applied for each of the five local filters separately. The feature vector therefore consists in two peak indicators in each local filter (appearance of peak

Spatial Filtering for Structural Health Monitoring, Table 1 Damage scenarios

Case	Samples	Location of damage (sensor)	Location of damage (local filter)
1	1–350	None	None
2	351–400	1	[1:5]
3	401–450	2	[1:5]
4	451–500	3	[1:5]
5	501–550	4	[1:5] and [4:8]
6	551–600	5	[1:5] and [4:8]

at 64 Hz for the modal filter tuned to 230 Hz, and appearance of peak at 230 Hz for the modal filter tuned to 64 Hz). Note that the peak indicator used in this example is slightly different from the peak indicator presented in section “[Spatial and Modal Filtering](#)” but shares similar properties. As the feature vector is multivariate, the Hotelling T^2 control chart has been applied to automate the damage localization in each local filter. The first 200 undamaged samples have been considered to

Spatial Filtering for Structural Health Monitoring, Fig. 8 Automated damage detection in local filter (1:5) and local filter (4:8)

Spatial Filtering for Structural Health Monitoring, Fig. 9 Automated damage detection in local filter (8:12) and local filter (12:16)

estimate the covariance matrix, as well as to compute the control limit (γ is fixed to 0.25 %).

Figures 8, 9, and 10 show the Hotelling T^2 control chart. There is only one missing alarm in local filter [1:5] for a damage at sensor four. However, that missing alarm is compensated thanks to the overlapping of the local filters. Indeed, the damage at sensors four and five is correctly located in local filter [4:8]. The results show that the method has successfully, and automatically, localized all the damage cases.

Summary

There is a strong incentive for the development of online automated SHM techniques for large civil infrastructures. The objective of such systems is to be able to assess the structural integrity of safety critical civil infrastructure in real time. This is particularly important to detect the onset of damage due to aging or more severe damage due to accidental event such as an earthquake or a collision.

Spatial Filtering for Structural Health Monitoring, Fig. 10 Automated damage detection in local filter (16:20)

With the deployment of very large sensor networks on structures, alternatives to modal identification techniques can be interesting when the focus lies in fast and efficient damage detection and localization. This is the aim of the method presented in this chapter. The three important ingredients are (i) the use of a linear combiner to perform data reduction in the time domain through modal filtering, (ii) the transformation of the time-domain output of modal filters to the frequency domain and the subsequent feature extraction to detect the appearance of spurious peaks, and (iii) the use of control charts to automate the damage detection and localization process.

The fully integrated and automated methodology allows to process efficiently data from large sensor networks and to condense it into very limited information for diagnostics in the form of control charts. The efficiency of this technology has been illustrated on a laboratory experiment of a 3.78 m long steel I-beam.

Introduction

The seismic design of structures considers that all ground supports are subjected simultaneously to identical seismic excitation. This assumption is not valid for extended structures since it has been recognized that seismic motion exhibits no negligible variability. This variability, called spatial variability of ground motion (SVGGM), must hence be considered in the design of extended structures.

Many questions arise: what is SVGGM and how does one model it? Does SVGGM increase or decrease internal forces of a structure? Is there any general conclusion that can be drawn while considering SVGGM?

This entry aims at answering these questions. The first part of this entry addresses the description of SVGGM through models in terms of coherency function. Subsequently, the response of structures subjected to SVGGM is derived. At this stage, the concept of pseudo-static and dynamic responses is introduced. To understand the effect of the SVGGM on structures, two case studies are presented: a single degree of freedom (SDOF) system and a multi-degree of freedom (MDOF) system, subjected to SVGGM.

Spatial Variability of Seismic Motion (SVGGM): What It Is and How to Describe It

Seismic Motion and Its Measurement

The seismic motion is regarded as one of the most important and unknown load which acts on a structure. This huge motion results from mainly two causes: (a) explosive volcanic eruptions which are very common in areas of volcanic activity and (b) tectonic activity associated with plate margins and faults. The majority of earthquakes worldwide are of this second type. Thus, the main cause of earthquakes is either the sudden movement of various plate boundaries or when plates scrape against each other. Some earthquakes are also caused by old plate boundaries or faults. The point from which starts this sudden movement is the epicenter of the earthquake. This point could be between 10 and 400 km below the surface of the earth.

Following this sudden movement, many waves radiate from the epicenter and propagate through the earth. It has been recognized that both P and S waves, known as body waves, emanate from the source and travel with a velocity that exceeds 4 km/s in earth. When they arrive at the free field, they are followed by both Love and Rayleigh waves. These latter, known as surface waves, travel only at the surface. The movements associated with body as well as surface waves are well known and are mainly decomposed into compressional and shear movement. At the free field, the seismic motion could be decomposed into two parts: (a) motion caused by body waves and (b) motion caused by surface waves.

The seismic motion is recorded by seismometers which are deployed in seismic areas. The number of seismometers is growing from year to year denoting the need for a better understanding of the seismic motion. While some of them are deployed in a single scheme, others are deployed in grouped schemes. This latter scheme forms what is called the dense seismic array. A typical dense array configuration is presented

Spatial Variability of Ground Motion: Seismic Analysis, Fig. 1 Typical dense array configuration

in Fig. 1 where in general a central station S1 is surrounded by other stations such as station S2 with a separating distance.

Many arrays have been and are being deployed around the world to assess the characteristics of seismic ground motions. Among them SMART-1 array “Strong Motion ARray in Taiwan,” located in Lotung, in the north-east corner of Taiwan deployed in 1980 remains one of the most important. Other dense seismic arrays have been deployed (Zerva 2009). The deployment of these arrays enhanced greatly our knowledge on how the SVGM affects structure and what the main parameters used to describe the SVGM are.

What Is SVEGM?

Let’s consider that the medium is described using the Cartesian coordinate $\mathbf{x} = (x, y, z)$ and $\mathbf{u}(\mathbf{x}, t) = \{u(\mathbf{x}, t) \ v(\mathbf{x}, t) \ w(\mathbf{x}, t)\}^T$ is the seismic motion measured along these axis. Hence, $v(\mathbf{x}, t)$ is the vertical motion, whereas $u(\mathbf{x}, t)$ and $w(\mathbf{x}, t)$ are the horizontal motions. At any point of the soil, both horizontal and vertical motions could be recorded. For instance, let’s consider two points A and B at the free surface. Recorded earthquake along a particular axis at two points is obviously different in terms of amplitude and frequency. This difference is well accepted if

the separating distance between those points is somewhat important. However, data from dense seismic array show that even if the separating distance between two points is not very important (sometimes less than 50 m), the recorded motion at both points exhibits some differences.

The effect of this difference, called spatial variability of earthquake motion (SVEGM), on extended structures is addressed in this entry. Other sources of variability such as the result from relative surface fault motion for recording stations located on either side of a causative fault, soil liquefaction, and landslides (Zerva and Zervas 2002) are not considered herein. Finally, although SVEGM has been extensively studied for horizontal component and at free surface, some dense seismic arrays have been instrumented to record motion with respect to vertical component and/or at depth.

What causes SVEGM? It has been recognized that SVEGM is caused by several effects (Der Kiureghian 1996) (Fig. 1):

1. Incoherence effects due to scattering in the heterogeneous ground and extended source effects.
2. Traveling-wave effects, in which nonvertical waves reach different points on the ground surface at different times, producing a time shift between the motions at those points; this effect is also known as “wave passage effect.”
3. Site effects due to the variation by the filtering effects of overlying soil columns; this effect is known as “site effect.”

Although the attenuation of seismic motion increases the variability of seismic motion, it is not usually included since its effect on structures will not be visible below a separating distance of a dozen kilometers, which is greater than the usual separating distance for structures.

How to Measure and Describe SVEGM

For the purpose of simplicity, two points A and B located at the free surface with $z = 0$ are considered. Thus, coordinates of both points are, respectively, $\mathbf{x}_A = (x_A, 0, 0)$ and $\mathbf{x}_B = (x_B, 0, 0)$. Even if the motion could be recorded along the

Spatial Variability of Ground Motion: Seismic Analysis,
Fig. 2 Propagation of seismic waves

three axes, only the horizontal motion which is along the x axis, i.e., $u(\mathbf{x}_A, t)$ and $u(\mathbf{x}_B, t)$, is considered herein (Fig. 2).

The SVEGM is described by models in terms of correlation or coherence functions. This latter, which is the most used, is the ratio of the cross-spectral density function of the motion at two points separated by a horizontal offset to the square root of the product between the auto-spectral density functions at the two points:

$$\rho_{AB}(\omega) = \frac{S_{AB}(\omega)}{\sqrt{S_A(\omega)S_B(\omega)}} \quad (1)$$

where

$$L = x_B - x_A,$$

$S_{AB}(\omega)$ is the cross-spectral density function of the motion along the x axis for the two points A and B.

$S_A(\omega)$ and $S_B(\omega)$ are the auto-spectral density functions of the motion along the x axis at, respectively, points A and B.

The coherency function is often written as

$$\rho_{AB}(\omega) = |\rho_{AB}(\omega)| \exp[i\theta_{AB}(\omega)] \quad (2)$$

with

$$\theta_{AB}(\omega) = \tan^{-1} \left(\frac{\text{Im}(S_{AB}(\omega))}{\text{Re}(S_{AB}(\omega))} \right) \quad (3)$$

where

$\text{Im}(S_{AB}(\omega))$ and $\text{Re}(S_{AB}(\omega))$ stands for imaginary and real parts of $S_{AB}(\omega)$.

$|\rho_{AB}(\omega)|$ is the lagged coherency and $\text{Re}(S_{AB}(\omega))$ as unlagged coherency. It is worth noting that the coherency function is complex, and lagged coherency is usually called coherence function. This latter describes the similarity of the waveforms at two stations without taking into account the difference in the arrival times of the waves.

If the subscript A and B are skipped and replaced by the separating distance L , then the coherency function is rewritten as

$$\rho(L, \omega) = |\rho(L, \omega)| \exp[i\theta(L, \omega)] \quad (4)$$

This coherency function measures the coherency along the x axis and at the free surface. It could be measured at depth by, for instance, considering that both points A and B are located at the same depth, i.e., $y = -h$, which leads to the following coherency function

$$\rho(h, L, \omega) = |\rho(h, L, \omega)| \exp[i\theta(h, L, \omega)] \quad (5)$$

Models in terms of coherency functions have been developed during last decades (Abrahamson et al. 1991; Der Kiureghian 1996; Zendagui et al. 1999). They could be divided into three categories: empirical, semiempirical, and physically based models. An exhaustive list of these models could be found in Zerva (2009). The common feature of these models is that the

coherency function decreases with separating distance and frequency.

Generation of Variable Seismic Excitation and Response Spectra

The generation of variable seismic excitation has been extensively studied. The method developed by Shinozuka (1971) remains the most popular. This method has been extended and modified by others to take into account nonstationarity of processes (Deodatis 1996). A spectral-representation-based simulation algorithm has been developed by Deodatis (1996). The simulation uses the coherency function and allows the generation of acceleration as well as displacement time histories. This latter is necessary while performing non linear structural analysis. A recent method developed by Benmansour et al. (2012) solves the problem of integrability of seismic motion to avoid the use of baseline correction.

Alternatively, Berrah and Kausel (1992) developed an interesting method that modifies a particular response spectrum to take into account SVGM.

Structure Subjected to SVGM: General Derivation

Consider a structure with N DOFs. For the analysis of such a system, consider that the displacement vector contains two parts: (1) V includes the N DOFs of the superstructure, and (2) v_s contains the N_g components of support displacements. The equation of dynamic equilibrium is written as

$$\begin{bmatrix} m & m_s \\ m_s^T & m_{ss} \end{bmatrix} \begin{Bmatrix} \ddot{V} \\ \ddot{v}_s \end{Bmatrix} + \begin{bmatrix} c & c_s \\ c_s^T & c_{ss} \end{bmatrix} \begin{Bmatrix} \dot{V} \\ \dot{v}_s \end{Bmatrix} + \begin{bmatrix} k & k_s \\ k_s^T & k_{ss} \end{bmatrix} \begin{Bmatrix} V \\ v_s \end{Bmatrix} = \begin{Bmatrix} 0 \\ R(t) \end{Bmatrix} \quad (6)$$

The mass, damping, and stiffness matrices can be determined from properties of the structure, while the support motions $\ddot{v}_s(t)$, $\dot{v}_s(t)$, and $v_s(t)$ must be specified. It is desired to determine the displacements V in the superstructure DOF and the support forces $R(t)$.

To write the governing equations in a form similar to that of the case of a single excitation, the displacements are separated into two parts:

$$\begin{Bmatrix} V \\ v_s \end{Bmatrix} = \begin{Bmatrix} u_s \\ v_s \end{Bmatrix} + \begin{Bmatrix} U \\ 0 \end{Bmatrix} \quad (7)$$

In this equation, u_s is the vector of structural displacements due to static application of prescribed support displacements v_s at each time instant. The two parts are related as

$$\begin{bmatrix} k & k_s \\ k_s^T & k_{ss} \end{bmatrix} \begin{Bmatrix} u_s \\ v_s \end{Bmatrix} = \begin{Bmatrix} 0 \\ R_s(t) \end{Bmatrix} \quad (8)$$

$R_s(t)$ are the support forces necessary to statically impose displacements v_s that vary with time; obviously, u_s varies with time and is therefore known as the vector of quasi-static displacements. Observe that $R_s(t) = 0$ in the case of identical support ground motion. The displacements of the superstructure U are known as dynamic displacements.

With the total structural displacements split into quasi-static and dynamic displacements, consider hence the first of the two partitioned equations (Eq. 6):

$$m\ddot{V} + m_s\ddot{v}_s + c\dot{V} + c_s\dot{v}_s + kV + k_sv_s = 0 \quad (9)$$

Substituting Eq. 7 and transferring all terms involving v_s and u_s to the right-hand side lead to

$$m\ddot{U} + c\dot{U} + kU = P_{eff}(t) \quad (10)$$

where the vector of effective earthquake forces is

$$P_{eff}(t) = -(m\ddot{u}_s + m_s\ddot{v}_s + c\dot{u}_s + c_s\dot{v}_s + ku_s + k_sv_s) \quad (11)$$

Equation 8 gives

$$ku_s + k_sv_s = 0 \quad (12)$$

This relation also enables us to express the quasi-static displacement u_s in terms of the specified support displacements v_s :

$$u_s = [\Lambda]v_s \quad (13)$$

where $[\Lambda] = -k^{-1}k_s$ is the influence matrix.

Equation 13 can be written in a different form as

$$u_s = \sum_{i=1}^{N_s} \Lambda_i v_{si}(t) \quad (14)$$

where Λ_i is the i th column of the influence matrix $[\Lambda]$.

Substituting Eqs. 12 and 13 in Eq. 11, one gets

$$P_{eff}(t) = -(m[\Lambda] + m_s)\ddot{v}_s(t) - (c[\Lambda] + c_s)\dot{v}_s \quad (15)$$

For many practical applications, further simplification of P_{eff} is possible in two stages. First, the damping term is usually small relative to the inertia term and can be dropped. Second, for structures with mass idealized as lumped at the DOFs, the mass matrix is diagonal, implying that m_s is a null matrix and m is diagonal. With these simplifications, P_{eff} is expressed as

$$P_{eff}(t) = -m[\Lambda]\ddot{v}_s(t) \quad (16)$$

By using Eq. 14, P_{eff} can be expressed as

$$P_{eff}(t) = -\sum_{i=1}^{N_s} m\Lambda_i \ddot{v}_{si}(t) \quad (17)$$

The dynamic response U can be computed by modal analysis, as the superposition of the modal contributions

$$U(t) = \sum_{n=1}^N \phi_n q_n(t) \quad (18)$$

where ϕ_n are the natural modes and q_n are scalar multipliers called modal coordinates. Instead of Eq. 18, the modal equation can be expressed for the n th mode as

$$\ddot{q}_n + 2\xi_n \omega_n \dot{q}_n + \omega_n^2 q_n = -\sum_{i=1}^{N_s} \Gamma_{ni} \ddot{v}_{si}(t) \quad (19)$$

where

$$\Gamma_{ni} = \frac{L_{ni}}{M_n}, \quad L_{ni} = \phi_n^T m \Lambda_i \quad \text{and} \quad M_n = \phi_n^T m \phi_n \quad (20)$$

The solution of Eq. 19 can be written as

$$q_n(t) = \sum_{i=1}^{N_s} \Gamma_{ni} D_{ni}(t) \quad (21)$$

where $D_{ni}(t)$ is the displacement response of the n th-mode SDOF system to support acceleration $\ddot{v}_{si}(t)$.

The displacement response of the structure (Eq. 7) contains two parts:

1. The dynamic displacements are obtained by combining Eqs. 18 and 21:

$$U(t) = \sum_{i=1}^{N_s} \sum_{n=1}^N \Gamma_{ni} \phi_n D_{ni}(t) \quad (22)$$

2. The quasi-static displacements u_s are given by Eq. 14.

Combining the two parts gives the total displacements of the structure

$$V(t) = \sum_{i=1}^{N_s} \Lambda_i v_{si}(t) + \sum_{i=1}^{N_s} \sum_{n=1}^N \Gamma_{ni} \phi_n D_{ni}(t) \quad (23)$$

The equivalent static forces in structural DOFs are given by

$$F = kV + k_s v_s \quad (24)$$

Substituting Eq. 7 for V and using Eq. 12 give

$$F = kU(t) \quad (25)$$

These forces depend on the dynamic displacements only given by Eq. 22. Therefore,

$$F(t) = \sum_{i=1}^{N_s} \sum_{n=1}^N \Gamma_{ni} k \phi_n D_{ni}(t) \quad (26)$$

The equivalent static forces along support DOFs are also given by the last term on the left-hand side of Eq. 6:

$$F_s = k_s^T V + k_{ss} v_s \quad (27)$$

Spatial Variability of Ground Motion: Seismic Analysis, Fig. 3 A SDOF system subjected to SVG

Substituting Eq. 7 and using Eq. 8 for the quasi-static support forces $R_s(t)$ give

$$F_s(t) = k_s^T U(t) + R_s(t) \quad (28)$$

Application 1: SDOF System Subjected to SVG

Derivation of the Relative Displacement

Consider a simple multi-support structure represented by a SDOF system with two supports 1 and 2 excited by, respectively, $u_{g1}(t)$ and $u_{g2}(t)$ (Fig. 3). The columns are assumed to be weightless and inextensible in the vertical (axial) direction, and the resistance to girder displacement provided by each column is represented by its spring constant k_1 and k_2 . For the purpose of simplicity, it is assumed that the slab, which has a mass m , is infinitely rigid and that damping is neglected. The total displacement of the mass from the initial position G to the final position G' is $u(t)$

The forces acting on the slab:

- Inertial forces: $f_I = m\ddot{u}$.
- Elastic force on column (1): $f_{e1} = k_1(u - u_{g1})$
- Elastic force on column (2): $f_{e2} = k_2(u - u_{g2})$.

Hence, the equation of motion is an expression of the equilibrium of these forces given by

$$m\ddot{u} + (k_1 + k_2)u = k_1 u_{g1}(t) + k_2 u_{g2}(t) \quad (29)$$

The natural frequency is defined by

$$\omega = \sqrt{\frac{k_1 + k_2}{m}} \quad (30)$$

The quasi-static displacement is thus

$$u_s(t) = \frac{k_1 u_{g1}(t) + k_2 u_{g2}(t)}{k_1 + k_2} \quad (31)$$

At this stage, it is considered that the support motions are harmonic variable both in amplitude and phase:

$$\begin{cases} u_{g1}(t) = A_1 \sin \bar{\omega}_1 t \\ u_{g2}(t) = A_2 \sin \bar{\omega}_2 t \end{cases} \quad (32)$$

The total dynamic and quasi-static displacements are hence

$$u(t) = \frac{k_1}{k_1 + k_2} \frac{A_1}{\left(1 - \left(\frac{\omega_1}{\omega}\right)^2\right)} \sin \bar{\omega}_1 t + \frac{k_2}{k_1 + k_2} \frac{A_2}{\left(1 - \left(\frac{\omega_2}{\omega}\right)^2\right)} \sin \bar{\omega}_2 t \quad (33)$$

Spatial Variability of Ground Motion: Seismic Analysis, Fig. 4 Variation of elastic forces at column 1 for case S-1

$$u_s(t) = \frac{k_1}{k_1 + k_2} A_1 \sin \bar{\omega}_1 t + \frac{k_2}{k_1 + k_2} A_2 \sin \bar{\omega}_2 t \quad (34)$$

Finally, the dynamic response could be derived as follows:

$$U(t) = u(t) - u_s(t) \quad (35)$$

Case Study

As the purpose of this entry is to see how SVGM affects a structure, it will be considered hereafter two cases: a uniform seismic motion at supports 1 and 2 equal to u_{g1} and a variable seismic motion, i.e., u_{g1} at support 1 and u_{g2} at support 2. The natural frequency is equal to 24 rad/s . The results are presented in terms of elastic forces of the column (1). For the case of spatially variable ground motion, two cases will be considered:

$$\text{Case S-1} \quad \begin{cases} u_{g1} = 0.1 \sin 10t \\ u_{g2} = 0.1 \sin 15t \end{cases} (m) \quad (36)$$

$$\text{Case S-2} \quad \begin{cases} u_{g1} = 0.1 \sin 20t \\ u_{g2} = 0.1 \sin 25t \end{cases} (m) \quad (37)$$

The frequencies of excitation have been chosen below and above the natural frequency. It is interesting to see that for both cases (Eqs. 36 and 37), SVGM (dashed line) exhibits greater

value than uniform load (continuous line) (Figs. 4 and 5). Thus, for these cases, it seems that SVGM induces greater values of elastic forces than uniform seismic motion.

What about the variation of the quasi-static and dynamic components for both cases? Results show great difference on the part of both components depending on frequency of excitations. Hence, by analyzing the variations of the two components, quasi-static and dynamic (Figs. 6 and 7), it is found that for case S-1 the amplification caused by variable motion is mainly due to the importance of the quasi-static component. In this case, the frequency of the structure is larger than those of the imposed displacement. The SDOF system could be considered herein as a rigid structure. However, for case S-2, the frequency of the structure is close to the frequency of the excitation. In this case, the dynamic component is the main cause of the amplification of the response.

Application 2: MDOF System Subjected to SVGM

Derivation of the Relative Displacements

In this part, responses of a MDOF system under uniform and variable seismic input will be computed. It is assumed herein that the MDOF is composed of five masses connected by five springs (Fig. 8). The motion, in terms of

Spatial Variability of Ground Motion: Seismic Analysis, Fig. 5 Variation of elastic forces at column 1 for case S-2

Spatial Variability of Ground Motion: Seismic Analysis, Fig. 6 Variation of the pseudo-static and dynamic components of the elastic forces at column 1 for case S-1

Spatial Variability of Ground Motion: Seismic Analysis, Fig. 7 Variation of the pseudo-static and dynamic components of the elastic forces at column 1 for case S-2

Spatial Variability of Ground Motion: Seismic Analysis, Fig. 8 MDOF system under SVG

displacements, is imposed at the outer masses and the middle one, v_{s1} , v_{s3} et v_{s5} . Hence, only two masses do not have imposed displacements and their displacements are noted: V_2 et V_4 . Thus, the displacement vector could be decomposed

into two parts $\{v_s\} = \langle v_{s1} \ v_{s3} \ v_{s5} \rangle^T$ and $\{V\} = \langle V_2 \ V_4 \rangle^T$.

The equation of dynamic equilibrium for all the DOFs is written as

$$\begin{bmatrix} m_1 & & & & \\ & m_2 & & & \\ & & m_3 & & \\ & & & m_4 & \\ & & & & m_5 \end{bmatrix} \begin{Bmatrix} \ddot{v}_{s1} \\ \ddot{V}_2 \\ \ddot{v}_{s3} \\ \ddot{V}_4 \\ \ddot{v}_{s5} \end{Bmatrix} + \begin{bmatrix} k_1 & -k_1 & & & \\ -k_1 & k_1 + k_2 + k_5 & -k_2 & & \\ & -k_2 & k_2 + k_3 & -k_3 & \\ & & -k_3 & k_3 + k_4 + k_5 & -k_4 \\ & & & -k_4 & -k_4 \end{bmatrix} \begin{Bmatrix} v_{s1} \\ V_2 \\ v_{s3} \\ V_4 \\ v_{s5} \end{Bmatrix} = \begin{Bmatrix} R_1 \\ 0 \\ R_3 \\ 0 \\ R_5 \end{Bmatrix} \quad (38)$$

By considering only DOFs 2 and 4,

$$\begin{bmatrix} m_2 & 0 \\ 0 & m_4 \end{bmatrix} \begin{Bmatrix} \ddot{V}_2 \\ \ddot{V}_4 \end{Bmatrix} + \begin{bmatrix} k_1 + k_2 + k_5 & -k_5 \\ -k_5 & k_3 + k_4 + k_5 \end{bmatrix} \begin{Bmatrix} V_2 \\ V_4 \end{Bmatrix} = \begin{Bmatrix} k_1 v_{s1} + k_2 v_{s3} \\ k_3 v_{s3} + k_4 v_{s5} \end{Bmatrix} = \begin{bmatrix} k_1 & k_2 & 0 \\ 0 & k_3 & k_4 \end{bmatrix} \begin{Bmatrix} v_{s1} \\ v_{s3} \\ v_{s5} \end{Bmatrix} \quad (39)$$

The pseudo-static component is obtained by neglecting the inertial forces

$$0 + \begin{bmatrix} k_1 + k_2 + k_5 & -k_5 \\ -k_5 & k_3 + k_4 + k_5 \end{bmatrix} \begin{Bmatrix} u^s_2 \\ u^s_4 \end{Bmatrix} = \begin{bmatrix} k_1 & k_2 & 0 \\ 0 & k_3 & k_4 \end{bmatrix} \begin{Bmatrix} v_{s1} \\ v_{s3} \\ v_{s5} \end{Bmatrix} \quad (40)$$

Thus,

$$\{u^s\} = \begin{Bmatrix} u^s_2 \\ u^s_4 \end{Bmatrix} = \begin{bmatrix} k_1 + k_2 + k_5 & -k_5 \\ -k_5 & k_3 + k_4 + k_5 \end{bmatrix}^{-1} \begin{bmatrix} k_1 & k_2 & 0 \\ 0 & k_3 & k_4 \end{bmatrix} \begin{Bmatrix} v_{s1} \\ v_{s3} \\ v_{s5} \end{Bmatrix} \quad (41)$$

If $k_i = k$

$$\{u^s\} = \begin{Bmatrix} u^s_2 \\ u^s_4 \end{Bmatrix} = \frac{1}{8} \begin{bmatrix} 3 & 4 & 1 \\ 1 & 4 & 3 \end{bmatrix} \begin{Bmatrix} v_{s1} \\ v_{s3} \\ v_{s5} \end{Bmatrix} \quad (42)$$

The equation of movement could be rewritten in terms of the dynamic component $\{U\} = \{V\} - \{u^s\}$:

$$\begin{aligned}
& \begin{bmatrix} m_2 & 0 \\ 0 & m_4 \end{bmatrix} \begin{Bmatrix} \ddot{U}_2 \\ \ddot{U}_4 \end{Bmatrix} + \begin{bmatrix} k_1 + k_2 + k_5 & -k_5 \\ -k_5 & k_3 + k_4 + k_5 \end{bmatrix} \begin{Bmatrix} U_2 \\ U_4 \end{Bmatrix} \\
&= \begin{bmatrix} m_2 & 0 \\ 0 & m_4 \end{bmatrix} \begin{bmatrix} k_1 + k_2 + k_5 & -k_5 \\ -k_5 & k_3 + k_4 + k_5 \end{bmatrix}^{-1} \\
& \begin{bmatrix} k_1 & k_2 & 0 \\ 0 & k_3 & k_4 \end{bmatrix} \begin{Bmatrix} \ddot{v}_{s1} \\ \ddot{v}_{s3} \\ \ddot{v}_{s5} \end{Bmatrix}
\end{aligned} \quad (43)$$

$$\begin{Bmatrix} v_{s1} = 0.1 \sin 30t \\ v_{s3} = 0.1 \sin 35t \\ v_{s5} = 0.1 \sin 30t \end{Bmatrix} (m) \quad (47)$$

Case M-3 variability in terms of temporal delay and frequency close to those of the system:

$$\begin{Bmatrix} v_{s1} = 0.1 \sin 30t \\ v_{s3} = 0.1 \sin 30(t - 0.03) \\ v_{s5} = 0.1 \sin 30(t - 0.06) \end{Bmatrix} (m) \quad (48)$$

Case M-4 variability in terms of temporal delay and frequency greater than of the system:

$$\begin{Bmatrix} v_{s1} = 0.1 \sin 50t \\ v_{s3} = 0.1 \sin 50(t - 0.03) \\ v_{s5} = 0.1 \sin 50(t - 0.06) \end{Bmatrix} (m) \quad (49)$$

If $m_i = m$ and $k_i = k$, then

$$\begin{aligned}
& m \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{Bmatrix} \ddot{U}_2 \\ \ddot{U}_4 \end{Bmatrix} + k \begin{bmatrix} 3 & -1 \\ -1 & 3 \end{bmatrix} \begin{Bmatrix} U_2 \\ U_4 \end{Bmatrix} \\
&= -\frac{m}{8} \begin{bmatrix} 3 & 4 & 1 \\ 1 & 4 & 3 \end{bmatrix} \begin{Bmatrix} \ddot{v}_{s1} \\ \ddot{v}_{s3} \\ \ddot{v}_{s5} \end{Bmatrix}
\end{aligned} \quad (44)$$

The natural modes are

$$\{\phi_1\} = \begin{Bmatrix} 1 \\ 1 \end{Bmatrix} \text{ and } \{\phi_2\} = \begin{Bmatrix} 1 \\ -1 \end{Bmatrix} \quad (45)$$

Case Study

In this part, elastic forces at the spring k_1 obtained by considering uniform imposed displacements will be compared to those obtained when imposing variable displacements v_{s1} , v_{s3} et v_{s5} . For the sake of simplicity, it will be considered that the uniform displacement is set equal to v_{s1}

For the purpose of study, let's consider that

$$\begin{aligned}
m &= 1t, \quad k = 600kN/m \Rightarrow \\
\omega_1 &= 34.64rad/s \text{ et } \omega_2 = 49rad/s
\end{aligned}$$

For the case of spatially variable ground motion, four cases will be considered:

Case M-1 variability in terms of maximum amplitude:

$$\begin{Bmatrix} v_{s1} = 0.10 \sin 30t \\ v_{s3} = 0.15 \sin 30t \\ v_{s5} = 0.30 \sin 30t \end{Bmatrix} (m) \quad (46)$$

Case M-2 variability in terms of phases:

It is worth noting that these cases model incoherence effect (Eqs. 46 and 47) and wave passage effect (Eqs. 48 and 49). Results obtained in terms of elastic forces at spring 1 for the four above cases are presented in Figs. 9, 10, 11, and 12.

It is observed that SVGm caused by incoherence effect leads to values of elastic forces greater than those obtained for uniform loading (Figs. 9 and 10). This could be readily observed while varying amplitude (Eq. 46, Fig. 9) or frequency (Eq. 47, Fig. 10). In turn, SVGm caused by wave passage effect does not yield greater values of elastic forces than uniform loading for the case where the frequency of excitation is close to the natural frequency of the structure (Eq. 48, Fig. 11). However, this conclusion is not valid for case M-4 where the excitation frequency is greater than the natural frequency of the system (Fig. 12).

Summary

This entry aims at describing the modeling of SVGm and its effects on structures. The total *force* is divided into two components: pseudo-static and dynamic forces. After deriving a general formulation for the case of MDOF systems, two cases have been considered: SDOF and MDOF systems.

It has been shown that SVGm could increase or decrease the elastic forces for both cases.

Introduction

Earthquake disaster in the past has motivated studies on earthquake-resistant buildings to save lives and resources (Newmark and Hall 1982). With this objective, physical models and numerical methods are used to predict the dynamic behavior of structures. The numerical methods provide quantitative analyses of physical phenomena. They can be used to design structures with geometry and materials for an adequate dynamic behavior under seismic excitation. The most frequently used in structural dynamics are the finite element method (FEM) and the boundary element method (BEM).

Based on wave propagation, the spectral finite element or spectral element method (SEM) was introduced by Beskos in 1978, organized and seeded by Doyle (1997) in the 1990s. It allows calculating relatively complex structures with different boundary conditions and discontinuities using simple theories. It combines important characteristics of FEM, dynamic stiffness method (DSM), and spectral analysis (Lee 2009).

The dynamic stiffness matrices and shape functions used in SEM are exact within the scope of the underlying physical theory, and the method allows a reduced number of degrees of freedom. The matrices are depended on frequency, but using spectral analysis, the dynamic response can be easily composed by wave superposition. Harmonic, random, or damped transient excitations can be decomposed using the discrete Fourier transform (DFT). The discrete frequencies are used to calculate the spectral matrix and discrete responses. Then, the complete dynamic response is computed by the sum of frequency components (inverse DFT). As FEM, SEM uses the assembly of a global matrix using elementary matrices and spatial discretization. However, differently from FEM, only discontinuities and locations where loads are applied need to be meshed (Ahmida and Arruda 2001).

It can be a useful tool because it joins DSM with spectral analysis to produce accurate solutions in both frequency and time domains at a low computational cost due to a dramatic system

reduction, making it more adequate for uncertainty and optimization analyses. Furthermore, it can easily be associated with other numerical methods such as FEM and BEM. The limitations of SEM are general nonlinear analysis, or when exact wave solutions are not available, as it occurs in geometrically complex structures. When using SEM it is important to be careful with the time–frequency transformations to avoid leakage and aliasing errors (Lee 2009).

This chapter presents spectral element for straight and curved frame elements. First, the equations of motion are developed and physical and kinematic assumptions are presented. Then the spectrum relation is established and the spectral element is derived. Two simple examples – a two- and a three-dimensional frame structures, excited by a real earthquake signal – are analyzed. The purpose is to present the methodology and concepts of dynamic structural analysis via the spectral finite element method.

Classical Straight Frame

Equations of Motion

Consider a straight, long, and slender beam, as shown in Fig. 1. A Cartesian reference frame is placed such that the x -axis is along neutral axis of the beam. Thus, for a rectangular cross section, if h is the beam thickness, the position y will vary in the range $-h/2 \leq y \leq h/2$. Along the z -axis is the beam width.

Here, it is considered a plane frame element under flexural moments and axial forces. In straight beams, flexural and longitudinal behaviors are decoupled, and they may be modeled separately, the former via the Euler–Bernoulli beam theory and the latter via the elementary rod theory.

The Euler–Bernoulli theory assumes the vertical deflection is constant across any cross section and that cross sections remain plane after deformation, which means that the shear deformation is neglected. On the other hand, the classical rod theory considers only axial displacements and neglects lateral contractions due to Poisson's effect. Under these assumptions, the displacement field for a straight beam is given by:

Spectral Finite Element Approach for Structural Dynamics,

Fig. 1 Straight frame element model

$$\begin{aligned}\bar{u}(x, y) &= u(x) - y\theta_z(x) \\ \bar{v}(x, y) &= v(x)\end{aligned}$$

where $\bar{u}$ is the displacement in the x -direction (axial displacement), $\bar{v}$ is the displacement in the y -direction (vertical displacement), and θ_z is the rotation with respect to the z -axis.

Then, from differentiation of the displacement field, axial and transverse shear strains at a given cross section of the beam are expressed:

$$\begin{aligned}\epsilon_{xx} &= \frac{\partial \bar{u}}{\partial x} = \frac{\partial u}{\partial x} - y \frac{\partial \theta_z}{\partial x} \\ \epsilon_{xy} &= \frac{1}{2} \left(\frac{\partial \bar{u}}{\partial y} + \frac{\partial \bar{v}}{\partial x} \right) = \frac{1}{2} \left(-\theta_z + \frac{\partial v}{\partial x} \right).\end{aligned}$$

The Euler–Bernoulli beam theory neglects the shear deformation, although not the shear force. This implies that the transverse shear strain must vanish, which yields:

$$\epsilon_{xy} = 0 \rightarrow \theta_z = \frac{\partial v}{\partial x}.$$

The expression for the cross-section rotation can be used to write the axial strain, which is the only nonzero strain in the Euler–Bernoulli beam model, in terms of the vertical and the longitudinal displacements, as follows:

$$\epsilon_{xx} = \frac{\partial u}{\partial x} - y \frac{\partial^2 v}{\partial x^2}.$$

Moreover, neglecting all stresses except for the predominant axial stress, one can write:

$$\sigma_{xx} = E\epsilon_{xx} = E \frac{\partial u}{\partial x} - yE \frac{\partial^2 v}{\partial x^2}.$$

Once the stress and strains are determined, Newton's laws or variational formulations, such

as Hamilton's principle, may be used to determine the equations of motion for this classical beam model, which, in the absence of damping, is given by:

$$\begin{aligned}EA \frac{\partial^2 u}{\partial x^2} - \rho A \frac{\partial^2 v}{\partial t^2} &= q_x(x, t) \\ \frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 v}{\partial x^2} \right) + \rho A \frac{\partial^2 v}{\partial t^2} &= q_y(x, t)\end{aligned}$$

where E is the Young's modulus, I is the area moment of inertia with respect to the z -axis, ρ is the material density, A is the cross-section area, and $q_x(x, t)$ and $q_y(x, t)$ are, respectively, the longitudinal and vertical distributed loads along the beam length. The boundary conditions associated to this beam problem are:

$$\begin{aligned}u &= 0 \quad \text{or} \quad F_x = EA \frac{\partial u}{\partial x} \\ v &= 0 \quad \text{or} \quad V_y = -\frac{\partial}{\partial x} \left(EI \frac{\partial^2 v}{\partial x^2} \right) \\ \theta_z &= 0 \quad \text{or} \quad M_z = EI \frac{\partial^2 v}{\partial x^2}\end{aligned}$$

The term EI is usually called the *bending stiffness*.

If some internal viscoelastic damping η is present, the equations of motion for the straight frame are modified to:

$$\begin{aligned}EA \frac{\partial^2 u}{\partial x^2} - \eta A \frac{\partial u}{\partial t} - \rho A \frac{\partial^2 u}{\partial t^2} &= q_x(x, t) \\ \frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 v}{\partial x^2} \right) + \eta A \frac{\partial v}{\partial t} + \rho A \frac{\partial^2 v}{\partial t^2} &= q_y(x, t).\end{aligned}$$

Spectral Analysis

Assuming a harmonic solution for the displacements of the beam (or applying the Fourier transform), i.e., by writing:

Spectral Finite Element Approach for Structural Dynamics, Fig. 2 Spectrum relations of a damped frame element: (a) real part of wavenumbers and (b) imaginary part of wavenumbers

$$u(x, t) = \sum_n \hat{u}_n(x, \omega_n) e^{i\omega_n t},$$

$$v(x, t) = \sum_n \hat{v}_n(x, \omega_n) e^{i\omega_n t}$$

in the homogenous case and considering constant properties along the beam, the equations of motion, in the frequency domain, are:

$$\frac{d^2 \hat{u}}{dx^2} + k_x^2 \hat{u} = 0, \quad k_x = \pm \sqrt{\frac{\omega^2 \rho A - i\omega \eta A}{EA}}$$

$$\frac{d^4 \hat{v}}{dx^4} - \beta^4 \hat{v} = 0, \quad \beta^2 = \pm \sqrt{\frac{\omega^2 \rho A - i\omega \eta A}{EI}}.$$

The second homogeneous equation, relative to the transverse displacement, can be split into a product of two terms which must vanish. Thus, it yields:

$$\frac{d^2 \hat{v}}{dx^2} + \beta^2 \hat{v} = 0$$

$$\frac{d^2 \hat{v}}{dx^2} - \beta^2 \hat{v} = 0.$$

Then, considering a second Fourier transformation, now in the spatial domain, $\hat{u}(x, \omega) = \sum_m \tilde{u}(k_m, \omega) e^{-ik_m x}$, $\hat{v}(x, \omega) = \sum_m \tilde{v}(k_m, \omega) e^{-ik_m x}$, gives:

$$-k_1^2 + k_x^2 = 0 \rightarrow k_1 = \pm k_x$$

$$-k_2^2 + \beta^2 = 0 \rightarrow k_2 = \pm \beta$$

$$-k_3^2 - \beta^2 = 0 \rightarrow k_3 = \pm i\beta$$

where k_1, k_2, k_3 are the wavenumbers. They are function of the angular frequency ω , and this relationship constitutes the spectrum or dispersion relation, which is plotted in Fig. 2. Notice that when some damping is present, longitudinal and flexural modes are complex waves; thus, they exhibit a decaying behavior while propagating. In the undamped case, there are two real wavenumbers (the longitudinal and first flexural waves), which are propagating waves, and an imaginary wavenumber (the second flexural wave), which is a purely spatial decaying wave, the so-called evanescent wave. Phase and group speeds, c_0 and c_G , respectively, can be also derived (see Fig. 3), and they are expressed as:

$$c_0 = \frac{\omega}{k}, \quad c_G = \frac{d\omega}{dk}.$$

In the undamped case, unlike in the case of longitudinal motion, the phase and group speeds related to flexural waves depend on the cross-section properties, given by the area and the second moment of inertia. The group speed is twice the phase speed and both depend on frequency and, hence, are dispersive. It should be noted that, with the Euler–Bernoulli assumptions, the wave speeds tend to infinity as the frequency increases,

Spectral Finite Element Approach for Structural Dynamics, Fig. 3 Wave speeds of a frame element, real part in solid line, and imaginary part in dotted line: (a) group speeds and (b) speed ratios between group and phase speeds

which is not reasonable. This theory is, therefore, only suitable for low frequencies.

The displacement solution may be expressed in the spectral form as:

$$u(x, t) = \sum_n (A_1^+ e^{-ik_{xn}x} + A_1^- e^{ik_{xn}x}) e^{i\omega_n t}$$

$$v(x, t) = \sum_n (A_2^+ e^{-i\beta_n x} + A_3^+ e^{-\beta_n x} + A_2^- e^{i\beta_n x} + A_3^- e^{\beta_n x}) e^{i\omega_n t},$$

i.e., as a superposition of waves propagating in opposite directions.

It is worth recalling here that the cross-section rotation is related to the transverse displacement by the following expression:

$$\theta_z = \frac{\partial v}{\partial x}.$$

Thus, it may be also written as a superposition of waves, as follows:

$$\theta_z(x, t) = \sum_n (-iA_2^+ e^{-i\beta_n x} - A_3^+ e^{-\beta_n x} + iA_2^- e^{i\beta_n x} + A_3^- e^{\beta_n x}) \beta_n e^{i\omega_n t}.$$

From the classical theories for beams and rods, the internal loads related to the frame may be derived from the displacement field and are given by:

$$F_x = EA \frac{\partial u}{\partial x}$$

$$V_y = -\frac{\partial}{\partial x} \left(EI \frac{\partial^2 v}{\partial x^2} \right).$$

$$M_z = EI \frac{\partial^2 v}{\partial x^2}$$

Thus, they may be expressed in spectral form as:

$$F_x(x, t) = EA \sum_n k_{xn} (-iA_1^+ e^{-ik_{xn}x} + iA_1^- e^{ik_{xn}x}) e^{i\omega_n t}$$

$$V_y(x, t) = EI \sum_n \beta_n^3 (-iA_2^+ e^{-i\beta_n x} + A_3^+ e^{-\beta_n x} + iA_2^- e^{i\beta_n x} - A_3^- e^{\beta_n x}) e^{i\omega_n t}$$

$$M_z(x, t) = EI \sum_n \beta_n^2 (-A_2^+ e^{-i\beta_n x} + A_3^+ e^{-\beta_n x} - A_2^- e^{i\beta_n x} + A_3^- e^{\beta_n x}) e^{i\omega_n t}.$$

Displacements and loads evaluated at an arbitrary position along the frame may be expressed in matrix form, as follows:

$$\hat{\mathbf{q}} = \begin{bmatrix} \hat{u} \\ \hat{v} \\ \hat{\theta}_z \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & -1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 1 \\ 0 & -i\beta & -\beta & 0 & i\beta & \beta \end{bmatrix} \begin{bmatrix} \Lambda_x^+ & 0 \\ 0 & \Lambda_x^- \end{bmatrix} \begin{bmatrix} A_1^+ \\ A_2^+ \\ A_3^+ \\ B_1^- \\ B_2^- \\ B_3^- \end{bmatrix}$$

$$\hat{\mathbf{f}} = \begin{bmatrix} \hat{F}_x \\ \hat{V}_y \\ \hat{M}_z \end{bmatrix} = E \begin{bmatrix} -iAk_x & 0 & 0 & -iAk_x & 0 & 0 \\ 0 & -iI\beta^3 & I\beta^3 & 0 & iI\beta^3 & -I\beta^3 \\ 0 & -I\beta^2 & I\beta^2 & 0 & -I\beta^2 & I\beta^2 \end{bmatrix} \begin{bmatrix} \Lambda_x^+ & 0 \\ 0 & \Lambda_x^- \end{bmatrix} \begin{bmatrix} A_1^+ \\ A_2^+ \\ A_3^+ \\ B_1^- \\ B_2^- \\ B_3^- \end{bmatrix}$$

where

$$\Lambda_x^+ = \begin{bmatrix} e^{-ik_x x} & 0 & 0 \\ 0 & e^{-i\beta x} & 0 \\ 0 & 0 & e^{-\beta x} \end{bmatrix},$$

$$\Lambda_x^- = \begin{bmatrix} e^{ik_x(x-L)} & 0 & 0 \\ 0 & e^{i\beta(x-L)} & 0 \\ 0 & 0 & e^{\beta(x-L)} \end{bmatrix}.$$

Here, the reference for wave amplitudes related to negative-going waves, i.e., those propagating to the left or in the negative sense of the x -axis, is placed at the end of an element of frame ($x = L$). Thus, instead of A_1^-, A_2^-, A_3^- , one has B_1^-, B_2^-, B_3^- . This is done for the purpose of numerical conditioning in the case where there are highly evanescent waves.

From Mace et al. (2005) and Mead (1973), the classification of waves into positive- or negative-

going waves consists in analyzing the sense of decreasing wave amplitudes or, if the amplitude remains constant, the sense of the time-averaged power transmission. The latter can be evaluated by regarding the sign of $\Re\{i\omega \mathbf{f}_L^T \mathbf{q}_L\}$: if it is negative, the corresponding wave is a positive-going wave; otherwise, it is a negative-going wave. Alternatively, the sign of the group speed may be used, which may be shown to follow the time-averaged power transmission sign.

Spectral Element for a Classical Frame

Consider an element of classical frame (Euler–Bernoulli beam combined with an elementary rod) with length L . The displacements at both ends of the spectral element can be expressed as a function of the wave amplitudes as follows:

$$\begin{bmatrix} \hat{u}(0) \\ \hat{v}(0) \\ \hat{\theta}_z(0) \\ \hat{u}(L) \\ \hat{v}(L) \\ \hat{\theta}_z(L) \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & -e^{-ik_x L} & 0 & 0 \\ 0 & 1 & 1 & 0 & e^{-i\beta L} & e^{-\beta L} \\ 0 & -i\beta & -\beta & 0 & i\beta e^{-i\beta L} & \beta e^{-\beta L} \\ e^{-ik_x L} & 0 & 0 & -1 & 0 & 0 \\ 0 & e^{-i\beta L} & e^{-\beta L} & 0 & 1 & 1 \\ 0 & -i\beta e^{-i\beta L} & -\beta e^{-\beta L} & 0 & i\beta & \beta \end{bmatrix} \begin{bmatrix} A_1^+ \\ A_2^+ \\ A_3^+ \\ B_1^- \\ B_2^- \\ B_3^- \end{bmatrix}$$

$$\begin{bmatrix} \hat{\mathbf{q}}_0 \\ \hat{\mathbf{q}}_L \end{bmatrix} = \begin{bmatrix} \Phi_q^+ & \Phi_q^- \Lambda_L^+ \\ \Phi_q^+ \Lambda_L^+ & \Phi_q^- \end{bmatrix} \begin{bmatrix} \mathbf{A}^+ \\ \mathbf{B}^- \end{bmatrix}.$$

Analogously, the external loads applied to the frame may be written as:

$$\begin{bmatrix} -\hat{F}_x(0) \\ -\hat{V}_y(0) \\ -\hat{M}_z(0) \\ \hat{F}_x(L) \\ \hat{V}_y(L) \\ \hat{M}_z(L) \end{bmatrix} = E \begin{bmatrix} iAk_x & 0 & 0 & iAk_x e^{-ik_x L} & 0 & 0 \\ 0 & iI\beta^3 & -I\beta^3 & 0 & -iI\beta^3 e^{-i\beta L} & I\beta^3 e^{-\beta L} \\ 0 & I\beta^2 & -I\beta^2 & 0 & I\beta^2 e^{-i\beta L} & -I\beta^2 e^{-\beta L} \\ -iAk_x e^{-ik_x L} & 0 & 0 & -iAk_x & 0 & 0 \\ 0 & -iI\beta^3 e^{-i\beta L} & I\beta^3 e^{-\beta L} & 0 & iI\beta^3 & -I\beta^3 \\ 0 & -I\beta^2 e^{-i\beta L} & I\beta^2 e^{-\beta L} & 0 & -I\beta^2 & I\beta^2 \end{bmatrix} \begin{bmatrix} A_1^+ \\ A_2^+ \\ A_3^+ \\ B_1^- \\ B_2^- \\ B_3^- \end{bmatrix}$$

$$\begin{bmatrix} \hat{\mathbf{F}}_0 \\ \hat{\mathbf{F}}_L \end{bmatrix} = \begin{bmatrix} -\Phi_f^+ & -\Phi_f^- \Lambda_L^+ \\ \Phi_f^+ \Lambda_L^+ & \Phi_f^- \end{bmatrix} \begin{bmatrix} \mathbf{A}^+ \\ \mathbf{B}^- \end{bmatrix}.$$

With the general method of computing $\mathbf{A}^+$ and $\mathbf{B}^-$ from the displacement equation and replacing it in the expression for external loads, one can write:

$$\mathbf{K}_\infty = \frac{E(1+i)}{2} \begin{bmatrix} iAk_x & 0 & 0 \\ 0 & 2iI\beta^3 & (1+i)I\beta^2 \\ 0 & (1+i)I\beta^2 & 2I\beta \end{bmatrix}.$$

$$\begin{bmatrix} \hat{\mathbf{F}}_0 \\ \hat{\mathbf{F}}_L \end{bmatrix} = \mathbf{K}(\omega) \begin{bmatrix} \hat{\mathbf{q}}_0 \\ \hat{\mathbf{q}}_L \end{bmatrix},$$

$$\mathbf{K} = \begin{bmatrix} -\Phi_f^+ & -\Phi_f^- \Lambda_L^+ \\ \Phi_f^+ \Lambda_L^+ & \Phi_f^- \end{bmatrix} \begin{bmatrix} \Phi_q^+ & \Phi_q^- \Lambda_L^+ \\ \Phi_q^+ \Lambda_L^+ & \Phi_q^- \end{bmatrix}^{-1}.$$

Throw-Off Spectral Element for a Straight Frame
A semi-infinite element of beam can be easily modeled via SEM by assuming the wave amplitudes related to waves propagating to the left (negative-going waves) are zero, i.e., considering there is no reflection. In this case, the displacement and force vectors at the left side of the element are given by:

$$\begin{aligned} \hat{\mathbf{q}}_0 &= \Phi_q^+ \mathbf{A}^+ \\ \hat{\mathbf{F}}_0 &= -\Phi_f^+ \mathbf{A}^+. \end{aligned}$$

Thus, the spectral matrix for the throw-off element of frame is:

$$\hat{\mathbf{F}}_0 = \mathbf{K}_\infty(\omega) \hat{\mathbf{q}}_0, \quad \mathbf{K}_\infty = -\Phi_f^+ (\Phi_q^+)^{-1}$$

Curved Beam

Equations of Motion

Consider a slender in-plane curved beam as shown in Fig. 4. The circumferential reference frame is placed such that the s -axis is along the neutral axis of the beam, here supposed to be equidistant of the upper and lower surfaces of the beam. The beam thickness h varies in the range $-h/2 \leq r \leq +h/2$ along the radial r -axis and its width lies along the z -axis. Based on the Euler–Bernoulli beam theory, which neglects shear deformation, the kinematics of a curved beam can be written as:

$$\begin{aligned} \bar{u}_s(r, s) &= u_s(s) + r \left(\frac{\partial u_s(s)}{\partial s} - \frac{v_r(s)}{R} \right) \\ \bar{v}_r(r, s) &= v_r(s) \end{aligned}$$

where $\bar{u}_s$ is the displacement in the s -direction (tangential displacement), $\bar{v}_r$ is the displacement in the y -direction (radial displacement), $\bar{\psi}$ is the rotation with respect to the z -axis, and R is the radius of the centerline.

**Spectral Finite Element
Approach for Structural
Dynamics, Fig. 4** Curved
beam element model

Then, from differentiation of the displacement field, considering a significant strain in s -direction, a strain at a given cross section of the curved beam is expressed:

$$\varepsilon_{ss} = \frac{\partial u_s}{\partial s} - \frac{v_r}{R} + r \left(\frac{\partial^2 v_r}{\partial s^2} + \frac{1}{R} \frac{\partial u_s}{\partial s} \right).$$

Moreover, neglecting all stresses except for the predominant circumferential stress, one can write:

$$\sigma_{ss} = E\varepsilon_{ss} = E \left[\frac{\partial u_s}{\partial s} - \frac{v_r}{R} \right] + rE \left(\frac{\partial^2 v_r}{\partial s^2} + \frac{1}{R} \frac{\partial u_s}{\partial s} \right).$$

Then, as a result of the application of Newton's laws or variational formulations, the equations of motion for the undamped curved beam are derived:

$$\begin{aligned} & \frac{EI}{R} \left(\frac{1}{R} \frac{\partial^2 u_s}{\partial s^2} - \frac{\partial^3 v_r}{\partial s^3} \right) + \frac{EA}{R} \left(\frac{\partial v_r}{\partial s} + R \frac{\partial^2 u_s}{\partial s^2} \right) \\ & - \rho A \frac{\partial^2 u_s}{\partial t^2} = q_s(s, t) \\ & \frac{EI}{R} \left(\frac{\partial^3 u_s}{\partial s^3} - R \frac{\partial^4 v_r}{\partial s^4} \right) - \frac{EA}{R} \left(\frac{v_r}{R} + \frac{\partial u_s}{\partial s} \right) \\ & + \rho A \frac{\partial^2 v_r}{\partial t^2} = q_r(s, t) \end{aligned}$$

where $q_s(s, t)$ and $q_r(s, t)$ are, respectively, tangential and radial distributed loads along the curved beam length. The boundary conditions associated to this problem are:

$$\begin{aligned} u_s = 0 & \quad \text{or} \quad T_s = EA \left(\frac{\partial u_s}{\partial s} - \frac{v_r}{R} \right) \\ v_r = 0 & \quad \text{or} \quad V_r = -EI \left(\frac{1}{R} \frac{\partial^2 u_s}{\partial s^2} + \frac{\partial^3 v_r}{\partial s^3} \right) \\ \psi = 0 & \quad \text{or} \quad M_{zs} = EI \left(\frac{1}{R} \frac{\partial u_s}{\partial s} + \frac{\partial^2 v_r}{\partial s^2} \right). \end{aligned}$$

If some internal viscoelastic damping η is present, the equations of motion are modified to:

$$\begin{aligned} & \frac{EI}{R} \left(\frac{1}{R} \frac{\partial^2 u_s}{\partial s^2} + \frac{\partial^3 v_r}{\partial s^3} \right) + \frac{EA}{R} \left(-\frac{\partial v_r}{\partial s} + R \frac{\partial^2 u_s}{\partial s^2} \right) \\ & - \eta A \frac{\partial u_s}{\partial t} - \rho A \frac{\partial^2 u_s}{\partial t^2} = q_s(s, t) \\ & \frac{EI}{R} \left(\frac{\partial^3 u_s}{\partial s^3} + R \frac{\partial^4 v_r}{\partial s^4} \right) + \frac{EA}{R} \left(\frac{v_r}{R} - \frac{\partial u_s}{\partial s} \right) \\ & + \eta A \frac{\partial v_r}{\partial t} + \rho A \frac{\partial^2 v_r}{\partial t^2} = q_r(s, t). \end{aligned}$$

Spectral Analysis

As before, in the straight beam case, two Fourier transforms can be successively applied to the displacement solution of a curved beam, which allows writing:

$$\begin{aligned} u_s(s, t) &= \sum_n \hat{u}_{sn}(s, \omega_n) e^{i\omega_n t} = \sum_n \sum_m \tilde{u}_s(k_m, \omega) e^{-ik_m s} e^{i\omega_n t} \\ v_r(s, t) &= \sum_n \hat{v}_{rn}(s, \omega_n) e^{i\omega_n t} = \sum_n \sum_m \tilde{v}_r(k_m, \omega) e^{-ik_m s} e^{i\omega_n t}. \end{aligned}$$

In the homogenous case and considering constant properties along the beam, the displacement solution is substituted in the equations of motion, which yields, in the frequency domain,

Spectral Finite Element Approach for Structural Dynamics, Fig. 5 Spectrum relations of a damped curved beam element: (a) real part of wavenumbers and (b) imaginary part of wavenumbers

$$\begin{bmatrix} -\frac{EI k^2}{R^2} - E A k^2 + i \eta A \omega + \omega^2 \rho A & \frac{i E I k^3}{R} + \frac{i E A k}{R} \\ \frac{i E I k^3}{R} + \frac{i E A k}{R} & E I k^4 + \frac{E A}{R^2} - i \eta A \omega - \omega^2 \rho A \end{bmatrix} \begin{bmatrix} \tilde{u}_s \\ \tilde{v}_r \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}.$$

A nontrivial solution for this system of equations is obtained by setting the determinant to vanish, which results in a sixth-order polynomial equation in k , the characteristic equation, or spectrum relation:

$$k^6 - \left[k_0^2 + \frac{2}{R^2} \right] k^4 - \left[\beta_0^4 + k_0^2 \frac{1}{R^2} - \frac{1}{R^4} \right] k^2 + \left[k_0^2 - \frac{1}{R^2} \right] \beta_0^4 = 0$$

where $\beta_0^4 = \frac{\rho A \omega^2 + i \eta A \omega}{EI}$ and $k_0^2 = \frac{\rho A \omega^2 + i \eta A \omega}{EA}$.

This equation provides three pairs of wavenumbers $\pm k_{s1}$, $\pm k_{s2}$, $\pm k_{s3}$. One pair is linked to extensional waves and the other two pairs to flexural waves (Fig. 5).

Then, the displacement solution may be expressed in the spectral form as:

$$\begin{aligned} u_s(s, t) &= \sum_n \left(\bar{A}_{s1}^+ e^{-ik_{s1}n s} + \bar{A}_{s2}^+ e^{-ik_{s2}n s} + \bar{A}_{s3}^+ e^{-ik_{s3}n s} + \bar{A}_{s1}^- e^{ik_{s1}n s} + \bar{A}_{s2}^- e^{ik_{s2}n s} + \bar{A}_{s3}^- e^{ik_{s3}n s} \right) e^{i\omega_n t} \\ v_r(s, t) &= \sum_n \left(A_{s1}^+ e^{-ik_{s1}n s} + A_{s2}^+ e^{-ik_{s2}n s} + A_{s3}^+ e^{-ik_{s3}n s} + A_{s1}^- e^{ik_{s1}n s} + A_{s2}^- e^{ik_{s2}n s} + A_{s3}^- e^{ik_{s3}n s} \right) e^{i\omega_n t}, \\ \psi(s, t) &= \frac{\partial v_r(s, t)}{\partial s} = \sum_n \left(-ik_{s1}n A_{s1}^+ e^{-ik_{s1}n s} - ik_{s2}n A_{s2}^+ e^{-ik_{s2}n s} - ik_{s3}n A_{s3}^+ e^{-ik_{s3}n s} + ik_{s1}n A_{s1}^- e^{ik_{s1}n s} + ik_{s2}n A_{s2}^- e^{ik_{s2}n s} + ik_{s3}n A_{s3}^- e^{ik_{s3}n s} \right) e^{i\omega_n t}, \end{aligned}$$

Spectral Finite Element Approach for Structural Dynamics, Fig. 6 Amplitude ratios for a damped curved beam element

i.e., as a superposition of waves propagating in opposite directions. From the homogeneous system of equations for $\tilde{u}_s$, $\tilde{v}_r$, amplitude ratios for each wave mode are obtained (Fig. 6):

$$\alpha_{sm} = \frac{\bar{A}_{sm}}{A_{sm}} = -\frac{EI k_{smn}^4 + EAR^{-2} - i\eta A\omega - \rho A\omega^2}{i(EIk_{smn}^3 + EAk_{smn})/R}.$$

Expressions for the internal loads in curved beams have been derived in terms of the displacement field and are rewritten below:

$$\begin{aligned} T_s &= EA \left(\frac{\partial u_s}{\partial s} - \frac{v_r}{R} \right) \\ V_r &= -EI \left(\frac{1}{R} \frac{\partial^2 u_s}{\partial s^2} + \frac{\partial^3 v_r}{\partial s^3} \right) \\ M_{zs} &= EI \left(\frac{1}{R} \frac{\partial u_s}{\partial s} + \frac{\partial^2 v_r}{\partial s^2} \right). \end{aligned}$$

Thus, substituting the spectral solutions for the displacement field, it yields:

$$\begin{aligned} T_s(s, t) &= EA \sum_n \left(-ik_{s1n} \alpha_{s1} A_{s1}^+ e^{-ik_{s1n}s} - ik_{s2n} \alpha_{s2} A_{s2}^+ e^{-ik_{s2n}s} - ik_{s3n} \alpha_{s3} A_{s3}^+ e^{-ik_{s3n}s} \right) e^{i\omega_n t} \\ &\quad + ik_{s1n} \alpha_{s1} A_{s1}^- e^{ik_{s1n}s} + ik_{s2n} \alpha_{s2} A_{s2}^- e^{ik_{s2n}s} + ik_{s3n} \alpha_{s3} A_{s3}^- e^{ik_{s3n}s} \\ &\quad - \frac{EA}{R} \sum_n \left(\frac{A_{s1}^+ e^{-ik_{s1n}s} + A_{s2}^+ e^{-ik_{s2n}s} + A_{s3}^+ e^{-ik_{s3n}s}}{A_{s1}^- e^{ik_{s1n}s} + A_{s2}^- e^{ik_{s2n}s} + A_{s3}^- e^{ik_{s3n}s}} \right) e^{i\omega_n t} \\ V_r(s, t) &= -\frac{EI}{R} \sum_n \left(k_{s1n}^2 \alpha_{s1} A_{s1}^+ e^{-ik_{s1n}s} + k_{s2n}^2 \alpha_{s2} A_{s2}^+ e^{-ik_{s2n}s} + k_{s3n}^2 \alpha_{s3} A_{s3}^+ e^{-ik_{s3n}s} \right) e^{i\omega_n t} \\ &\quad - k_{s1n}^2 \alpha_{s1} A_{s1}^- e^{ik_{s1n}s} - k_{s2n}^2 \alpha_{s2} A_{s2}^- e^{ik_{s2n}s} - k_{s3n}^2 \alpha_{s3} A_{s3}^- e^{ik_{s3n}s} \\ &\quad - EI \sum_n \left(\frac{ik_{s1n}^3 A_{s1}^+ e^{-ik_{s1n}s} + ik_{s2n}^3 A_{s2}^+ e^{-ik_{s2n}s} + ik_{s3n}^3 A_{s3}^+ e^{-ik_{s3n}s}}{-ik_{s1n}^3 A_{s1}^- e^{ik_{s1n}s} - ik_{s2n}^3 A_{s2}^- e^{ik_{s2n}s} - ik_{s3n}^3 A_{s3}^- e^{ik_{s3n}s}} \right) e^{i\omega_n t} \\ M_{zs}(s, t) &= \frac{EI}{R} \sum_n \left(-ik_{s1n} \alpha_{s1} A_{s1}^+ e^{-ik_{s1n}s} - ik_{s2n} \alpha_{s2} A_{s2}^+ e^{-ik_{s2n}s} - ik_{s3n} \alpha_{s3} A_{s3}^+ e^{-ik_{s3n}s} \right) e^{i\omega_n t} \\ &\quad + ik_{s1n} \alpha_{s1} A_{s1}^- e^{ik_{s1n}s} + ik_{s2n} \alpha_{s2} A_{s2}^- e^{ik_{s2n}s} + ik_{s3n} \alpha_{s3} A_{s3}^- e^{ik_{s3n}s} \\ &\quad + EI \sum_n \left(\frac{k_{s1n}^2 A_{s1}^+ e^{-ik_{s1n}s} + k_{s2n}^2 A_{s2}^+ e^{-ik_{s2n}s} + k_{s3n}^2 A_{s3}^+ e^{-ik_{s3n}s}}{-k_{s1n}^2 A_{s1}^- e^{ik_{s1n}s} - k_{s2n}^2 A_{s2}^- e^{ik_{s2n}s} - k_{s3n}^2 A_{s3}^- e^{ik_{s3n}s}} \right) e^{i\omega_n t} \end{aligned}$$

Displacements and loads evaluated at an arbitrary position along the curved beam may be expressed in matrix form, as follows:

$$\hat{\mathbf{q}}_{CB} = \begin{bmatrix} \hat{u}_s \\ \hat{v}_r \\ \hat{\psi} \end{bmatrix} = \begin{bmatrix} \alpha_{s1} & \alpha_{s2} & \alpha_{s3} & \alpha_{s1} & \alpha_{s2} & \alpha_{s3} \\ 1 & 1 & 1 & 1 & 1 & 1 \\ -ik_{s1} & -ik_{s2} & -ik_{s3} & ik_{s1} & ik_{s2} & ik_{s3} \end{bmatrix} \begin{bmatrix} \Lambda_s^+ & 0 \\ 0 & \Lambda_s^- \end{bmatrix} \begin{bmatrix} A_{s1}^+ \\ A_{s2}^+ \\ A_{s3}^+ \\ B_{s1}^- \\ B_{s2}^- \\ B_{s3}^- \end{bmatrix}$$

$$\hat{\mathbf{f}}_{CB} = \begin{bmatrix} \hat{T}_s \\ \hat{V}_r \\ \hat{M}_{zs} \end{bmatrix} = \begin{pmatrix} C_1 \begin{bmatrix} -ik_{s1} & -ik_{s2} & -ik_{s3} & ik_{s1} & ik_{s2} & ik_{s3} \\ k_{s1}^2 & k_{s2}^2 & k_{s3}^2 & -k_{s1}^2 & -k_{s2}^2 & -k_{s3}^2 \\ -ik_{s1} & -ik_{s2} & -ik_{s3} & ik_{s1} & ik_{s2} & ik_{s3} \end{bmatrix} \Gamma_s \\ + C_2 \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ ik_{s1}^3 & ik_{s2}^3 & ik_{s3}^3 & -ik_{s1}^3 & -ik_{s2}^3 & -ik_{s3}^3 \\ k_{s1}^2 & k_{s2}^2 & k_{s3}^2 & -k_{s1}^2 & -k_{s2}^2 & -k_{s3}^2 \end{bmatrix} \end{pmatrix} \begin{bmatrix} \Lambda_s^+ & 0 \\ 0 & \Lambda_s^- \end{bmatrix} \begin{bmatrix} A_{s1}^+ \\ A_{s2}^+ \\ A_{s3}^+ \\ B_{s1}^- \\ B_{s2}^- \\ B_{s3}^- \end{bmatrix}$$

where

$$\Lambda_s^+ = \begin{bmatrix} e^{-ik_{s1}s} & 0 & 0 \\ 0 & e^{-ik_{s2}s} & 0 \\ 0 & 0 & e^{-ik_{s3}s} \end{bmatrix}, \quad \Lambda_s^- = \begin{bmatrix} e^{ik_{s1}(s-s_0)} & 0 & 0 \\ 0 & e^{ik_{s2}(s-s_0)} & 0 \\ 0 & 0 & e^{ik_{s3}(s-s_0)} \end{bmatrix},$$

$$\Gamma_s = \text{diag}[\alpha_{s1} \quad \alpha_{s2} \quad \alpha_{s3} \quad \alpha_{s1} \quad \alpha_{s2} \quad \alpha_{s3}],$$

$$C_1 = \begin{bmatrix} EA & 0 & 0 \\ 0 & -EI/R & 0 \\ 0 & 0 & EI/R \end{bmatrix}, \quad C_2 = \begin{bmatrix} -EA/R & 0 & 0 \\ 0 & -EI & 0 \\ 0 & 0 & EI \end{bmatrix}.$$

It should be noticed that the reference for the wave amplitudes related to negative-going waves is placed at the end of the beam element, i.e., at $s = s_0$.

Spectral Element

Consider an element of curved beam with circumferential length s_0 . The displacements at both ends of the spectral element can be expressed as a function of the wave amplitudes as follows:

$$\begin{bmatrix} \hat{u}_s(0) \\ \hat{v}_r(0) \\ \hat{\psi}(0) \\ \hat{u}_s(s_0) \\ \hat{v}_r(s_0) \\ \hat{\psi}(s_0) \end{bmatrix} = \begin{bmatrix} \alpha_{s1} & \alpha_{s2} & \alpha_{s3} & \alpha_{s1}e^{-ik_{s1}s_0} & \alpha_{s2}e^{-ik_{s2}s_0} & \alpha_{s3}e^{-ik_{s3}s_0} \\ 1 & 1 & 1 & e^{-ik_{s1}s_0} & e^{-ik_{s2}s_0} & e^{-ik_{s3}s_0} \\ -ik_{s1} & -ik_{s2} & -ik_{s3} & ik_{s1}e^{-ik_{s1}s_0} & ik_{s2}e^{-ik_{s2}s_0} & ik_{s3}e^{-ik_{s3}s_0} \\ \alpha_{s1}e^{-ik_{s1}s_0} & \alpha_{s2}e^{-ik_{s2}s_0} & \alpha_{s3}e^{-ik_{s3}s_0} & \alpha_{s1} & \alpha_{s2} & \alpha_{s3} \\ e^{-ik_{s1}s_0} & e^{-ik_{s2}s_0} & e^{-ik_{s3}s_0} & 1 & 1 & 1 \\ -ik_{s1}e^{-ik_{s1}s_0} & -ik_{s2}e^{-ik_{s2}s_0} & -ik_{s3}e^{-ik_{s3}s_0} & ik_{s1} & ik_{s2} & ik_{s3} \end{bmatrix} \begin{bmatrix} A_{s1}^+ \\ A_{s2}^+ \\ A_{s3}^+ \\ B_{s1}^- \\ B_{s2}^- \\ B_{s3}^- \end{bmatrix}$$

$$\begin{bmatrix} \hat{\mathbf{q}}_0 \\ \hat{\mathbf{q}}_{s_0} \end{bmatrix} = \begin{bmatrix} \Phi_{qs}^+ & \Phi_{qs}^- \Lambda_{s_0}^+ \\ \Phi_{qs}^+ \Lambda_{s_0}^+ & \Phi_{qs}^- \end{bmatrix} \begin{bmatrix} \mathbf{A}_s^+ \\ \mathbf{B}_s^- \end{bmatrix}.$$

Analogously, the external loads applied may be written as:

$$\begin{bmatrix} -\hat{T}_s(0) \\ -\hat{V}_r(0) \\ \hat{M}_{zs}(0) \\ \hat{T}_s(s_0) \\ \hat{V}_r(s_0) \\ -\hat{M}_{zs}(s_0) \end{bmatrix} = \begin{bmatrix} C_1 \\ +C_2 \end{bmatrix} \begin{bmatrix} ik_{s1} & ik_{s2} & ik_{s3} & -ik_{s1}e^{-ik_{s1}s_0} & -ik_{s2}e^{-ik_{s2}s_0} & -ik_{s3}e^{-ik_{s3}s_0} \\ -k_{s1}^2 & -k_{s2}^2 & -k_{s3}^2 & k_{s1}^2e^{-ik_{s1}s_0} & k_{s2}^2e^{-ik_{s2}s_0} & k_{s3}^2e^{-ik_{s3}s_0} \\ -ik_{s1} & -ik_{s2} & -ik_{s3} & ik_{s1}e^{-ik_{s1}s_0} & ik_{s2}e^{-ik_{s2}s_0} & ik_{s3}e^{-ik_{s3}s_0} \\ -ik_{s1}e^{-ik_{s1}s_0} & -ik_{s2}e^{-ik_{s2}s_0} & -ik_{s3}e^{-ik_{s3}s_0} & ik_{s1} & ik_{s2} & ik_{s3} \\ k_{s1}^2e^{-ik_{s1}s_0} & k_{s2}^2e^{-ik_{s2}s_0} & k_{s3}^2e^{-ik_{s3}s_0} & -k_{s1}^2 & -k_{s2}^2 & -k_{s3}^2 \\ ik_{s1}e^{-ik_{s1}s_0} & ik_{s2}e^{-ik_{s2}s_0} & ik_{s3}e^{-ik_{s3}s_0} & -ik_{s1} & -ik_{s2} & -ik_{s3} \end{bmatrix} \Gamma_s \begin{bmatrix} A_{s1}^+ \\ A_{s2}^+ \\ A_{s3}^+ \\ B_{s1}^- \\ B_{s2}^- \\ B_{s3}^- \end{bmatrix} + \begin{bmatrix} -1 & -1 & -1 & -e^{-ik_{s1}s_0} & -e^{-ik_{s2}s_0} & -e^{-ik_{s3}s_0} \\ -ik_{s1}^3 & -ik_{s2}^3 & -ik_{s3}^3 & ik_{s1}^3e^{-ik_{s1}s_0} & ik_{s2}^3e^{-ik_{s2}s_0} & ik_{s3}^3e^{-ik_{s3}s_0} \\ k_{s1}^2 & k_{s2}^2 & k_{s3}^2 & -k_{s1}^2e^{-ik_{s1}s_0} & -k_{s2}^2e^{-ik_{s2}s_0} & -k_{s3}^2e^{-ik_{s3}s_0} \\ e^{-ik_{s1}s_0} & e^{-ik_{s2}s_0} & e^{-ik_{s3}s_0} & 1 & 1 & 1 \\ ik_{s1}^3e^{-ik_{s1}s_0} & ik_{s2}^3e^{-ik_{s2}s_0} & ik_{s3}^3e^{-ik_{s3}s_0} & -ik_{s1}^3 & -ik_{s2}^3 & -ik_{s3}^3 \\ -k_{s1}^2e^{-ik_{s1}s_0} & -k_{s2}^2e^{-ik_{s2}s_0} & -k_{s3}^2e^{-ik_{s3}s_0} & k_{s1}^2 & k_{s2}^2 & k_{s3}^2 \end{bmatrix} \begin{bmatrix} \hat{\mathbf{F}}_0 \\ \hat{\mathbf{F}}_{s_0} \end{bmatrix} = \begin{bmatrix} -\Phi_{fs}^+ & -\Phi_{fs}^- \Lambda_{s_0}^+ \\ \Phi_{fs}^+ \Lambda_{s_0}^+ & \Phi_{fs}^- \end{bmatrix} \begin{bmatrix} \mathbf{A}_s^+ \\ \mathbf{B}_s^- \end{bmatrix}.$$

With the general method for computing $\mathbf{A}_s^+$ and $\mathbf{B}_s^-$ from the displacement equation and replacing it in the expression for external loads, one can write:

$$\begin{bmatrix} \hat{\mathbf{F}}_0 \\ \hat{\mathbf{F}}_{s_0} \end{bmatrix} = \mathbf{K}_{CB}(\omega) \begin{bmatrix} \hat{\mathbf{q}}_0 \\ \hat{\mathbf{q}}_{s_0} \end{bmatrix},$$

$$\mathbf{K}_{CB}(\omega) = \begin{bmatrix} -\Phi_{fs}^+ & -\Phi_{fs}^- \Lambda_{s_0}^+ \\ \Phi_{fs}^+ \Lambda_{s_0}^+ & \Phi_{fs}^- \end{bmatrix} \begin{bmatrix} \Phi_{qs}^+ & \Phi_{qs}^- \Lambda_{s_0}^+ \\ \Phi_{qs}^+ \Lambda_{s_0}^+ & \Phi_{qs}^- \end{bmatrix}^{-1}.$$

Rod Under Torsion (Shaft)

Consider a rod element subjected to a distributed torsion moment (torque) m_x as shown in Fig. 7. Due to the applied load, at a position x , the cross section rotates about the x -axis by an angle $\theta_x(x)$. Here, it is assumed that the cross section remains plane while twisting. For wavelengths which are greater than ten times the cross-section dimensions, the Saint-Venant theory is also valid (Petyt 2010). In this case, the kinematics of a rod under torsion may be approximated as:

$$\begin{aligned} u(x, y, z) &= \psi(y, z) \frac{\partial \theta_x(x)}{\partial x} \\ v(x, y, z) &= -z \theta_x(x) \\ w(x, y, z) &= y \theta_x(x) \end{aligned}$$

where $\psi(y, z)$ is a function which represents the warping of the cross section. In this chapter, only rods of circular cross section are considered. In this case, there is no warping ($\psi = 0$) and the nonzero strain components are:

$$\begin{aligned} \epsilon_{xy} &= \frac{1}{2} \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \rightarrow \epsilon_{xy} = -\frac{z}{2} \frac{\partial \theta_x}{\partial x}, \quad \gamma_{xy} = -z \frac{\partial \theta_x}{\partial x} \\ \epsilon_{xz} &= \frac{1}{2} \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial y} \right) \rightarrow \epsilon_{xz} = \frac{y}{2} \frac{\partial \theta_x}{\partial x}, \quad \gamma_{xz} = y \frac{\partial \theta_x}{\partial x}. \end{aligned}$$

The associated stresses are given by:

$$\begin{aligned} \sigma_{xy} &= G \gamma_{xy} \rightarrow \sigma_{xy} = -zG \frac{\partial \theta_x}{\partial x} \\ \sigma_{xz} &= G \gamma_{xz} \rightarrow \sigma_{xz} = yG \frac{\partial \theta_x}{\partial x} \end{aligned}$$

where G is the shear modulus. In cylindrical coordinates, the resultant stress is:

$$\sigma_{xr} = G \gamma_{xr} \rightarrow \sigma_{xr} = rG \frac{\partial \theta_x}{\partial x}.$$

By applying Newton's laws or variational formulations, the equation of motion for this element is derived:

Spectral Finite Element Approach for Structural Dynamics, Fig. 7 Rod element model under torsion (shaft)

$$\frac{\partial}{\partial x} \left[GJ \frac{\partial \theta_x}{\partial x} \right] - \eta J \frac{\partial \theta_x}{\partial t} - \rho J \frac{\partial^2 \theta_x}{\partial t^2} = -m_x$$

where θ_x is the rotation with respect to the x -axis, J is the torsion constant or the polar moment of area with respect to the x -axis for concentric circular rods (round shafts), η is the damping (viscous) coefficient per unit volume, and ρ is the mass density.

The associated boundary conditions in this case are the rotation θ_x and the internal torque $M_x = GJ \frac{\partial \theta_x}{\partial x}$.

Spectral Analysis

As it was done in previous sections, by applying two Fourier transforms (time and space), the displacement field is written as spectral solutions, in the form:

$$\begin{aligned} \theta_x(s, t) &= \sum_n \hat{\theta}_{xn}(x, \omega_n) e^{i\omega_n t} \\ &= \sum_n \sum_m \tilde{\theta}_x(k_{xnm}, \omega) e^{-ik_m s} e^{i\omega_n t}. \end{aligned}$$

Then, assuming geometric and material properties constant along the rod length and substituting this expression in the homogeneous differential equation of motion, the spectrum relation is obtained:

$$\begin{aligned} (-GJk_{xx}^2 - i\omega\eta J + \omega^2 \rho J) \theta_x &= 0, \\ k_{xx} &= \pm \sqrt{\frac{\omega^2 \rho J - i\omega\eta}{GJ}}. \end{aligned}$$

Thus, the rotation θ_x and the internal moment M_x evaluated at an arbitrary point along the rod may be expressed as:

$$\begin{aligned} \theta_x(x, t) &= \sum_n (A_{xx1}^+ e^{-ik_{xxn}x} + A_{xx1}^- e^{ik_{xxn}x}) e^{i\omega_n t} \\ M_x(x, t) &= \sum_n ik_{xxn} GJ (-A_{xx1}^+ e^{-ik_{xxn}x} + A_{xx1}^- e^{ik_{xxn}x}) e^{i\omega_n t}. \end{aligned}$$

Setting the reference for negative-going waves at $x=L$, the rotation and the internal load are written in matrix form:

$$\begin{aligned} \hat{q}_{xx} = \hat{\theta}_x &= [1 \ 1] \begin{bmatrix} e^{-ik_{xx}x} & 0 \\ 0 & e^{ik_{xx}(x-L)} \end{bmatrix} \begin{bmatrix} A_{xx1}^+ \\ B_{xx1}^- \end{bmatrix} \\ \hat{f}_{xx} = \hat{M}_x &= ik_{xx} GJ [-1 \ 1] \begin{bmatrix} e^{-ik_{xx}x} & 0 \\ 0 & e^{ik_{xx}(x-L)} \end{bmatrix} \begin{bmatrix} A_{xx1}^+ \\ B_{xx1}^- \end{bmatrix}. \end{aligned}$$

Spectral Element

The spectral element of a shaft element in torsion of length L is straightforwardly obtained by writing the rotations with respect to the x -axis at both ends as a function of the wave amplitudes, as follows:

$$\begin{bmatrix} \hat{\theta}_x(0) \\ \hat{\theta}_x(L) \end{bmatrix} = \begin{bmatrix} 1 & e^{-ik_{xx}L} \\ e^{-ik_{xx}L} & 1 \end{bmatrix} \begin{bmatrix} A_{xx1}^+ \\ B_{xx1}^- \end{bmatrix},$$

i.e.,

$$\begin{bmatrix} \hat{q}_{xx0} \\ \hat{q}_{xxL} \end{bmatrix} = \begin{bmatrix} \Phi_{qxx}^+ & \Phi_{qxx}^- A_L^+ \\ \Phi_{qxx}^+ A_L^+ & \Phi_{qxx}^- \end{bmatrix} \begin{bmatrix} A_{xx}^+ \\ B_{xx}^- \end{bmatrix}.$$

The applied torque may be also evaluated at both ends:

$$\begin{bmatrix} -\hat{M}_x(0) \\ \hat{M}_x(L) \end{bmatrix} = ik_{xx} GJ \begin{bmatrix} 1 & -e^{-ik_{xx}L} \\ -e^{-ik_{xx}L} & 1 \end{bmatrix} \begin{bmatrix} A_{xx1}^+ \\ B_{xx1}^- \end{bmatrix}$$

or

$$\begin{bmatrix} \hat{F}_{xx0} \\ \hat{F}_{xxL} \end{bmatrix} = \begin{bmatrix} -\Phi_{fxx}^+ & -\Phi_{fxx}^- A_L^+ \\ \Phi_{fxx}^+ A_L^+ & \Phi_{fxx}^- \end{bmatrix} \begin{bmatrix} A_{xx}^+ \\ B_{xx}^- \end{bmatrix}.$$

**Spectral Finite Element
Approach for Structural
Dynamics, Fig. 8** 3D
frame member

Thus, by writing the wave amplitudes as function of the rotation vector and substituting it into the expression for external applied moments, the spectral element matrix is obtained:

$$\begin{bmatrix} \hat{F}_{xx0} \\ \hat{F}_{xxL} \end{bmatrix} = \mathbf{K}_{xx}(\omega) \begin{bmatrix} \hat{q}_{xx0} \\ \hat{q}_{xxL} \end{bmatrix},$$

$$\mathbf{K}_{xx}(\omega) = \begin{bmatrix} -\Phi_{fxx}^+ & -\Phi_{fxx}^- \Lambda_L^+ \\ \Phi_{fxx}^+ \Lambda_L^+ & \Phi_{fxx}^- \end{bmatrix} \begin{bmatrix} \Phi_{qxx}^+ & \Phi_{qxx}^- \Lambda_L^+ \\ \Phi_{qxx}^+ \Lambda_L^+ & \Phi_{qxx}^- \end{bmatrix}^{-1},$$

$$\mathbf{K}_{xx}(\omega) = GJk_{xx} \sin(k_{xx}L) \begin{bmatrix} \cos(k_{xx}L) & -1 \\ -\cos(k_{xx}L) & 1 \end{bmatrix}.$$

3D Frame Structure

A 3D frame structure is a combination of one-dimensional elements in the 3D space that are capable to support axial, bending, and torsion efforts (Fig. 8). Thus, using the expressions derived in the previous sections, a spectral element for a 3D frame element can be easily built. It is composed of six degrees of freedom per node (three translations and three rotations), which allow an axial deformation and torsion along the main axis and bending in the two transverse planes. Its displacement field may be expressed as:

$$\begin{aligned} \bar{u}(x, y, z, t) &= u(x, t) & \bar{\theta}_x(x, y, z, t) &= \theta_x(x, t) \\ \bar{v}(x, y, z, t) &= v(x, t) & \bar{\theta}_y(x, y, z, t) &= \theta_y(x, t) = -\frac{\partial w(x, t)}{\partial x} \\ \bar{w}(x, y, z, t) &= w(x, t) & \bar{\theta}_z(x, y, z, t) &= \theta_z(x, t) = \frac{\partial v(x, t)}{\partial x} \end{aligned}$$

It is important to emphasize at this point that the expression for the rotation w.r.t. the y-axis requires a negative sign as a result of the assumption that translations are positive in the sense of the Cartesian coordinates and also the respect of the right-hand rule for the coordinate system. By superposing the spectral solutions for a beam element under axial, flexural, and torsion deformations, the displacement solution vector is given by:

$$\hat{\mathbf{q}}_{3D}(x) = \begin{bmatrix} \hat{u}(x) \\ \hat{v}(x) \\ \hat{w}(x) \\ \hat{\theta}_x(x) \\ \hat{\theta}_y(x) \\ \hat{\theta}_z(x) \end{bmatrix} = [\Phi_q^+ \quad \Phi_q^-] \begin{bmatrix} \Lambda_x^+ & 0 \\ 0 & \Lambda_x^- \end{bmatrix} \begin{bmatrix} \mathbf{A}^+ \\ \mathbf{B}^- \end{bmatrix},$$

where:

$$\Phi_q^+ = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & i\beta_z & \beta_z & 0 \\ 0 & -i\beta_y & -\beta_y & 0 & 0 & 0 \end{bmatrix},$$

$$\Phi_q^- = \begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & -i\beta_z & -\beta_z & 0 \\ 0 & i\beta_y & \beta_y & 0 & 0 & 0 \end{bmatrix},$$

$$\mathbf{\Lambda}_x^+ = \begin{bmatrix} e^{-ik_x x} & 0 & 0 & 0 & 0 & 0 \\ 0 & e^{-i\beta_y x} & 0 & 0 & 0 & 0 \\ 0 & 0 & e^{-\beta_y x} & 0 & 0 & 0 \\ 0 & 0 & 0 & e^{-i\beta_z x} & 0 & 0 \\ 0 & 0 & 0 & 0 & e^{-\beta_z x} & 0 \\ 0 & 0 & 0 & 0 & 0 & e^{-ik_{xx} x} \end{bmatrix},$$

$$\mathbf{\Lambda}_x^- = \begin{bmatrix} e^{ik_x(x-L)} & 0 & 0 & 0 & 0 & 0 \\ 0 & e^{i\beta_y(x-L)} & 0 & 0 & 0 & 0 \\ 0 & 0 & e^{\beta_y(x-L)} & 0 & 0 & 0 \\ 0 & 0 & 0 & e^{i\beta_z(x-L)} & 0 & 0 \\ 0 & 0 & 0 & 0 & e^{\beta_z(x-L)} & 0 \\ 0 & 0 & 0 & 0 & 0 & e^{ik_{xx}(x-L)} \end{bmatrix}.$$

The corresponding internal loads acting on a 3D frame member are:

$$\begin{aligned} F_x &= EA \frac{\partial u}{\partial x} & M_x &= GJ \frac{\partial \theta_x}{\partial x} \\ V_y &= -\frac{\partial}{\partial x} \left(EI_z \frac{\partial^2 v}{\partial x^2} \right) & M_y &= -EI_y \frac{\partial^2 w}{\partial x^2} \\ V_z &= -\frac{\partial}{\partial x} \left(EI_y \frac{\partial^2 w}{\partial x^2} \right) & M_z &= EI_z \frac{\partial^2 v}{\partial x^2} \end{aligned}$$

$$\begin{aligned} \hat{\mathbf{f}}_{3D}(x) &= \begin{bmatrix} \hat{F}_x(x) \\ \hat{V}_y(x) \\ \hat{V}_z(x) \\ \hat{M}_x(x) \\ \hat{M}_y(x) \\ \hat{M}_z(x) \end{bmatrix} \\ &= [\Phi_f^+ \quad \Phi_f^-] \begin{bmatrix} \mathbf{\Lambda}_x^+ & 0 \\ 0 & \mathbf{\Lambda}_x^- \end{bmatrix} \begin{bmatrix} \mathbf{A}^+ \\ \mathbf{B}^- \end{bmatrix}, \end{aligned}$$

with:

which, in vector form, yields:

$$\Phi_f^+ = \begin{bmatrix} -ik_x EA & 0 & 0 & 0 & 0 & 0 \\ 0 & -iEI_z \beta_y^3 & EI_z \beta_y^3 & 0 & 0 & 0 \\ 0 & 0 & 0 & -iEI_y \beta_z^3 & EI_y \beta_z^3 & 0 \\ 0 & 0 & 0 & 0 & 0 & -ik_{xx} GJ \\ 0 & 0 & 0 & EI_y \beta_z^2 & -EI_y \beta_z^2 & 0 \\ 0 & -EI_z \beta_y^2 & EI_z \beta_y^2 & 0 & 0 & 0 \end{bmatrix},$$

$$\Phi_f^- = \begin{bmatrix} -ik_x EA & 0 & 0 & 0 & 0 & 0 \\ 0 & iEI_z \beta_y^3 & -EI_z \beta_y^3 & 0 & 0 & 0 \\ 0 & 0 & 0 & iEI_y \beta_z^3 & -EI_y \beta_z^3 & 0 \\ 0 & 0 & 0 & 0 & 0 & ik_{xx} GJ \\ 0 & 0 & 0 & EI_y \beta_z^2 & -EI_y \beta_z^2 & 0 \\ 0 & -EI_z \beta_y^2 & EI_z \beta_y^2 & 0 & 0 & 0 \end{bmatrix}.$$

A spectral element of frame with length L is straightforwardly obtained by writing displacement and external loads at both ends, as follows:

$$\begin{bmatrix} \hat{\mathbf{q}}_{3D0} \\ \hat{\mathbf{q}}_{3DL} \end{bmatrix} = \begin{bmatrix} \Phi_q^+ & \Phi_q^- \Lambda_L^+ \\ \Phi_q^+ \Lambda_L^+ & \Phi_q^- \end{bmatrix} \begin{bmatrix} \mathbf{A}^+ \\ \mathbf{B}^- \end{bmatrix}$$

$$\begin{bmatrix} \hat{\mathbf{F}}_{3D0} \\ \hat{\mathbf{F}}_{3DL} \end{bmatrix} = \begin{bmatrix} -\hat{\mathbf{f}}_{3D}(x=0) \\ \hat{\mathbf{f}}_{3D}(x=L) \end{bmatrix}$$

$$= \begin{bmatrix} -\Phi_f^+ & -\Phi_f^- \Lambda_L^+ \\ \Phi_f^+ \Lambda_L^+ & \Phi_f^- \end{bmatrix} \begin{bmatrix} \mathbf{A}^+ \\ \mathbf{B}^- \end{bmatrix}.$$

Then, the spectral element matrix of a 3D frame member is readily obtained:

$$\begin{bmatrix} \hat{\mathbf{F}}_{3D0} \\ \hat{\mathbf{F}}_{3DL} \end{bmatrix} = \mathbf{K}_{3D}(\omega) \begin{bmatrix} \hat{\mathbf{q}}_{3D0} \\ \hat{\mathbf{q}}_{3DL} \end{bmatrix},$$

$$\mathbf{K}_{3D}(\omega) = \begin{bmatrix} -\Phi_f^+ & -\Phi_f^- \Lambda_L^+ \\ \Phi_f^+ \Lambda_L^+ & \Phi_f^- \end{bmatrix} \begin{bmatrix} \Phi_q^+ & \Phi_q^- \Lambda_L^+ \\ \Phi_q^+ \Lambda_L^+ & \Phi_q^- \end{bmatrix}^{-1}.$$

Spectral Element Modeling

In previous sections, it has been shown how to formulate spectral element matrices for straight and curved frame members. However, in real engineering systems, those structures do not appear isolated; they are usually connected to other basic structures involving or not discontinuities. In this section, it will be shown that the spectral element method can be efficiently used to compute the forced response of coupled systems in the frequency and in the time domains. This is particularly useful in earthquake engineering, as it allows simulating the effect of seismic ground motion at a very low computational cost compared to conventional computational analyses via FEM or BEM. This is possible as SEM allows building exact element matrices at each frequency. Therefore, mesh refinement is not

required with the increase in frequency, and it is possible to build spectral models with very few degrees of freedom. On the other hand, as it makes use of matrix formulations as FEM does. The assemblage of spectral elements is quite simple via the direct stiffness method (Doyle 1997). It is also important to note that the global problem is solved in the frequency domain. For every discrete frequency, an assemblage process identical to that of the static case is performed and the global response vector is obtained. The discrete Fourier transform is used to obtain the spectral representation of the input data, and the inverse DFT allows one to recover the response of the coupled system in the time domain.

Global Dynamic Stiffness Matrix Assembling Procedure

Consider a frame element as shown in Fig. 9. Two types of coordinate system are defined: a global one, defined by the orthogonal X , Y , and Z directions, and a local one, defined by x , y , and z axes with the x -axis parallel to the main axis (neutral axis) of the frame member.

The spectral element matrix, as formulated previously for frame member, is written with respect to the local reference frame, as follows:

$$\hat{\mathbf{K}}_{xyz}(\omega) \hat{\mathbf{q}}_{xyz}(\omega) = \hat{\mathbf{F}}_{xyz}(\omega).$$

Load and displacement vectors in the global reference frame may be related to those defined in the local coordinate system by application of successive rotations from the local axes to the global axes:

$$\begin{aligned} \hat{\mathbf{q}}_{XYZ} &= \mathbf{T} \hat{\mathbf{q}}_{xyz} \\ \hat{\mathbf{F}}_{XYZ} &= \mathbf{T} \hat{\mathbf{F}}_{xyz} \end{aligned}$$

with:

$$\mathbf{T} = \begin{bmatrix} \mathbf{R}_x(\psi) \mathbf{R}_y(\varphi) \mathbf{R}_z(\theta) & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_x(\psi) \mathbf{R}_y(\varphi) \mathbf{R}_z(\theta) & \dots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{R}_x(\psi) \mathbf{R}_y(\varphi) \mathbf{R}_z(\theta) \end{bmatrix},$$

Spectral Finite Element Approach for Structural Dynamics, Fig. 9 Frame element relative to local and global coordinate systems

where $\mathbf{R}_x$, $\mathbf{R}_y$, and $\mathbf{R}_z$ are rotation matrices, therefore unitary ($\mathbf{R}^T \mathbf{R} = \mathbf{I}$), defined as:

$$\mathbf{R}_x = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \psi & \sin \psi \\ 0 & -\sin \psi & \cos \psi \end{bmatrix},$$

$$\mathbf{R}_y = \begin{bmatrix} \cos \varphi & 0 & -\sin \varphi \\ 0 & 1 & 0 \\ \sin \varphi & 0 & \cos \varphi \end{bmatrix},$$

$$\mathbf{R}_z = \begin{bmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Applying the transformation matrix to the local system, the equilibrium system of equations for a frame member in the global reference frame is written:

$$\hat{\mathbf{K}}_{XYZ}(\omega) \hat{\mathbf{q}}_{XYZ}(\omega) = \hat{\mathbf{F}}_{XYZ}(\omega),$$

with:

$$\hat{\mathbf{K}}_{XYZ}(\omega) = \mathbf{T} \hat{\mathbf{K}}_{xyz}(\omega) \mathbf{T}^T.$$

The transformation of coordinate system is performed for each structural member. This allows one to enforce kinematic compatibility and equilibrium at all nodes connecting structural members. Then, the global dynamic system is constructed following classic direct stiffness procedure:

$$\hat{\mathbf{K}}_G(\omega) = \sum_i \mathbf{L}^{(i)T} \hat{\mathbf{K}}_{XYZ}^{(i)}(\omega) \mathbf{L}^{(i)},$$

where $\mathbf{L}^{(i)}$ is the incidence matrix linking the local vector of degrees of freedom of a structural member i to the global vector of degrees of freedom.

For each discrete frequency, the global problem to be solved is:

$$\hat{\mathbf{K}}_G \hat{\mathbf{q}}_G = \hat{\mathbf{F}}_G,$$

Spectral Finite Element Approach for Structural Dynamics, Fig. 10 Seismic records using as input displacements in numerical experiments

Spectral Finite Element Approach for Structural Dynamics, Fig. 11 3D frame model

subjected to:

$$\begin{aligned}\hat{\mathbf{F}}_F &= \hat{\mathbf{F}}_0, \\ \hat{\mathbf{q}}_P &= \hat{\mathbf{q}}_0,\end{aligned}$$

where the subscripts F and P are used, respectively, to denote sets of degrees of freedom where Neumann (prescribed loads) and Dirichlet (prescribed displacements/rotations) boundary conditions are applied.

The solution of the global system is possible by rewriting it as:

$$\begin{bmatrix} \hat{\mathbf{K}}_{FF} & \hat{\mathbf{K}}_{FP} \\ \hat{\mathbf{K}}_{PF} & \hat{\mathbf{K}}_{PP} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{q}}_F \\ \hat{\mathbf{q}}_0 \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{F}}_0 \\ \hat{\mathbf{F}}_P \end{bmatrix},$$

Spectral Finite Element Approach for Structural Dynamics, Fig. 12 Response of the 3D frame structure to the earthquake measured at $(x = 10, y = 10)$ m

which allows one to get:

$$\begin{aligned}\hat{\mathbf{q}}_F &= \hat{\mathbf{K}}_{FF}^{-1}(\hat{\mathbf{F}}_0 - \hat{\mathbf{K}}_{FP}\hat{\mathbf{q}}_0) \\ \hat{\mathbf{F}}_P &= (\hat{\mathbf{K}}_{PP} - \hat{\mathbf{K}}_{PF}\hat{\mathbf{K}}_{FF}^{-1}\hat{\mathbf{K}}_{FP})\hat{\mathbf{q}}_0 + \hat{\mathbf{K}}_{PF}\hat{\mathbf{K}}_{FF}^{-1}\hat{\mathbf{F}}_0.\end{aligned}$$

Numerical Examples

Earthquake Signal

Seismic records from the Loma Prieta earthquake which struck the San Francisco Bay area of

California in 1989 are used as input displacements applied to the bottom nodes of the framework. The input signal in time domain has been obtained from an online database available in Silva et al. (2000) and it is shown in Fig. 10.

3D Frame

Here, the dynamic response of a 3D framework subjected to seismic ground motion is analyzed. The model is presented in Fig. 11. Each frame member is made of steel with mass density $\rho = 7,800 \text{ Kg.m}^{-3}$, Young's modulus $E = 210 \text{ GPa}$, structural loss factor $\eta = 0.04$, and Poisson's ratio $\nu = 0.3$. All members have a circular cross section of radius 0.15 m.

The response of the structure at $(x = 10, y = 10) \text{ m}$ along the three orthogonal directions is shown in Fig. 12, in the time and in the frequency domains. It is worth pointing out that the SEM has yielded a great reduction of the problem size compared to classic FEM. The response obtained from the SEM using 16 elements is in good agreement with the one obtained by solving a classic FE problem composed of 1200 FE elements. An animation of the framework dynamics during the passage of seismic waves is simulated via the SEM and it is shown in Video 1.

2D Frame

A 2D frame structure modeled using straight and curved beam elements is shown in Fig. 13. The frame has a square cross section $0.20 \text{ m} \times 0.20 \text{ m}$ and steel as material, with Young's modulus $E = 210 \text{ GPa}$, mass density $\rho = 7,800 \text{ kg/m}^3$, and structural damping $\eta = 0.02$.

As in the previous section, the structure is excited at the base nodes by the Loma Prieta earthquake signal. Because of the in-plane configuration, only the east–west and vertical displacement data are used.

The output displacements at the node $(x = 5, y = 0) \text{ m}$ are shown in Fig. 14. The results are validated with FEM results obtained using

Spectral Finite Element Approach for Structural Dynamics, Video 1 Animation of a 3D frame under seismic ground motion

Spectral Finite Element Approach for Structural Dynamics, Fig. 13 2D frame model

ANSYS®. As in the previous numerical problem, fewer degrees of freedom were required to solve the problem via the spectral element method compared to the classic FEM, which results in CPU time savings. The 2D frame motion caused by the earthquake passage was computed via the SEM and it is available in Video 2. The methodology presented in this chapter can be used to derive other elements, such as plates and shells (Doyle 1997), and to study more complex structures under dynamic excitation.

Spectral Finite Element Approach for Structural Dynamics, Video 2 Animation of a 2D frame under seismic ground motion

Summary

Elementary matrix of straight and curved beams, rod under axial force, and torsion were developed using spectral finite element approach. This method can be used to analyze the structural dynamic behavior. From the perspective of earthquake engineering, SEM allows to design structures subject to seismic excitation. The approach has advantages such as low computational cost, accuracy in frequency/time response, and simple modeling of complex structures. The equations of motion, spectral relation, and the spectral elementary matrix were derived. The simple elements were combined into a 3D frame element and a global matrix was assembled. Time and frequency responses of 3D and 2D frame structures under a

known seismic ground motion were computed with SEM and results were validated using well-known FEM commercial software.

Introduction

Conventional steel moment-resisting frames (MRFs) are currently designed to form a global plastic mechanism under the design basis earthquake (DBE) by developing plastic hinges at the ends of the beams and the bases of the columns. This design methodology offers many advantages, including collapse prevention and initial economy; however, plastic hinges in structural members involve difficulty to inspect and repair damage and local buckling as well as residual drifts. The socioeconomic losses associated with damage and residual drifts are repair costs, increased downtime, and possibly demolition due to the complications associated with large residual drifts (McCormick et al. 2008).

A challenge of modern earthquake engineering is the development, standardization, and practical implementation of resilient minimal-damage structures with the inherent potential to overcome the socioeconomic losses related to earthquake damage by minimizing or avoiding inelastic deformations and residual drifts. Examples of minimal-damage steel structures include frames equipped with rate-dependent passive dampers (Karavasilis et al. 2011; Whittle et al. 2012),

frames with steel energy dissipation devices (Karavasilis et al. 2012), and self-centering moment-resisting frames (SC-MRFs) with posttensioned (PT) connections.

SC-MRFs exhibit softening force–drift behavior while eliminating inelastic deformations and residual drifts under strong earthquakes as the result of gap openings developed in beam-to-column interfaces and self-centering capability due to elastic pretensioning elements (e.g., high-strength steel bars) which clamp beams to the columns. PT connections use carefully designed energy dissipation devices which are activated when gaps open and can be classified into yielding devices which dissipate energy through inelastic deformations and devices which dissipate energy through friction. Yielding devices were proposed as angles bolted on the top and bottom flanges of the beam and on the column flanges, dissipating energy through inelastic bending (Ricles et al. 2001, 2002; Garlock et al. 2005); buckling-restrained steel bars placed between the beam flanges and welded on the beam and column, dissipating energy through axial deformations (Christopoulos et al. 2002); reduced flange plates welded around a square hollow section column and bolted on the beam flanges (Chou et al. 2006); and reduced-section or cross-shaped steel plates placed below the bottom flange of the beam (Chou and Lai 2009). Friction-based devices were proposed as friction-bolted surfaces placed on the top and bottom flanges of the beam (Rojas et al. 2004; Kim and Christopoulos 2008a), on the web of the beam (Tsai et al. 2008), or on the bottom flange of the beam (Wolski et al. 2009).

A new steel PT beam–column connection using web hourglass shape steel pins (WHPs) as EDs has been recently developed by the authors. The development phases included (a) large-scale experimental evaluation (Vasdravellis et al. 2013a) of the proposed connection, (b) detailed finite element models (FEM) and associated parametric studies (Vasdravellis et al. 2013b), and (c) numerical simulations and seismic analysis of SC-MRFs equipped with PT connections with WHPs (Dimopoulos et al. 2013). A more recent study evaluated the

hysteresis and fracture capacity of WHPs made of high performance steel, i.e., high-strength steel and stainless steel (Vasdravellis et al. 2014). It was found that the connection isolates inelastic deformations in WHPs, avoids damage in other connection parts as well as in beams and columns, and eliminates residual drifts. The WHPs do not interfere with the composite slab and are very easy to replace without bolting or welding, and so, the connection enables nondisruptive repair and rapid return to building occupancy in the aftermath of a strong earthquake. This chapter presents the development of the PT connection through the experimental evaluation and the main results of the numerical analyses.

Steel Posttensioned Connection with Web Hourglass Pins

Figure 1 shows a schematic representation of an SC-MRF incorporating the proposed PT connection and the details of an exterior PT connection. Two high-strength steel bars located at the mid-depth of the beam, one at each side of the web, pass through holes drilled on the column flanges. The bars are posttensioned and anchored to the exterior column flange and hence clamp the beam to the column. Four cylindrical steel pins (WHPs) are inserted in aligned holes drilled on the web of the beam and on strong supporting plates. The supporting plates are welded to the column flanges and are of greater thickness to provide fixed support boundary conditions to the WHPs. Energy dissipation is provided by the inelastic bending of the WHPs, which are symmetrically placed (close to the top and bottom beam flange) to provide increased lever arm and hence increased internal moment resistance. As shown in Fig. 2, the WHPs are designed to have an hourglass shape to provide enhanced energy dissipation and fracture capacity (Kobori et al. 1992). Both sides of the beam web are reinforced with steel plates to increase the contact surface of the WHPs with the web. In that way, possible ovalization of the holes drilled on the web and the reinforcing plates under the WHP-bearing forces will be negligible, and

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,

Fig. 1 (a) SC-MRF incorporating the proposed PT connection; (b) exterior PT connection details

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 2 Geometry of half a WHP, assumed static system, and internal force diagrams

pinching behavior under cyclic deformations can be avoided. The connection includes beam flange-reinforcing plates to avoid excessive early yielding in the beam flanges under high

PT bar forces. In addition, the panel zone is strengthened with horizontal stiffeners and continuity plates along the web of the column.

Connection Behavior and Simplified Analysis

Flexural Behavior

The connection behavior is characterized by gap opening and closing in the beam–column interface as a result of the re-centering force in the PT bars. Figure 3 shows the gap-opening mechanism in the connection where d_{1u} and d_{1l} are the distances of the upper and lower WHPs from the center of rotation (COR), respectively; d_2 is the distance of the PT bars from the COR; F_{PT} is the total force in both PT bars; $F_{WHP,u}$ and $F_{WHP,l}$ are the forces in the upper and lower WHPs, respectively; and C_F is the compressive force on the beam–column bearing surface. It is assumed that the COR is located at the inner edge of the beam flange-reinforcing plate. This assumption was verified during the connection experiments described later.

Fig. 4 Force versus displacement cyclic behavior of one WHP

Figure 4 shows the assumed bilinear elastoplastic force–displacement ($F_{WHP,i}$ – δ) behavior of one of the four ($i = 1$ to 4) WHPs. Figure 5a plots the assumed cyclic moment–rotation (M – θ) behavior of the connection. M is the sum of the moment contributions from the PT bars, M_{PT} , and the WHPs, M_{WHP} . Figure 5b shows the nonlinear elastic moment contribution of both PT bars. In Fig. 5b, M_d is the decompression moment, i.e., equal to $F_{PT,i}d_2$, where $F_{PT,i}$ is the total initial posttensioning force in both PT bars. Figure 5c shows the moment contribution of the four WHPs. The M_{WHP} – θ curve changes slope two times since the upper WHPs yield at a rotation θ_2 and the lower WHPs yield afterwards at rotation θ_3 . Point 1 in Fig. 5a corresponds to the decompression moment, M_d , of the connection. After decompression, gap

opens, and the connection behavior becomes nonlinear elastic. Following the procedure described in Garlock et al. (2007), the stiffness K_1 between points 1 and 2 is equal to the sum of the rotational stiffness contribution of the PT bars, K_{PT} , and the rotational stiffness contribution of the WHPs, K_e :

$$K_1 = K_{PT} + K_e = \frac{K_{PT,a}K_b}{K_{PT,a} + K_b}d_2^2 + 2K_{fe}(d_{1l}^2 + d_{1u}^2) \quad (1)$$

where K_{fe} is the elastic stiffness of the force–displacement relationship of one WHP shown in Fig. 4, $K_{pt,a}$ is the total axial elastic stiffness of both PT bars, and K_b is the axial elastic stiffness of the beam. At point 2, the upper WHPs yield and M continues to increase with slope K_2 :

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 5 Conceptual cyclic moment-rotation behavior of the proposed PT connection

$$K_2 = K_{PT} + K_{p1}$$

$$= \frac{K_{PT,a}K_b}{K_{PT,a} + K_b}d_2^2 + 2(K_{fe}d_{1l}^2 + K_{fp}d_{1u}^2) \quad (2)$$

where K_{fp} is the post-elastic stiffness of the force-displacement relationship of one WHP shown in Fig. 4. At point 3, the lower WHPs yield and M continues to increase with slope K_3 :

$$K_3 = K_{PT} + K_{p2}$$

$$= \frac{K_{PT,a}K_b}{K_{PT,a} + K_b}d_2^2 + 2K_{fp}(d_{1l}^2 + d_{1u}^2) \quad (3)$$

When loading is reversed, the connection begins to unload, from point 4 to point 5, ideally with the same elastic stiffness, K_1 . After point 5, the connection unloads with stiffness equal to K_2 between points 5 and 6 and with stiffness K_3 between points 6 and 7 until the gap closes. The behavior of the connection is symmetric, since the WHPs are placed symmetrically to the beam centerline. The moment in the connection, M , is calculated as:

$$M = M_{PT} + M_{WHP} \quad (4)$$

Following the procedure described by Garlock et al. (2007), M_{PT} is given by:

$$M_{PT} = M_d + \frac{K_{PT,a}K_b}{K_{PT,a} + K_b}d_2^2\theta \quad (5)$$

According to Fig. 3, M_{WHP} can be obtained as:

$$M_{WHP} = F_{WHP,u}d_{1u} + F_{WHP,l}d_{1l} \quad (6)$$

Plastic Design of WHPs

Plastic analysis is used to calculate the force in the WHPs as they deform due to gap opening and closing. The assumed static system for half a WHP is shown in Fig. 2. The yield strength, V_{WHP} , of half a WHP is controlled either by the plastic moment of resistance, M_{pl} , or the plastic shear resistance, V_{pl} , (Eurocode 3 2003), i.e.:

$$M_{pl} = \frac{D_e^3}{6}f_y \quad (7)$$

$$V_{pl} = \frac{0.9\pi D_i^2 f_y}{\sqrt{3}} \quad (8)$$

where f_y is the yield strength of the WHP material, D_e is the equivalent external diameter (to be defined later), and D_i is the diameter at the mid-length of half a WHP, as indicated in Fig. 2. The factor 0.9 in Eq. 8 accounts for the relation between the average shear stress and the maximum shear stress in a circular section. The internal WHP part is connected to the external WHP part using a radius of 5 mm to avoid stress

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,

Fig. 6 Prototype steel building: (a) plan view and (b) elevation and cross-sections of the interior steel MRF used in this study

concentration and early fracture. It is assumed that D_e , which controls the WHP bending resistance, is equal to the diameter at the start of the round-shaped part with radius r . Plastic analysis assumes that the plastic moment of resistance should be reached at the ends before the plastic shear resistance is reached at the mid-length of half a WHP. By equilibrium, the aforementioned condition can be written as:

$$V_{WHP} = \frac{2M_{pl}}{L_{WHP}} < V_{pl} \quad (9)$$

where L_{WHP} is the clear length of the bending parts of half a WHP. From Eqs. 7 to 9, any combination of f_y , D_e , D_i , and L_{WHP} can be chosen to provide the desired V_{WHP} . The yield force of a WHP, $F_{y,WHP}$, is then calculated as:

$$F_{y,WHP} = 2V_{WHP} \quad (10)$$

The virtual work method along with analytical integration was applied to derive the elastic stiffness K_{fe} of a WHP:

$$K_{fe} = 2 \frac{9\pi D_e^3 D_i E G}{(40 E D_e^2 L_{WHP} + 48 G L_{WHP}^3)} \quad (11)$$

where E is the modulus of elasticity and G the shear modulus of the material. The WHP post-yield stiffness K_{fp} is assumed to be 2 % the initial stiffness, i.e., $K_{fp} = 0.02K_{fe}$.

Design of Prototype SC PT Connection with WHPs

Prototype Building

Figure 6a shows the plan view of the prototype building used for this study. The study focuses on the interior steel MRF shown in Fig. 6b. The yield stress of structural steel is equal to 300 MPa. The design seismic action, referred to herein as DBE, has a return period equal to 475 years and is expressed by the elastic design spectrum of Eurocode 8 (2004) with peak ground acceleration equal to 0.3 g and soil B. The interior MRF is first designed as a conventional MRF according to EC3 (2003) and EC8. The behavior (or strength reduction) factor q is equal to 6.5. Eurocode 8 imposes a serviceability limit on the peak story drift, θ_{max} , under the frequent earthquake (FOE) with a return period equal to 95 years. The FOE has intensity equal to 40 % the intensity of the DBE, and the limit on θ_{max} is 0.5 % and

0.75 % for non-ductile and ductile nonstructural components, respectively. A strength-based design under the DBE was first performed. Beams and columns from this design had to be increased to satisfy the limit on $\theta_{\max}$ under the FOE. The final sections are shown in Fig. 6b and were found iteratively, i.e., by decreasing the value of q , designing the MRF under the DBE, and then checking drifts under the FOE. The conventional MRF has story drifts equal to 0.64 % under the FOE, 1.6 % under the DBE, and 2.4 % under the maximum considered earthquake (MCE). The MCE has intensity equal to 150 % the intensity of the DBE.

The sections of the conventional MRF are used for designing the proposed PT connection (see next section). In that way, a SC-MRF using the proposed PT connections would have the same initial stiffness and period of vibration with the conventional MRF.

Performance-Based Design of PT Connection with WHPs

The design focuses on the exterior connection of the 2nd floor of the prototype steel MRF shown in Fig. 6b. This connection is designed as a PT connection with WHPs using the methodology presented by Garlock et al. (2007) that adopts two performance objectives and associated structural limit states, namely, (1) immediate occupancy under the DBE by avoiding damage in beams and columns while permitting gap opening and (2) collapse prevention under the MCE by avoiding PT bar yielding and beam local buckling while permitting minor yielding in beams and columns.

The design methodology proposed by Garlock et al. (2007) uses beam flange-reinforcing plates to avoid early beam flange yielding and buckling. However, the connection can experience sudden loss of strength and stiffness due to beam web local buckling when deformed beyond the MCE drift. In this work, the use of the structural details (drilled holes on the beam flanges and beam web stiffeners) proposed by Kim and Christopoulos (2009) in a connection designed according to the procedure described by Garlock is also examined with the aim to further delay beam local buckling

for drifts higher than the MCE drifts. Such a design approach is slightly different than the one proposed by Kim and Christopoulos (2008b) where the connection is designed to form a ductile plastic hinge for drifts approximately equal to the DBE drifts.

The design of the PT connection is based on drifts equal to 0.64 % under the FOE, 1.6 % under the DBE, and 2.4 % under the MCE according to the prototype building design. These drifts are significantly lower than those used in previous works which are based on the IBC 2 % drift limit under the DBE (Rojas et al. 2004; Garlock et al. 2007). To initiate the design procedure, the moment corresponding to point 2 in Fig. 5a, referred to herein as M_{IGO} , is set equal to 66 % of the nominal plastic moment of resistance of the beam section. In addition, M_d is set equal to 69 % of M_{IGO} . These M_{IGO} and M_d values provide an energy dissipation factor, β (Garlock et al. 2007), equal to 0.31. The posttensioning force and the length of the reinforcing plates are then designed. PT bars are designed to avoid yielding for $\theta \leq 0.07$ rad.

Hysteretic Characterization of WHPs

Component tests on the WHPs were conducted to assess their energy dissipation capacity and ductility under cyclic loading. Figure 7 shows the experimental setup for the tests. A pair of WHPs was tested to reproduce their behavior in the proposed PT connection. Two supporting plates were welded on a fixed plate. A plate simulating the web of the beam was bolted to a thick plate attached to the actuator. The thicknesses of the plates were equal to those of the plates designed for the large-scale PT connection tests discussed later.

Four coupon tests were conducted to identify the material properties of the WHPs. The results of the coupon tests are summarized in Table 1. The WHPs were made of 1020-Grade carbon steel, with an average yield strength 557 MPa, ultimate strength 598 MPa, and elongation at fracture equal to 20 %. This type of steel was chosen to achieve the required strength while keeping the sizes of the WHPs relatively small.

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 7 Component test setup for WHPs (dimensions in mm)

The hourglass shape of the WHPs was designed to be consistent with their bending moment diagram shown in Fig. 2. Such a design results in almost uniform distribution of inelastic deformations along the length of the WHPs and, hence, in enhanced energy dissipation and fracture capacity. For the tested configuration, the design resulted in WHPs with external diameter $D_e = 20$ mm, internal diameter $D_i = 14$ mm, and $L_{whp,i} = 40$ mm, while the external part had a diameter equal to 30 mm.

Figure 8a shows the deformed WHPs during the component test. WHPs were capable of sustaining repeated large inelastic cycles without fracture up to displacements associated with connection rotation of 0.07 rad. Figure 8b plots the force–displacement hysteresis of the WHPs. WHPs provide a yielding force equal to 150 kN which is in excellent agreement with the 147 kN WHP yielding force calculated by the plastic analysis procedure presented previously. The ultimate strength of the WHPs at the initiation of fracture is 160 kN. Slight pinching (short flat region) is observed at the points where the force

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Table 1 Material properties of WHPs from coupon tests

Coupon no.	Yield stress (MPa)	Tensile stress (MPa)	E (GPa)	% Elongation at fracture

Average	557	598	208	20

changes sign due to slight ovalization of the holes of the supporting plates under the bearing forces induced by the WHPs.

Large-Scale Experimental Program

Test Setup

Experiments on PT connections equipped with WHPs were conducted in the test setup shown in Fig. 9. The test specimens were based on the prototype second-floor exterior beam-to-column connection (see Fig. 6) at 0.6 scale. A strong 310UC158 column was used to minimize the column deformations since they do not influence the behavior of the main connection components (beam, PT bars, and WHPs). Two additional steel members were welded to the column to form a truss system which increases the horizontal stiffness of the test setup (310UC158 horizontal member and 200UC52 diagonal member in Fig. 9). The whole system was bolted on the strong floor. The displacement history was applied vertically by a hydraulic actuator positioned at a distance of 1,800 mm from the inner face of the column.

Test Specimens

Two connection specimens (SC-WHP1 and SC-WHP2) were designed according to the procedure described earlier. The resulting beam and column sizes and details of the connection specimens are summarized in Table 2. The specimens are identical except for the beam web stiffeners and beam flange drilled holes used in specimen SC-WHP2.

^a $F_{PT,i}$: Initial posttensioning force
^b L_{rp} : Length of reinforcing plates on the beam flanges

Figure 10a shows the SC-WHP1 specimen, while Fig. 10b shows a close-up view of its connection region. Beam flanges are reinforced with 700 mm long and 10 mm thick plates, while the web of the beam is reinforced with 10 mm

thick plates as shown in Fig. 10b. The thickness of the WHP-supporting plates is 36 mm, their width is 80 mm, and a weld radius of 6 mm was used for the welding of all the plates in the connection.

Figure 11 shows the SC-WHP2 specimen which is identical to the SC-WHP1 apart from four 540 mm long longitudinal stiffeners which are welded on the web and four 27 mm holes drilled on the flanges immediately after the end of the reinforcing plate. The longitudinal stiffeners have thickness 10 mm, start 270 mm before and are extended 270 mm beyond the end of the reinforcing plates. The longitudinal stiffeners aim to resist the web buckling in the beam which typically occurs after the end of the reinforcing plates due to the increased bending moment and compressive force developed in this section as the gap opening increases. The drilled holes aim to reduce the moment

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,

Fig. 10 SC-WHP1 specimen: (a) overview and (b) close-up view of the connection region

capacity of the beam in this region in order to allow for the formation of a plastic hinge under large drifts. A dog-bone detailing could be used instead.

Material Properties

The beam and column sections were made of steel with nominal yield strength equal to 300 MPa. The reinforcing plates, WHPs supporting plates, and stiffeners were made of steel with nominal yield strength equal to 350 MPa. Tensile tests were carried out on

coupons cut from the flanges and webs of the beams. Table 3 summarizes the mean actual yield stress, tensile stress, and modulus of elasticity resulting from the material tests. The coupon tests showed that the mean yield stresses are 361 and 388 MPa for the flanges and the web of the beam, respectively, indicating considerable overstrength of the steel material. The material of the PT bars has nominal yield strength equal to 930 MPa, tensile stress 1,050 MPa, and elongation capacity 6 %, according to the specifications of the supplier.

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 11 Details of SC-WHP2 specimen

Test Procedure

The loading protocol for the two specimens consists of cyclic vertical displacements of increasing amplitude imposed in a quasi-static fashion with a speed approximately equal to 21 mm/min. The AISC (2005) loading protocol was used. This protocol consists of three initial sets of six cycles at 6.75, 9, and 13.5 mm displacements, four subsequent cycles at 18 mm, and six sets of two cycles at 27, 36, and 54 mm. These displacements correspond to drifts equal to 0.00375, 0.005, 0.0075, 0.01, 0.015, 0.02, and 0.03. The specimens were further imposed to drifts equal to 0.06 and, then, up to 0.09–0.10 to identify the connection failure mode.

Experimental Results

Specimen SC-WHP1

Figure 12a shows the force–drift hysteresis of the SC-WHP1 specimen, while Fig. 12b shows the associated moment–rotation hysteresis. In Fig. 12a, the drift is calculated as the ratio of the vertical displacement at the tip of the actuator to the horizontal distance of the tip of the actuator to the inner face of the column. The rotation is calculated as the gap-opening angle at the beam–column interface measured during the tests. In Fig. 12b, the moment is calculated as the product of the actuator force and the distance

of the actuator tip to the inner face of the column. Figure 12a shows that the connection maintains self-centering capability for drifts up to 6 %. The initial stiffness of the connection is 5 kN/mm and is equal to the theoretical stiffness of a welded (fully restrained) connection. During the last cycle of 9 % drift, the connection lost its self-centering capability and experienced a residual drift equal to 3 %.

To assess the reparability of the proposed connection after a strong earthquake, the SC-WHP1 specimen was initially imposed to displacements up to the DBE level (i.e., 1.6 % drift). The test was then interrupted, and damaged WHPs were substituted by new ones. The substitution was easily accomplished according to the following steps: (a) a temporary support was placed below the beam close to the beam–column interface to accommodate the self-weight of the beam; (b) the PT force was relaxed; (c) the damaged WHPs were taken out with the aid of a wooden hammer; and (d) new WHPs were placed in the connection. Since no welding or bolting is needed for the WHPs replacement, the proposed connection can be repaired with minimal disturbance to building use or occupation in the aftermath of a major earthquake. After the substitution of the WHPs, the test was restarted. Figure 12a plots superimposed loops from the tests before and after the replacement of WHPs. During the first cycles, the connection loses part of its initial

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,
Fig. 12 Hysteretic response of SC-WHP1 specimen and comparison with analytical predictions

stiffness as a result of the unavoidable local yielding of the beam edges at the beam–column interface. Nevertheless, Fig. 12a shows that the connection gains its stiffness after drifts of 1 %. In fact, the two loops are perfectly superimposed to each other, demonstrating that the proposed connection can be repaired after a strong earthquake without compromising its stiffness, strength, and energy dissipation capacity.

Figure 12b plots superimposed moment–rotation loops from the tests before and after replacement of WHPs along with the analytical moment–rotation prediction using the analytical expressions of the simplified procedure described earlier. The moment contribution of the PT bars, M_{PT} , is calculated from the posttension force recorded by the load cells and is plotted in Fig. 12c, while the contribution of the WHPs, M_{WHP} , is found by subtracting M_{PT} from the total moment of the connection and is plotted in Fig. 12d.

Figure 12b shows that the connection achieves rotations larger than 0.035 rad with full self-centering capability. The experimental moments at decompression and gap opening are $M_d = 62$ kNm and $M_{IGO} = 95$ kNm, respectively. These values are slightly smaller than the design values of $M_d = 66$ kNm and $M_{IGO} = 100$ kNm. However, the predicted analytical curve captures well the cyclic behavior in terms of both stiffness and strength. The analytical prediction is also in good agreement with both the M_{PT} – θ and the M_{WHP} – θ loops, as shown in Fig. 12c, d, respectively.

Displacement measurements at the beam–column interface indicated a vertical translation of the beam axis with respect to its initial position of about 4 mm. This translation took place gradually during the testing procedure and is attributed to a gradual loss of friction between the beam and the column interface. Shear tabs could be welded on the column flange and bolted on the beam web using slotted holes to

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 13 Gap opening at 6 % imposed drift of the SC-WHP1 specimen

accommodate gravity loads and eliminate the vertical beam displacement without influencing the connection moment behavior. Another alternative to accommodate gravity loads could be the use of a seat angle positioned below the bottom flange of the beam.

Figure 13 shows a close-up view of the gap-opening angle corresponding to 6 % drift. Apart from the intended damage in the WHPs and local yielding in the beam edges at the beam–column interface, no other evidence of damage was observed for drifts lower or equal to 6 %. Yielding in the beam flanges at the beam–column bearing surface was evident from the first cycles of the test. In fact, it was visually verified that the extreme edges of the beam at the beam–column interface became rounded during the test. As a result, the location of the COR was not constant during the experimental process. At the initial cycles, the COR was located approximately at the center of the reinforcing plate, while at larger drifts, it was stabilized at the inner side of the reinforcing plates.

During the last cycle of 9 % drift, the specimen failed due to local buckling of the web of the beam immediately after the end of the reinforcing plates. Figure 14 shows a close-up view of the buckled region. Web buckling took place at 7 % drift, while local buckling of the beam flanges initiated at the same time. Strain gauge measurements did not indicate

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 14 Web buckling of the SC-WHP1 specimen

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 15 PT force versus drift for the SC-WHP1 specimen

yielding at any point throughout the beam section when local buckling initiated.

Figure 15 plots the variation of the force in the PT bars with respect to drift. The PT force increases with gap opening and returns to its initial value of 504 kN when gap closes. The loss in posttensioning during the test was about 7 kN. The maximum force in the PT bars has values of 850 kN and 970 kN at 6 % and 9 % drift, respectively. These values show that the PT bars remained elastic during the test since their nominal yield limit is 1,227 kN. A drop in the PT force due to beam local buckling is observed during the last cycle.

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,
Fig. 16 Hysteretic response of specimen SC-WHP2 and comparison with analytical predictions

Specimen SC-WHP2

Figure 16a shows the cyclic force–drift behavior of the SC-WHP2 specimen. The behavior is stable with full self-centering capacity up to 6 % drift similar to specimen SC-WHP1. A final experimental loop of 10 % drift caused the connection to fail, and a residual drift of 4 % was present at the end of the test.

The moment versus relative rotation hysteresis is plotted in Fig. 16b. The experimental M_d value was 60 kNm, while M_{IGO} was 92 kNm. These values are somewhat smaller than the corresponding values of the SC-WHP1 specimen due to the slightly smaller initial posttensioning force (504 instead of 518 kN). The simplified design procedure predicts well the cyclic envelope with the predicted values for M_d and M_{IGO} being 64 and 98 kNm, respectively. Figure 16c–d shows that the analytical predictions are in good

agreement with the individual experimental moment contributions M_{PT} and M_{WHP} .

The detailing employed for specimen SC-WHP2 resulted in a different failure mode. No web or flange buckling was observed in the beam section after the end of the beam flange-reinforcing plates. In addition, no plastic hinge was developed in this region. The strain gauges indicated that the yield strain was not reached in any point throughout the beam section at the end of the beam flange-reinforcing plate. Figure 17 shows that the SC-WHP2 specimen failed due to excessive yielding in the beam flanges at the beam–column interface under large bearing forces. Local yielding at the bearing interface of specimen SC-WHP2 was more pronounced than in specimen SC-WHP1 and resulted in a gradual reduction in posttensioning force. Figure 18 shows that the loss of force in the PT bars was

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 17 Local yielding in the beam flange at the bearing interface of the SC-WHP2 specimen

50 kN during the test, with the largest amount attributed to loading cycles associated with drifts larger than the MCE drift. A reduction of 15 kN in the force of the PT bars was observed as a result of the local failure at the final loading cycle.

Finite Element Simulations and Parametric Study

This section presents FEM models which can be used to reliably assess the design and behavior of the connection. A detailed nonlinear FEM model was developed in Abaqus (Dassault Systems 2010). The FEM model was calibrated against experimental results and found capable to trace the nonlinear cyclic behavior of the connection and capture all possible local failure modes. The calibrated FEM model was used to conduct a series of simulations to study the effect of different parameters on the connection behavior.

Models for the WHPs

The cyclic behavior of the WHPs was first simulated. The FEM model geometry reproduced the actual geometry of the test setup of the component tests that were carried out to characterize the behavior of the WHPs. Figure 19 shows the setup used for the WHPs characterization tests along

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 18 PT force versus drift for the SC-WHP2 specimen

with the FEM model and its boundary conditions. Since the actual geometry was symmetric, only one fourth of the specimens was modeled to decrease computational time.

Figure 20a shows the deformed shape of the WHP and the equivalent plastic strain (*PEEQ*) distribution at a displacement of 12 mm. Figure 20a shows that the hourglass shape geometry results in uniform distribution of plastic deformation along the length of the internal part of the WHP, while the external parts of the WHP and the supporting plates are essentially elastic. The *PEEQ* distribution in the WHP's supporting plates is plotted separately in Fig. 20b which shows minor plastic concentrations. These results agree with the experimental test observations where a negligible ovalization of the holes of the supporting plates was evidenced.

Figure 21 compares the force–displacement hysteresis from FEM analysis with the experimental hysteresis from the WHPs characterization tests. The FEM model can trace the nonlinear cyclic behavior of the WHPs with good accuracy. The model captures the pinching behavior at zero force which is observed in the experimental hysteretic curve as the result of the negligible ovalization of the holes of the supporting plates. Figure 21 shows that the experimental hysteresis of the WHPs deteriorates after a displacement amplitude of 12 mm. The WHP failed due to

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,
Fig. 19 The FEM model used for the WHPs

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,
Fig. 20 Deformed shape of the WHP and equivalent plastic strain (*PEEQ*) contour plot

ductile fracture at the section close to the internal support plate under a displacement amplitude of 12 mm.

Models for the Connection

A three-dimensional FEM model was developed to simulate the behavior of the connections as shown in Fig. 22. The geometry of the tests was reproduced in full detail. The column, the PT bars, the WHPs, and the plates were modeled using C3D8R solid elements. The beam was modeled using solid elements with incompatible modes (C3D8I). C3D8I are first-order elements that are enhanced by incompatible modes to

improve their bending behavior. The mesh was refined in regions where severe plastic deformations or buckling phenomena were expected to occur, i.e., close to the beam–column interface and at the end of the beam flange-reinforcing plates. A coarser mesh was used for regions that were expected to remain essentially elastic, i.e., the anchor block, the tip of the beam, and the top and bottom parts of the column. The WHPs and their supporting plates were modeled using the verified model for the WHPs described in the previous section.

The vertical load was applied as an imposed displacement, U_2 , at a distance equal to 1,800 mm

from the connection face as shown in Fig. 22a. The analysis consisted of several steps. In the first step, the contact interactions were established to ensure that numerical problems due to contact formulation will not be encountered during the next steps. The posttensioning force was applied during the second analysis step by imposing an axial displacement at the free ends of the PT bars

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 21 Comparison of the experimental and the numerical force–displacement hysteretic behavior of the WHPs

capable of producing the desired $F_{PT,i}$ in the beam. In the subsequent steps, the cyclically displacement history was applied. Displacement-controlled nonlinear analysis was performed.

Assessment of the Finite Element Model

Figure 23 plots the force–drift hysteresis from FEM analyses along with the experimental hysteresis of the two connection specimens. The FEM model can capture well the overall cyclic behavior of the connections. The predicted values for the M_d and M_{IGO} are in very good agreement with the corresponding experimental ones, while the initial and post-elastic stiffness are almost identical. The variation of F_{PT} from experiments is compared with the FEM prediction in Fig. 24. The FEM simulations and experiments are in reasonably good agreement. The numerical model predicts a slightly smaller loss in F_{PT} than that measured one in the experiments for specimen SC-WHP1, while the loss in F_{PT} is more accurately predicted for specimen SC-WHP2.

Following the loading protocol of the experimental program, the FEM models were pushed to large drifts to investigate all possible global and local failure modes. Figure 23 shows that the two

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 22 FEM model details: (a) FEM

discretization, (b) model for specimen SC-WHP1, and (c) model for specimen SC-WHP2

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 23 Force–drift hysteresis of the two

connection specimens tested in Kim and Christopoulos (2008b) and comparison with FEM results: (a) SC-WHP1 and (b) SC-WHP2

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 24 F_{PT} -drift plots for the two connection

specimens tested in Kim and Christopoulos (2008b) and comparison with FEM results: (a) SC-WHP1 and (b) SC-WHP2

large last cycles of 9 % drift for specimen SC-WHP1 and 10 % drift for specimen SC-WHP2 resulted in residual inelastic drifts and loss of self-centering capability. These large drifts resulted in different failure modes of the two connection specimens, consistent with the experimental observations. The FEM model for specimen SC-WHP1 failed due to web buckling immediately after the end of the reinforcing plates. The FEM model for specimen SC-WHP2 failed due to yielding in the region of the drilled holes on the beam flange and in the bearing interface, while the web of the beam remained elastic until the end of the analysis. This can be verified by the *PEEQ* value distribution in the deformed configurations of the connections (Fig. 25) for

three drift levels: DBE (i.e., Design Basis Earthquake (Charney and Downs 2004)) = 1.6 %, MCE = 2.4 %, and Ultimate = 9–10 %. In this figure, darker areas indicate larger plastic strain concentration. The FEM models captured the failure modes observed in the experimental program. Figure 25 shows that under the DBE drift, the connection damage is isolated in the WHPs. Under the MCE drift, damage is concentrated in the WHPs and in the beam flanges in the beam–column interface. Damage in the beam–column interface is more evident in the connection SC-WHP2. Under the ultimate drift, damage in the connection is spread along the beam web immediately after the end of the reinforcing plates and in the beam flanges at the

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,

Fig. 25 Contour plots of the equivalent plastic strain ($PEEQ$) in the connection at different drift levels: SC-WHP1 (*left*) and SC-WHP2 (*right*)

bearing interface. Figure 25f shows that damage in the beam flanges is more evident in the SC-WHP2 model.

The comparisons between the FEM analyses and experiments show that the proposed FEM model is capable of reproducing the inelastic response of the tested PT connections up to the ultimate deformation levels and to capture accurately all possible failure modes. Therefore, it is a reliable tool for the simulation of the hysteretic behavior of PT steel connections (Figs. 23 and 24).

Seismic Analysis of SC-MRFs Using PT Connections with WHPs**Modeling of PT Connection with WHPs for Nonlinear Analysis in OpenSees**

A model for the PT connection with WHPs and the associated beams and columns was developed in OpenSees (Mazzoni et al. 2006) as shown in Fig. 26. The beams and columns were modeled using the nonlinear force-based beam-column fiber element which can strictly satisfy equilibrium and accurately capture the distribution of

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,
Fig. 26 Model for an exterior PT connection with WHPs and associated columns and beam

inelasticity along the depth of the section and along the length of the physical member. For the beam, two fiber elements with cross-sections having different flange thickness were used to account for the beam flange-reinforcing plates. Each fiber was associated with uniaxial bilinear elastoplastic stress-strain behavior (Steel01 in OpenSees) with a post-yield stiffness ratio equal to 0.01.

Rigid elastic beam-column elements were used to model the beam-column interface where gap opening and closing take place. To accurately capture the gap-opening mechanism in the beam-column interface, three zero-length contact spring elements were placed at equal spaces along the beam flange thickness. These contact springs were associated with an elastic compression – no tension force-displacement behavior (ENT material in OpenSees). A value

of the compression stiffness equal to 20 times the axial stiffness of the beam K_b was assigned to these contact springs. Larger values for this stiffness were found to produce practically the same results but with higher computational cost, i.e., more iterations to achieve convergence and equilibrium in nonlinear analysis. To capture the hysteretic energy dissipation capacity of the connection, two zero-length hysteretic springs were placed at the exact locations of WHPs along the depth of the beam web. These springs were associated with a smooth hysteretic Giuffre-Menegotto-Pinto model with isotropic hardening (Steel 02 material in OpenSees). To account for panel zone shear deformations and possible yielding, the panel zone was modeled using the Scissors model which introduces four additional rigid elastic beam-column elements and two nodes in the center of the panel zone

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,
Fig. 27 Base shear coefficient – roof drift behavior from nonlinear monotonic (pushover) static analysis

connected with two zero-length rotational springs. These springs are associated with bilinear elastoplastic hysteretic rules (Steel01 material in OpenSees) with properties calculated to reflect the contribution of the column web (including doubler plates) and the column flanges in the force–shear deformation panel zone behavior. This simple panel zone model has been found to produce identical results to those of the more computationally expensive Krawinkler panel zone model (Charney and Downs 2004). PT bars were modeled using a truss element running parallel to beam centerline axis and connected to the exterior nodes of the panel zones of the exterior columns of the SC-MRF. The truss element has a cross-section area A_{PT} equal to that of both PT bars. To account for posttensioning, an initial strain equal to $F_{PT,i}/(A_{PT} \cdot E_{PT})$ was first assigned to the truss element where E_{PT} is the modulus of elasticity of the PT bar material. However, posttensioning results in shortening of the beams which in turn decreases the posttensioning force. To account for this decrease, the initial strain in the truss element

was increased to ensure that the posttensioning force in the PT bars will be equal to $F_{PT,i}$ after the beam shortening.

The accuracy of the developed model in OpenSees was assessed by comparing the force–deformation and moment–rotation responses of the connection with the experimental results. Detailed comparisons can be found in (Dimopoulos et al. 2013), where it is shown that the numerical model is in acceptable agreement with the experimental response and can be considered as reliable.

Nonlinear Monotonic and Cyclic Static Analysis

Figure 27 shows the base shear coefficient (V/W) – roof drift (θ_r) behavior of the conventional MRF and the SC-MRF from nonlinear monotonic (pushover) static analysis. V is the base shear and W is the seismic weight. An inverted triangular force distribution along with roof displacement control was used in these analyses. The MRF and the SC-MRF have comparable base shear strengths and comparable

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures,

Fig. 28 Base shear coefficient – roof drift behavior from nonlinear cyclic (push–pull) static analysis

initial stiffness. The pushover curves are plotted along with points associated with structural limit states and vertical lines corresponding to roof drifts expected under the FOE, DBE, and MCE. The structural limit states for the conventional MRF are beam yielding and base column yielding and occur at θ_r equal to 0.82 % and 0.92 %, respectively. The conventional MRF avoids damage under the FOE but experiences significant damage under the DBE. The structural limit states for the SC-MRF are decompression in a PT connection, WHP yielding, base column yielding, and beam yielding. Figure 27 shows that the beams of the SC-MRF are damage-free for θ_r equal or lower than 3 %, i.e., drifts higher than the MCE. Damage in the SC-MRF is experienced at the column bases that yield at θ_r equal to 0.97 %. No PT bar yielding is observed. The first decompression occurs at θ_r equal to 0.4 % while WHPs yield at θ_r equal to 0.62 % which is almost equal to the FOE drift. Decompression does not involve damage, while yielding of the WHPs is acceptable under low drifts since WHPs can be easily replaced without bolting or welding. The conventional MRF experiences softening at θ_r equal to 1.25 %, while the SC-MRF shows a more gradual softening behavior. In particular, the SC-MRF shows softening due to decompression in the PT connections at low drifts and further softening due to plastic deformations at the column bases and yielding of a large number of WHPs at θ_r equal to 1 %. Figure 28 shows the $V/W - \theta_r$ behavior of the MRF and the SC-MRF from nonlinear cyclic

(push–pull) static analysis. The first cycle of the analysis is performed up to the DBE drift while the next cycle up to the MCE drift. The SC-MRF shows full re-centering capability under the DBE, adequate energy dissipation, and a small residual drift under the MCE due to plastic deformations at the column bases. The conventional MRF shows large energy dissipation capacity due to plastic deformations at the beam ends and at the column bases and the possibility of experiencing large residual drifts under the DBE and MCE.

Nonlinear Dynamic Time History Analyses

Ground Motions

A set of 20 earthquake ground motions recorded on ground type B were used in 2D nonlinear dynamic time history analyses to evaluate the performance of the SC-MRF and the performance of the conventional MRF. None of the ground motions exhibit near-fault forward directivity effects. The ground motions were scaled to the DBE level using the scaling procedure of Somerville (1997). Table 4 provides the scale factors and information on the 20 earthquake ground motions.

Modeling for Nonlinear Dynamic Analysis

Two-dimensional nonlinear analytical models of the conventional MRF and the SC-MRF were developed for nonlinear dynamic analyses in OpenSees. Nonlinear beam–column fiber elements were used for the beams and columns

and the Scissors model (Charney and Downs 2004) for the panel zones of the conventional MRF and the SC-MRF. A diaphragm constraint is imposed on each floor level of the conventional MRF. Stiff truss elements were used to connect the internal nodes of each bay of the SC-MRF to allow beam shortening due to posttensioning, gap opening in PT connections, and to consider the use of a discontinuous slab proposed by Chou et al. (2009). The model of Fig. 26 was used to model the PT connections and the associated beams and columns of the SC-MRF. Each dynamic analysis was extended well beyond the actual earthquake time (the ground motions were padded with zeros) to allow for damped free vibration decay and accurate residual drifts calculation.

Seismic Response Results

Figure 29 compares the roof drift time histories of the conventional MRF and the SC-MRF under the 5082-235 ground motion scaled to the DBE and MCE. Near the end of the time histories, the SC-MRF oscillates around the origin, indicating negligible residual drift, while the conventional MRF experiences residual drifts. The peak roof displacements of the MRF and the SC-MRF are similar. Figure 30 shows the stress–strain hysteresis at points A and B (extreme column base flange fibers), and C and D (extreme beam flange fibers) of the first story of the conventional MRF under the 5082-235 ground motion scaled to the DBE and MCE. Figure 31 presents similar information for the SC-MRF. The stress–strain hysteresis immediately after the end of the beam

D, E, and F of the SC-MRF under the 5082-235 ground motion scaled at the DBE and MCE

Steel Posttensioned Connections with Web Hourglass Pins: Toward Earthquake Resilient Steel Structures, Fig. 32 Statistics of peak story drifts of the

conventional MRF and the SC-MRF under 20 earthquake ground motions scaled to the FOE, DBE, and MCE

flange-reinforcing plate (points E and F) of the SC-MRF is also shown. The SC-MRF eliminates beam plastic deformations under both the DBE and MCE, while the conventional MRF experiences appreciable beam damage. Figures 28 and 29 show that the column bases of the SC-MRF experience larger plastic deformations than those of the column bases of the conventional MRF.

Figure 32 shows μ , $\mu + \sigma$, and median $\theta_{s-\max}$ values under the earthquake ground motions of Table 4 scaled to the FOE, DBE, and MCE. The μ , $\mu + \sigma$ and median height-wise $\theta_{s-\max}$ distributions show identical shapes. The MRF has the largest $\theta_{s-\max}$ in the fourth story with μ values equal to 0.75 % under the FOE, 1.65 % under the DBE, and 2.2 % under the MCE, i.e., close to the design values of 0.64 % under the FOE and 1.6 % under the DBE and smaller than the design value of 2.4 % under the MCE. The SC-MRF has the largest $\theta_{s-\max}$ in the fourth story with mean values equal to 0.75 % under the FOE, 1.8 % under the DBE, and 2.5 % under the MCE, i.e., slightly larger than the DBE and MCE design ones. Figure 33 shows μ , $\mu + \sigma$, and median values of the residual story drifts, $\theta_{s-\text{res}}$. $\theta_{s-\text{res}}$ values show a

uniform height-wise distribution for the conventional MRF and large dispersion compared to that of $\theta_{s-\max}$. The largest $\theta_{s-\text{res}}$ of the conventional MRF occurs in the first story with mean values equal to 0.1 % under the DBE and 0.3 % under the MCE. The associated $\mu + \sigma$ $\theta_{s-\text{res}}$ values are equal to 0.25 % under the DBE and 0.6 % under the MCE. The latter $\theta_{s-\text{res}}$ values indicate that repair of damage in the conventional MRF would be costly and disruptive after the DBE and not financially viable after the MCE (Mc Cormick et al. 2008). These results highlight the need for Eurocode 8 to include residual deformations as an additional seismic performance parameter. The SC-MRF practically eliminates residual story drifts apart from the first story that has μ and $\mu + \sigma$ $\theta_{s-\text{res}}$ values equal to 0.1 % and 0.15 % under both the DBE and MCE. The latter $\theta_{s-\text{res}}$ values are lower than the global sway imperfections defined in EC3 (2003) and so it can be assumed that there will be no need for these residual drifts to be straightened out. Figure 33 shows small $\mu + \sigma$ $\theta_{s-\text{res}}$ values in the third story of the SC-MRF due to modest yielding in the beam ends.

conventional MRF and the SC-MRF under 20 earthquake ground motions scaled to the FOE, DBE, and MCE

Conclusions

A new steel posttensioned connection was developed for use in self-centering moment-resisting frames. The connection performance was validated through a large-scale experimental program and extensive numerical analyses, including seismic analysis of steel frames equipped with the proposed connection. The main conclusions of this research are:

(a) *Based on the experimental results:*

- The proposed connection has stable self-centering behavior, enhanced energy dissipation capacity, and strength and stiffness comparable to those of a welded connection.
- The proposed connection eliminates residual deformations and avoids beam damage for drifts lower or equal to 6 %.
- A simplified analytical procedure using plastic analysis and simple mechanics was found to accurately predict the connection behavior.
- Repeatable tests on a connection specimen were conducted along with replacing

damaged WHPs. These tests showed that WHPs can be easily replaced without welding or bolting, and hence, the proposed connection can be repaired with minimal disturbance to building use or occupation in the aftermath of a major earthquake.

- Web local buckling at the connection region after the beam flange-reinforcing plates can be avoided by using web stiffeners. However, this detailing results in excessive local yielding at the beam–column interface due to high bearing forces.
- To accommodate the gravity loads of the frame and to facilitate the replacement procedure of the damaged WHPs, it is necessary to include a vertical loading transfer system, e.g., a shear tab with slotted holes or a seat angle below the beam.
- It should be emphasized that the tests described herein were performed on a 300 mm deep beam section. For a given rotation, the demand on the WHPs and PT bars is expected to increase for deeper sections. The response of the proposed

connection should be verified by using deeper beam sections.

(b) *Based on the finite element simulations:*

- The developed nonlinear FEM models can be reliably used to assess the design of the proposed connection as they are capable to trace the hysteretic behavior and predict the local failure modes both of the individual WHPs and the connection when subjected to either monotonic or cyclic loading.
- The FEM analyses confirm that for drifts equal or lower than those expected under the design basis earthquake (DBE), damage in a carefully designed connection is concentrated in the WHPs which are components that can be very easily replaced without welding or bolting.

(c) *Based on the seismic analyses of steel frames with the proposed connection:*

- The proposed model for the PT connection with WHPs and the associated beams and columns has been calibrated against experimental results and found to accurately simulate the hysteretic behavior of the PT connection.
- Nonlinear static monotonic (pushover) analysis shows that the conventional MRF and the SC-MRF have comparable base shear strength and initial stiffness. The conventional MRF experiences significant damage in beams at the DBE drift. On the other hand, the SC-MRF has damage-free beams for drifts even higher than the MCE drift.
- Nonlinear static cyclic (push–pull) analysis shows that the SC-MRF has full re-centering capability and adequate energy dissipation capacity under the DBE.
- Seismic analyses show that the conventional MRF and the SC-MRF have comparable peak story drifts. In particular, the conventional MRF has slightly lower peak story drifts than the SC-MRF. For both frames through the mean peak story drifts are close to the design values.
- Seismic analyses show that the SC-MRF practically eliminates residual story drifts

apart from the first story which sustains small residual drifts due to plastic deformations at the column bases. The mean plus one standard deviation value of the first story residual drift of the SC-MRF is equal to 0.15 % under both the DBE and MCE which is considered small and does not need to be straightened out.

- Seismic analyses show that the mean plus one standard deviation value of the maximum residual story drift of the conventional MRF is 0.25 % under the DBE and 0.6 % under the MCE. These values indicate that repair of damage in the conventional MRF would be costly and disruptive after the DBE and not financially viable after the MCE.
- Seismic analyses show that the beams of the SC-MRF do not exhibit any yielding even under the MCE, while significant inelastic deformations are developed in the beams of the MRF under both the DBE and MCE. On the other hand, the column bases of the SC-MRF experience larger inelastic deformations than those of the conventional MRF.

Summary

This contribution presents the experimental and analytical validation on a new self-centering steel posttensioned connection using web hourglass shape steel pins (WHPs) as energy dissipation devices. The connection isolates inelastic deformations in WHPs, avoids damage in other connection parts as well as in beams and columns, and eliminates residual drifts. WHPs do not interfere with the composite slab and can be very easily replaced without bolting or welding, and so, the connection enables nondisruptive repair and rapid return to building occupancy in the aftermath of a strong earthquake. The experimental results are first presented followed by parametric studies using nonlinear finite element models. A simplified nonlinear model for the connection and the associated beams and columns that consist of nonlinear beam–column

elements and hysteretic and contact zero-length spring elements appropriately placed in the beam–column interface was also developed in OpenSees. The model was calibrated against experimental results and found to accurately simulate the connection behavior. A prototype building was selected and designed as a conventional steel moment-resisting frame (MRF) according to Eurocode 8 or as a self-centering steel MRF (SC-MRF) using the connection with WHPs. Seismic analyses results show that the conventional MRF and the SC-MRF have comparable peak story drifts and highlight the inherent potential of the SC-MRF to eliminate damage in beams and residual drifts. It is shown that repair of damage in the conventional MRF will be costly and disruptive after the design basis earthquake and not financially viable after the maximum considered earthquake due to large residual drifts.

Introduction

The use of metals as the principal construction material for modern buildings and bridges dates back to the beginning of the Industrial Revolution (Bodsworth 2001; Ashton 1968). Three metallic materials have been commonly used in the construction industry: cast and wrought iron, steel,

and aluminum. Cast iron, which was first manufactured as early as fifth century BC, is typically considered to be too brittle and difficult to join but received widespread application in construction through the late eighteenth century. The use of cast iron is uncommon in today's construction industry, but some ductile cast irons continue to be used in specialized applications such as water pipes. The use of cast iron was rapidly replaced by wrought iron, which was easier to work with, leading to the construction of the first large metal structure, the Iron Bridge at Coalbrookdale by A. Darby in 1780 (www.greatbuildings.com/buildings/Iron_Bridge_at_Coalbrookdale.html). Extensive use of iron continued through the first half of the nineteenth century, culminating in iconic structures such as the Crystal Palace in London (http://en.wikipedia.org/wiki/The_Crystal_Palace).

Wrought iron began to be replaced by steel in civil structures when the latter became commercially available in large quantities in the late nineteenth century AD through the development of the Siemens and Bessemer processes and the development of rolling technologies (Bodsworth 2001; Ashton 1968; Halmos 2000). Initially steel was rolled into flat plates and small sections (angles and channels or L- and C-sections) that were assembled into larger structural sections through riveting (Fig. 1), just as it had been done for wrought iron. Riveted, or built-up sections, were used through the first half of the twentieth century.

Steel rolling, which began to produce large sections at the turn of the twentieth century (Fig. 2), led to the development of optimal W- (or H-) sections for carrying flexure and axial loads. Advanced fabrication techniques, recycling, and improvements in energy consumption during production have resulted in extremely efficient and sustainable construction practices in the steel industry in the twenty-first century. Much of today's structural steel is manufactured in minimills that utilize scrap steel as their source materials; some estimates are that up to 95 % of steel is recycled in the USA.

The use of aluminum, which became common in the 1940s when the need to build light

airplanes made its strength-to-weight ratio very attractive, is also limited in today's construction industry due to cost and welding issues. Its use is limited mostly to facades, finishes, and nonstructural elements.

Steel for Seismic Applications

A large number of improvements through better metallurgy (heat treatments (Tylecote 1976) and the development of alloy steels with large deformation capacity, Fig. 3) and joinery (welding and high-strength bolts, Fig. 4) in the twentieth century have made steel the preferred construction

material to withstand the large cyclic loads imposed by earthquakes.

The use of steel in multistory framed buildings began in the 1880s in Chicago, notably with the Home Insurance Building (Condit 1968) and similar skyscraper buildings. The use of steel frames was still in its maturing stage when the excellent behavior of steel structures, when subjected to large ground motions, became evident after the San Francisco earthquake and fire of 1906 (Kurzman 2001). These events highlighted the lateral resistance (strength) and deformation capacity (ductility) of steel structures (Hamburger and Meyer 2006), but also their susceptibility to fire unless suitably protected (Fig. 5).

Steel Structures, Fig. 5 Damaged buildings from the 1906 San Francisco earthquake and fire. The two tall steel frames were under construction and were not damaged.

The structure of the burned building in the center of the photograph was undamaged (en.wikipedia.org)

Most structural members were made up of riveted plates and connections for larger structures (Fig. 6) and riveted smaller rolled sections for buildings (Fig. 7). Structures that contained steel columns and beams encased in masonry or concrete survived the earthquake and fire relatively unscathed (Fig. 5). The superior performance of steel frames was enshrined in the report by ASCE (1906), which stated: *The well-designed steel frame offers the best solution of the question of an earthquake proof building, as all the stresses can be cared for.*

This and similar observations by many others led to the widespread utilization of such systems in the earthquake-prone areas of the Western USA in the first half of the twentieth century. These structures consisted of rolled steel sections joined by connections made by riveted steel

angles or plates. Initially, the encasement was made from masonry rubble inside masonry facades, but this was later replaced by encasement with lightly reinforced concrete (Fig. 7). Today, the synergistic use of steel in tension and concrete in compression has led to the development of composite steel–concrete construction particularly for high-rise construction (Viest et al. 1997).

Three important developments have occurred in the steel construction industry since the 1950s. The first development is the change of joining methods, as rivets have been replaced by both high-strength bolts and welds. The use of industrialized welding, which was developed in the early twentieth century for the shipping industry, led to much simpler, stronger, and stiffer connections (Fig. 8). These connections were considered

for many years to be the most reliable structural system in seismic areas. Failures in welded connections observed after the 1994 Northridge (Fig. 9) and 1995 Kobe earthquakes (FEMA 355E 2000a) have led to radical changes in the specifications for such joints. While both joining methods can be used in seismic construction, the use of welding requires extensive planning, inspection, and QA/QC procedures to ensure desirable ductile performance (FEMA 355B 2000b). In the aftermath of those failures, design requirements for bolted connections have also been increased even though few bolted

connection failures have been observed after earthquakes, except for the case of under-designed brace connections. Welded connections are still preferred by many designers because of their perceived superior strength and stiffness characteristics and ease of design when compared to bolted connections.

The second development is that most floors in steel structures have become composite ones, with the use of shear studs to connect floor beams and girders to concrete slab cast in metal deck (Viest et al. 1997). The use of the metal deck as both formwork and reinforcement, the

**Steel Structures,**

Fig. 9 Laboratory simulation of connection weld brittle failure as observed in the 1994 Northridge earthquake (The photo shows the area circled in red in Fig. 7 (© RTLeon))

ease of welding the shear studs that act as connectors between the steel beam and the concrete floor, and the tremendous increases in strength and stiffness have made composite floor construction a most economical system (Fig. 10). Floors of this type provide sufficient in-plane stiffness, such that all parts of the lateral force-resisting system can be assumed to work together (rigid floor diaphragm assumption), so that all lateral load-resisting systems can act concurrently. This characteristic is important as many frames in the USA utilize lateral load systems engaging only partially the perimeter frames.

The third important change has been the development of numerous new structural systems and proprietary connections that have given designers a very wide choice of technologies for use in seismic design. The development of such systems has been made possible by both extensive experimental testing and advanced simulation tools brought forth by the use of computers and improvements in analytical methods. Some of these systems are discussed under *Structural Systems* later in this article. Striking evidence of the advantages of these new systems can be seen in the excellent performance of steel *eccentrically braced frames* (EBF) in the recent

Steel Structures,**Fig. 10** Typical composite floor system (© RTLeon)**Steel Structures,****Fig. 11** Ductility of steel as shown by the $>25\%$ elongation of the original coupon (*bottom*) to the fractured one (*top*) (© RTLeon)

Christchurch earthquakes (Clifton et al. 2011) as compared to that of modern reinforced *special moment-resisting reinforced concrete frame* (SMRF-CR) and shear wall structures (Leon et al. 2014).

Steel Properties

For structural design purposes, steel is an iron-carbon alloy that contains many additional alloying elements such as Mn, Mo, Cr, Ni, and V. A large variety of mechanical properties can be achieved with steels by either varying its alloys (primarily carbon which constitutes 0.2–0.6 % of steel) and/or subjecting the material to different heat treatments that change its grain microstructure.

Steel is an ideal material for seismic design because both of its isotropic and homogeneous properties and its ability to undergo large local plastic deformations before failure. Figure 11 shows a typical mild steel test coupon elongating in excess of 15 % over a 2 in. length and more than 50 % locally. The stress–strain (or load–deformation) behavior for this type of steel is shown by the red line in Fig. 12. After an initial stiff elastic response, the steel reaches its yield point (knee in the curve), the steel deforms plastically (i.e., undergoing large deformations with little small increments of load, shown by the flat portion of the curve), and picks up additional resistance as the deformation becomes large (last part of the curve, termed the strain-hardening region). The curve for a steel coupon subjected to large deformation reversals such as those experienced

Steel Structures,

Fig. 12 Cyclic stress–strain behavior of a mild structural steel
(© Alan Pense, Lehigh University)

locally during a large seismic event is shown by the rest of the curves in Fig. 12. If loaded cyclically, the steel will show fat, stable, and hardening hysteresis (stress–strain) loops, evidence of good energy dissipation capacity. Failure by ductile fracture will ideally occur after many cycles of deformation. For seismic design, steel will perform best when deformed in shear.

Steels for structural use are classified as carbon steels, high-strength low-alloy steels, and alloy steels. For design purposes, these steels can be assumed to have a density of 7.85 g/cm^3 , a modulus of elasticity of 210 GPa, and a Poisson's ratio of 0.3. Carbon steels are classified based on the percentage of carbon. Mild carbon steels (0.15–0.29 % C) with yield points in the range of 220–250 MPa and tensile strengths of 400–500 MPa are the most common structural carbon steels. Typically, an increase in carbon percent raises the yield point and increases hardness, but reduces ductility and makes welding more difficult. These drawbacks can be minimized by heat treatments.

The stress–strain behavior of a mild carbon steel is characterized by a sharp yield point and large ultimate strains (percent elongation $>20\%$). High-strength low-alloy steels exhibit higher yield points (345–480 MPa) and somewhat larger tensile strengths (450–600 MPa) without an appreciable drop in ductility. Alloy steels are heat-treated steels (mostly quenched and tempered) with yield points of 550–760 MPa, but lower tensile to yield ratios and ductility than for other structural steels.

Other important engineering properties needed for seismic design are notch toughness and weldability. Notch toughness refers to the ability of the material to resist fracture propagation from an existing defect when subjected to dynamic loads. Fracture propagation is resisted through local plastic deformations and is primarily a function of temperature and heat treatment. Weldability is primarily a matter of obtaining a structural joint free of any undesirable defects by utilizing appropriate electrode materials and weld procedure specifications (WPS).

Structural Systems

As noted earlier, one of the great developments in seismic construction has been the promotion of a large variety of steel structural systems. These systems are classified as *special*, *intermediate*, and *ordinary* based on the amount of seismic detailing present. A *special* system will require great care in design and detailing to obtain the large deformation capacity needed to activate the plastic deformations and energy dissipation characteristic of these systems. The benefit of a special system is lower design lateral forces, which results in savings in both material and construction costs.

At its most basic, lateral force-resisting systems can be visualized as a continuum, with a pure frame system (Fig. 13a) at one extreme and a wall system at the other end (Fig. 13e). In these

Steel Structures, Fig. 13 Deformation mechanisms for typical steel seismic force-resisting systems (© RTLeon)

figures, only the primary structural elements are shown; secondary structural elements, such as out-of-plane braces, floor slabs, chord, collectors, and diaphragms, are not shown. Also not shown are *nonstructural elements*, such as partition walls, which are assumed not to contribute significantly to lateral resistance and should be designed so as not to interact with the primary structural members. If not properly isolated, nonstructural elements can have deleterious effects on frame behavior.

The *moment-resisting frame* (MRF), a combination of slender beams and columns, was the first type of steel structural system used and which showed excellent seismic behavior (Fig. 5). In a pure moment-resisting frame (MRF, Fig. 13a), the lateral deformations are to be accommodated primarily by bending of the beams and columns, shear deformation of the panel zone, and the formation of *plastic hinges*, or areas of concentrated plasticity, in the beams. The yielding of the beam steel and the formation of a plastic hinge are shown by the flaking of the whitewash in the critical section of the beam in Fig. 14. All of these deformation mechanisms can

be very ductile when properly designed, but pure frame structures tend to be rather flexible. To eliminate or limit damage to nonstructural elements and contents under both small earthquakes and large wind loads, special moment-resisting frames need to meet some maximum deformation criteria (typically $\approx 3\%$ drift under earthquake loads and 0.25% under wind loads) and thus are said to be *drift controlled*. It is clear that rigid and strong connections that limit the shear deformations of the panel zones and promote beam yielding are desirable (note thick end plate and large bolts in the connection in Fig. 14), as long as the local buckling of the beam flanges and web can be delayed. In addition, mechanisms that can reduce the strength demand at the welds at the joint without substantially decreasing stiffness, such as reduced beam sections (RBS, Fig. 15), are desirable. In an RBS, the steel in the beam flanges is cut to intentionally weaken the beam and promote the formation of a plastic hinge away from the welded connection.

At the other extreme, one can think of a wall structure composed of a steel frame infilled with a steel plate (Fig. 13e) as the analogue to a

Steel Structures,

Fig. 14 End-plate connection showing plastic hinging followed shortly by local buckling of the flanges (© RTLeon)

**Steel Structures,**

Fig. 15 End-plate connection showing reduced beam section (RBS) (© RTLeon)

reinforced concrete shear wall system. For economy reasons, in steel structures it is desirable to use a rather thin plate. When displaced laterally, the plate will buckle in compression along one diagonal, allowing a tension field to develop in the other diagonal (Fig. 16). This creates a large tensile strut mechanism that transfers the horizontal forces similarly to a braced frame (Fig. 13c). This force transfer is exactly the inverse of a concrete shear wall structure, where a compression strut will form, as the concrete is strong in compression but weak in tension. The great advantage of a steel shear wall over a concrete one is that whereas the behavior of a concrete shear wall will degrade rapidly due to an X-crack pattern that develops with cycling, the steel shear wall performance will not degrade substantially due to the

post-buckling strength of metal plates. Steel-plated shear walls are relatively modern structures, with a few implementations as far back as the late 1970s, but have become more accepted only in the last decade or so.

In between these two limits, one can visualize a large number of alternatives. Starting at the bottom of Fig. 13, one can visualize a system where the struts in the walls are replaced by discrete, strong, and rigid braces (or diagonal elements, Fig. 17). This system is known as a *buckling-restrained brace frames* (BRBF, Fig. 13d), because the braces in compression are so stout that they will not buckle but yield. The buckling in these systems is limited to an interior core of the brace, with the exterior portion being disconnected and acting only to restrict the

Steel Structures,

Fig. 16 Thin plate under lateral loads showing tension-field action from *top right to bottom left* and buckling in the opposite direction (© M. Kurata)

**Steel Structures,**

Fig. 17 Use of large BRBs in a modern structure (Berkeley Animal Shelter) (© ci. berkeley.ca.usa)

buckling of the brace. Many of these buckling-restrained braces are proprietary devices. BRBF systems originated in Japan in the early 1990s and are a very common type of structural system in the Western USA today.

The next system is similar, except that the braces are not so stiff and they will buckle slightly in compression. This system is known as a *special concentrically braced frame* (SCBF, Fig. 13c). In this system, the brace in tension is assumed to carry most of the force (generally about 70 %) as the compression brace will buckle and be able to provide only its post-buckling resistance. *Concentrically braced*

frames (CBF) originated when engineers began to stiffen MRF for wind loads in the 1910s using light diagonals, as in the Sather Tower in Berkeley, CA (Fig. 18). Modern CBF are much stiffer than SMRF, but generally less ductile as the buckling of the braces can lead to a concentration of deformations in a few floors. It is not clear when CBF began to be used in seismic systems (i.e., going from CBF to SCBF), but seismic design recommendations for braced frames began to appear in the 1960s. The original CBF had slender X-shaped braces in which only the brace in tension provided resistance. There are a large number of variations of this

Steel Structures, Fig. 18 Sather Tower under construction (1914)

system (Fig. 19), each with its own design requirements and behavior characteristics.

Finally, one can think of beginning to move the brace in each bay horizontally, such that a hybrid structure between a pure moment frame and a braced frame is achieved. This is known as an *eccentrically braced frame* (Fig. 13b). In these structures, the central portion of the beam, known as the link, will deform and yield in shear if the link is short and in a combination of flexure and shear if the link is longer. Eccentrically braced frames have performed extremely well in recent earthquakes (Fig. 20), with numerous such structures providing superior performance during the 2011 Christchurch earthquake (Clifton et al. 2011).

Basis of Design

The seismic design of steel structures is predicated on having little or no structural damage under a service-level earthquake, moderate but rapidly repairable damage under a moderate earthquake, and not to collapse and cause loss of lives in the event of the design-level earthquake. Until recently, design specifications typically addressed only the design-level earthquake through a series of prescriptive design provisions intended to address ultimate strength design (ULD) criteria (limit states). However, the costs and time related to both loss of contents and functionality under smaller events and the desire to provide some freedom from prescriptive building codes have begun to drive the design process toward a performance-based design (PBD) approach. A pure PBD approach will be completely non-prescriptive, giving the structural engineer complete freedom in determining both the limit states and how to comply with them. In the short term (next 5–15 years), it is likely that a hybrid model for seismic design with elements of both ULS and PBD will emerge.

Whether a ULD or a PBD approach is used, the basis for design of steel structures remains the need to provide ductility, redundancy, robustness, and resiliency. Ductility comes from a synergistic use of the very ductile behavior of steel at the material level to create elements, connections, and structural systems capable of sustaining large inelastic deformations without appreciable stiffness or strength degradation. From the design standpoint, most of our ductility is ensured through a series of prescriptive requirements that have been developed through observed performance in past earthquakes (Fig. 19), advanced analytical studies (Fig. 20), and complex laboratory testing (Figs. 14, 15, and 16).

Redundancy is the ability of the structure to redistribute forces as inelastic action occurs in order to efficiently activate all major lateral load resistance systems. In its simplest form, redundancy can be defined as providing multiple load paths in a structure. Redundancy is primarily a function of the number and ductility of the lateral

Steel Structures, Fig. 19 Different braced frame configurations (© RTLeon)

Steel Structures, Fig. 20 Damaged eccentrically brace frame, showing yielding of the shear link element (© RTLeon)

load-resisting systems employed, the system's rational 3D configuration, the ductility of connections, the strength of diaphragms and collector elements, and the detailing of the structure. Importantly, redundancy implies activating not only the lateral load-resisting system but also the gravity load system and other nonstructural elements that can contribute to the strength and stiffness of the system.

Robustness refers to the ability of the structural system to limit any failure to a relatively small part of the structure so that the consequences of the failure are not disproportionate to the initial failure. For example, a common way of determining the robustness of a moment frame is to remove an interior column in a lower floor (something that may happen during an earthquake) and assess the stability of the system under gravity loads (to make sure that the structure does not “pancake” and crush its

occupants). If the structure does not collapse, regardless of its damaged state, it will be considered robust. Clearly, a client can establish more stringent criteria for robustness in her/his structure if deemed necessary.

Resiliency refers to the ability of the structure to fulfill its intended functions after a large event. For example, a level-four trauma hospital would be resilient if it can continue to function uninterrupted after the design-level earthquake. While it is possible today to provide that level of performance for the structural system, it is rather more difficult to do it for all the other systems (from electricity, water, oxygen, and the myriad of IT systems) present in such hospitals. For a large store, it may mean being able to get back in business within a few days and at a minimum of cost. Resiliency can be quantified in many ways, including the ability to resist ground motions significantly larger than the design one, the

costs to repair the structure, the time needed to carry out such repairs, and the indirect costs associated with business interruption.

Connections

In order to satisfy ductility, redundancy, robustness, and resiliency criteria, steel structures in seismic areas need to be designed primarily to avoid any type of brittle failure modes, which can result in sudden losses of local or global strength, stiffness, and stability. In general, it is possible to design and fabricate steel members (beams, columns, braces, and walls) to avoid these type of failures through close attention to proper material selection, using compact sections (i.e., keeping a small enough ratio of the width of an element to its length.) and providing lateral bracing to prevent out-of-plane buckling. The potential weak links in steel structures are the connections, which must transfer very large forces through complex force paths. The design of connections for seismic loads is a complex design issue as it is difficult to predict failure modes and their interactions.

From the standpoint of steel as a material, brittle failures can occur because of a combination of poor selection of or unmatched materials, large stress concentrations due to poor design or execution, and large triaxial state of stresses. These conditions can often arise in connections. Problems with welded connections were evidenced by many failures in the 1994 Northridge earthquake (Fig. 9). In the welds to the beam flanges in these connections, large triaxial stresses arise from a combination of multidirectional forces, residual stresses from welding, and the inevitable imperfections in the welds. These conditions lead to brittle material behavior because shear forces, the source of most deformations in steel, are small when compared to normal forces. Even if only minor overall damage to the structures was observed in structures with failed connections after the Northridge earthquake, a major effort was launched in the USA to better understand connection behavior.

As part of that effort, known as the SAC Project (FEMA 355B 2000b), extensive experimental studies were conducted on bolted and welded connections. The probability of brittle failure in connections can be minimized by (1) proper attention to selecting appropriate base materials and welding consumables with high toughness; (2) careful consideration of surface preparation, preheating, and welding sequences; (3) inspection; and (4) nondestructive testing. This amounts to the need for a very comprehensive quality assurance/quality control (QA/QC) plan throughout all phases of the construction projects (materials, fabrication, and erection). In the USA, these requirements are now embodied in the required weld procedure specifications (WPS).

Connections with bolts are usually less susceptible to material-type problems, but require more care in the fabrication as slight misalignments and exceeding tolerances can lead to severe problems during erection. In addition, the force transfer mechanisms in connections with bolts are less obvious and require more detailed computations than those with welds. Finally, in general, bolted connections will be less rigid than welded ones, requiring that this semirigid behavior be included in the analyses, substantially complicating the design process. Bolted connections, such as the end plates shown in Figs. 14 and 15, when properly detailed, can provide excellent performance.

From the structural standpoint, ductility should arise in “plastic hinges” or zones of concentrated plasticity primarily in beams. The behavior of a plastic hinge can be visualized as that of a nonlinear rotational spring. The ability of these hinges to rotate depends primarily on delaying the onset of any local or global buckling of the section. Local buckling (Fig. 14) is mostly dependent on the slenderness (width/thickness) ratio of the flanges and webs, and codes prescribe strict limits to ensure that this type of buckling does not occur until large rotations are achieved. Global buckling of a beam or column, which in this case implies large out-of-plane displacements, is also controlled by slenderness criteria,

Steel Structures, Fig. 21 (a) T-stub bolted connection and (b) corresponding component model (© RTLeon)

in the form of length/moment of inertia ratios. Global buckling can be minimized by the addition of bracing along the member length, but this leads to additional costs and complications in the construction process. Global buckling or collapse of the structure can occur when large lateral deformations arise and the gravity forces result in large additional second-order effects. Global buckling is addressed in design by specifying strict drift (lateral deformation) limits and conducting advanced analyses that ensure overall stability.

As the results of the research began to filter into practice, a number of new design technologies became popular. For example, for the successful design of a T-stub connection (Fig. 21a), it is necessary to first determine all the possible ductile and brittle failure modes and prioritize them from most brittle to most ductile. One approach to this task is the component approach, in which each deformation mechanism in a joint is identified and individually quantified through a series of small laboratory component tests and associated analytical studies. These tests are carefully designed to measure one deformation component at a time. Each of these components is then represented by a spring with either linear or nonlinear characteristics (Fig. 21b). These

springs are arranged in series or in parallel and the overall moment-rotation ($M-\theta$) curve derived with the aid of simple computer programs that conduct the analysis of the spring system. In this example, the K1 and K2 springs model the panel zone deformation due to shear, while springs K3 and K4 model the bending deformations of the T-stubs. Springs K3 and K4 are made up of the contributions of several other springs that model different deformation components. With the aid of this approach, it is possible to achieve designs that meet and exceed current performance requirements. Care in the design of these connections can lead to very successful designs (Fig. 22).

Because the design of connections is a difficult and time-consuming task, in the USA, the idea of “prequalifying” connections has arisen (AISC 358 2010). In this case, an extensive experimental campaign is conducted to test a range of beam and column sizes with a particular type of connection. If the results indicate reliable ductile cyclic behavior to rotations around 4 %, after careful examination of all the results, the connection will become “prequalified.” This implies that a series of simple, predefined design steps is all that is necessary to design that type of connection.

proprietary connection
(ConXTech, www.conxtech.com)

An interesting and important consequence of the “prequalification” process is that a number of proprietary connections have entered the market. In these cases, the manufacturer of the connection will provide all the necessary connection design data and manufacture all proprietary pieces. For example, the ConXL connection (Fig. 23, ConXtech Inc.) consists of a concrete-filled tube HSS column, RBS beams, and a series of steel castings that make the field assemblage of the connection a fast and simple operation.

Summary

Properly designed modern steel structures can provide superior performance when subjected to very large earthquake motions. The key to good performance is in strict attention to detail in every phase of the construction process: (a) initial selection of the structural form; (b) ductile design of members, particularly with respect to plastic hinge formation; (c) careful attention to connection strength and ductility; (d) frequent

interaction between the designer and fabricator to ensure proper fabrication procedures and tolerances; and (e) proper erection, along with extensive QA/QC for any field welding and bolting needed.

Introduction

The stochastic analysis of structural vibrations deals with the description and characterization of structural loads and responses that are modeled as stochastic processes. The probabilistic characterization of the input process could be extremely complex in time domain where the probability density functions depend on the autocorrelation functions which experimentally have to be specified over given set points. Since this approach is difficult to be used in applications, stochastic vibration analysis of structural linear systems subjected to Gaussian input processes is quite often performed in the frequency domain by means of the spectral analysis. This analysis is a very powerful tool for the analytical and experimental treatment of a large class of physical as well as structural problems subjected to random excitations. The main reasons are (a) the spectrum has an immediate physical interpretation as a power-frequency distribution; (b) the spectrum provides information on the stochastic structure of the process; and (c) the spectrum may be estimated by fairly simple numerical techniques which do not require any specific assumption of the structure of the process.

In the framework of earthquake engineering, the stationary non-white input models were suggested first. These models, which account for site properties and for the dominant frequency in ground motion, fail to reproduce the time-varying intensity typical of real earthquakes ground-motion accelerograms. In order to overcome this drawback, the so-called quasi-stationary (or uniformly modulated) random processes have been introduced (see, e.g., Shinozuka and Sato 1967; Jennings et al. 1969; Hsu and Bernard 1978). These processes are constructed as the product of a stationary zero-mean Gaussian random process by a deterministic function of time; for this reason they are also called separable nonstationary stochastic processes.

Furthermore, a time-varying frequency content is observed in actual accelerogram records. This nonstationary frequency is prevalently due to different arrival times of the primary, secondary, and surface waves that propagate at different velocities through the Earth's crust. To take into account both the simultaneous amplitude and frequency non-stationarity, Spanos and Solomos (1983) proposed a non-separable model introducing a particular *evolutionary power spectral density* (EPSD) function; Fan and Ahmadi (1990) proposed a generalization of the Kanai-Tajimi filter model with time-dependent coefficients; Conte and Peng (1997) defined the ground-motion accelerations as the sum of a finite number of pairwise independent uniformly modulated zero-mean Gaussian stochastic process, the so-called sigma-oscillatory process.

Once the problem is formulated from a mathematical point of view, the further step deals with the evaluation of the structural response to perform the prediction of the safety of structural systems. In this framework, the maximum absolute peak of stationary or nonstationary stochastic responses may be useful in design information of several engineering situations (see, e.g., Lin 1976; Lutes and Sarkani 2004; Muscolino and Palmeri 2005; Li and Chen 2009). Approximate procedures to calculate the statistics of the maximum absolute peak of the response have been proposed. These procedures lead to the probabilistic assessment of structural failure as a function of barrier

crossing rates, distribution of peaks, and extreme values. The latter quantities can be evaluated, for stationary input process, as a function of the well-known *geometric spectral moments* (GSMs) introduced by Vanmarcke (1972). For stationary stochastic response processes, the GSMs are defined as the geometric moments of the one-sided *power spectral density* (PSD) of the response process. Application of spectral methods to nonstationary random processes is more difficult than for the stationary ones; indeed for nonstationary processes the geometric approach fails (Di Paola 1985; Muscolino 1991). To perform the structural reliability in the latter cases, the so-called *nongeometric spectral moments* (NGSMs) have been introduced (Michaelov et al. 1999a, b).

In this study the before outlined topics will be addressed in order to evaluate the spectral characteristics of the structural response that are useful to perform the reliability assessment of linear systems subjected to stationary or nonstationary mono-/multi-correlated excitations.

Spectral Representation of Stochastic Processes

To carry out the spectral analysis, it is necessary to determine the spectral properties of the involved functions. These properties may be determined through the *Fourier-Stieltjes transform* (Priestley 1999).

Let us consider now a zero-mean stationary stochastic process, $F(t)$. This process is characterized by the feature that its *statistical moments* do not change over time and generally arise from any "stable" system which has achieved a "steady state." Moreover, the probabilistic structure of a stationary process is invariant under a shift of the time origin. This is a consequence of the fact that a sample of the process will almost certainly not "decay" to zero at infinity. Then the stationary processes possess infinite energy. Since a stationary process possesses infinite energy, its k th sample, $F^{(k)}(t)$, cannot be represented by the Fourier transform. In fact in this case, the Dirichlet condition is not satisfied. It follows that the spectral representation of a sample of a stationary

stochastic process can be performed only by the *Fourier-Stieltjes integral* (Priestley 1999):

$$F^{(k)}(t) = \int_{-\infty}^{+\infty} \exp(i\omega t) dN^{(k)}(\omega) \quad (1)$$

where $i = \sqrt{-1}$ is the imaginary unit and $N^{(k)}(\omega)$ is the k th sample of the complex stochastic process $N(\omega)$, satisfying the condition

$$E\langle dN(\omega_1) dN^*(\omega_2) \rangle = \delta(\omega_1 - \omega_2) S_{NN}(\omega_1) d\omega_1 d\omega_2 \quad (2)$$

where $\delta(\bullet)$ is the Dirac delta, the symbol $E\langle \bullet \rangle$ means stochastic average, and the asterisk indicates the complex conjugate quantity. Notice that in Eq. 2 sometimes the Kronecker delta is introduced instead of the Dirac delta; this is to avoid the inconsistency of this relationship for $\omega_1 = \omega_2$ (Spanos and Solomos 1983). The relationship (2) shows that the stochastic process $N(\omega)$ is a process with orthogonal increments, in the sense that its increments $dN(\omega_1)$ and $dN(\omega_2)$ at any two distinct points ω_1 and ω_2 are uncorrelated random variables. Furthermore, in Eq. 2 $S_{NN}(\omega)$, which is a real and symmetric function, $S_{NN}(-\omega) = S_{NN}(\omega)$, is the *power spectral density* (PSD) function of the process $N(\omega)$. According to the theory of stationary stochastic process, the autocorrelation function, $R_{FF}(\tau)$, of the zero-mean stationary stochastic process $F(t)$ is a real function given as (Lin 1976; Lutes and Sarkani 2004; Li and Chen 2009)

$$\begin{aligned} R_{FF}(\tau) &= E\langle F(t + \tau) F(t) \rangle \\ &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \exp[i(\omega_1(t + \tau) - \omega_2 t)] \\ &\quad E\langle dN(\omega_1) dN^*(\omega_2) \rangle \end{aligned} \quad (3)$$

which in virtue of Eq. 2 leads to

$$R_{FF}(\tau) = E\langle F(t + \tau) F(t) \rangle = \int_{-\infty}^{\infty} \exp(i\omega\tau) S_{FF}(\omega) d\omega \quad (4)$$

In this equation $S_{FF}(\omega)$ is the PSD function of the stationary process $F(t)$.

In postulating the stationarity of the stochastic process, very strong assumptions regarding the structure of the process are made. Once these assumptions are dropped, the process can become nonstationary in many different ways. In the framework of the spectral analysis of nonstationary processes, Priestley (see, e.g., Priestley 1999) introduced the *evolutionary power spectral density* (EPDS) function. The EPDS function has essentially the same type of physical interpretation of the PSD function of stationary processes. The main difference is that whereas the PSD function describes the power-frequency distribution for the whole stationary process, the EPDS function is time dependent and describes the local power-frequency distribution at each instant time. The theory of EPDS function is the only one which preserves this physical interpretation for the nonstationary processes. Moreover, since the spectrum may be estimated by fairly simple numerical techniques, which do not require any specific assumption of the structure of the process, this model, based on the EPDS function, is nowadays the most adopted model for the analysis of structures subjected to nonstationary processes as the seismic motion due to earthquakes.

In the Priestley spectral representation of nonstationary processes, a sample of the nonstationary stochastic process is defined by the *Fourier-Stieltjes integral* as follows:

$$F^{(k)}(t) = \int_{-\infty}^{+\infty} \exp(i\omega t) a(\omega, t) dN^{(k)}(\omega) \quad (5)$$

where $a(\omega, t)$ is a slowly varying complex deterministic time-frequency modulating function which has to satisfy the condition $a(\omega, t) \equiv a^*(-\omega, t)$ and $N(\omega)$ is an orthogonal process satisfying the condition (2). In Eq. 2 $S_{NN}(\omega)$ is the PSD function of the so-called “embedded” stationary counterpart process, $N(\omega)$ (Michaelov et al. 1999a). It follows that the autocorrelation function of the zero-mean Gaussian nonstationary random process $F(t)$ can be obtained as

$$\begin{aligned}
 R_{FF}(t_1, t_2) &= E\langle F(t_1)F(t_2) \rangle \\
 &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \exp[i(\omega_1 t_1 - \omega_2 t_2)] a(\omega_1, t) \\
 &\quad a^*(\omega_2, t_2) E\langle dN(\omega_1) dN^*(\omega_2) \rangle d\omega_1 d\omega_2
 \end{aligned} \quad (6)$$

It is a real function which, in virtue of Eq. 2, leads to

$$\begin{aligned}
 R_{FF}(t_1, t_2) &= \int_{-\infty}^{\infty} \exp[i\omega(t_1 - t_2)] a(\omega, t_1) a^*(\omega, t_2) \\
 S_{NN}(\omega) d\omega &= \int_{-\infty}^{\infty} \exp[i\omega(t_1 - t_2)] S_{FF}(\omega, t_1, t_2) d\omega
 \end{aligned} \quad (7)$$

where

$$S_{FF}(\omega, t_1, t_2) = a(\omega, t_1) a^*(\omega, t_2) S_{NN}(\omega) \quad (8)$$

According to the Priestley evolutionary process model (Priestley 1999), the function

$$S_{FF}(\omega, t) = |a(\omega, t)|^2 S_{NN}(\omega) \quad (9)$$

is the so-called EPSPD function of the nonstationary process $F(t)$. In the previous equations the symbol $|\cdot|$ denotes the modulus of the function in brackets. The processes characterized by the EPSPD function $S_{FF}(\omega, t)$ are called *fully nonstationary* or *non-separable* random process, since both time and frequency content change, and they cannot be decoupled. If the modulating function is a time-dependent function, $a(\omega, t) \equiv a(t)$, the nonstationary process is called *quasi-stationary* or *uniformly modulated* or *separable* random process. In this case the time content change is independent by the frequency content change; indeed, the EPSPD function assumes the following expression:

$$S_{FF}(\omega, t) = a^2(t) S_{NN}(\omega) \quad (10)$$

In the stochastic analysis the one-sided PSD is generally used; the latter can be suitably defined in the Priestley representation by the following equation:

$$G_{FF}(\omega, t_1, t_2) = \begin{cases} a(\omega, t_1) a^*(\omega, t_2) G_{NN}(\omega) \equiv 2S_{FF}(\omega, t_1, t_2), & \omega \geq 0; \\ 0, & \omega < 0 \end{cases} \quad (11)$$

where $G_{NN}(\omega)$ ($G_{NN}(\omega) = 2S_{NN}(\omega)$, $\omega \geq 0$; $G_{NN}(\omega) = 0$, $\omega < 0$) is the one-sided PSD function of the stationary counterpart of the input process $F(t)$. In this case the autocorrelation function of the process $F(t)$ is given by the following relationship:

$$\begin{aligned}
 \bar{R}_{FF}(t_1, t_2) &= \int_{-\infty}^{\infty} \exp[i\omega(t_1 - t_2)] a(\omega, t_1) \\
 &\quad a^*(\omega, t_2) G_{NN}(\omega) d\omega
 \end{aligned} \quad (12)$$

Note that since the one-sided PSD function $G_{NN}(\omega)$ is not symmetric, the corresponding autocorrelation function, $\bar{R}_{FF}(t_1, t_2)$, is a complex function (Di Paola 1985), whose real part coincides with the function defined in Eq. 6:

$\text{Re}\{\bar{R}_{FF}(t_1, t_2)\} \equiv R_{FF}(t_1, t_2)$. It can be easily proved that the complex function (12) is the autocorrelation function of a complex process $\bar{F}(t)$ defined as (Di Paola and Petrucci 1990)

$$\bar{F}(t) = \sqrt{2} \int_0^{+\infty} \exp(i\omega t) a(\omega, t) dN(\omega) \quad (13)$$

The real part of $\bar{F}(t)$ is proportional to the process $F(t)$, while the imaginary part of $\bar{F}(t)$ is a nonstationary process having stationary counterpart proportional to Hilbert transform of the real part of the stationary counterpart of the process itself (Di Paola 1985; Di Paola and Petrucci 1990; Muscolino 1991). The complex process, $\bar{F}(t)$, which generates the complex

autocorrelation function (12), has been called *pre-envelope process* by Di Paola (1985).

Reliability of Linear Structural Systems Subjected to Stochastic Excitations

The structural systems are conceived and designed to survive to natural actions. If the excitations are modeled as random processes, the dynamic responses are random processes too, and the structural safety needs to be evaluated in a probabilistic sense. Among the models of failure, the simplest one, which is also the most widely used in practical analyses, is based on the assumption that a structure fails as soon as the response at a critical location exits a prescribed safe domain for the first time. The probability of failure, in this case, coincides with the first passage probability, i.e., the probability that the absolute value of the random response process $X(t)$ of a selected structural response (e.g., strain or stress at a critical point) will exceed a specified safety bound, b , within a specified time interval (Lin 1976). In random vibration theory, the problem of probabilistically predicting this event is termed *first passage problem*. Unfortunately, this is one of the most complicated problems in computational stochastic mechanics. The solution of this problem has not been derived in exact form, even in the simplest case of the stationary response of a single-degree-of-freedom (SDoF) linear oscillator under zero-mean Gaussian white noise (Lin 1976; Lutes and Sarkani 2004; Muscolino and Palmeri 2005). Hence, a large number of approximated techniques have been proposed in literature, which differ in generality, complexity, and accuracy. In the framework of approximate methods, the time-dependent reliability of the structure, based on the first passage failure criterion, can be expressed, for a symmetric barrier, as (Lutes and Sarkani 2004)

$$L_{|X|}(b, t) = L_{|X|}(b, 0) \exp \left[- \int_0^t \eta_X(b, \rho) d\rho \right] \quad (14)$$

where $\eta_X(b, t)$ is the so-called *hazard function* and $L_{|X|}(b, 0)$ is the reliability at time $t = 0$, which for the nonstationary case can be assumed as unity.

For narrow-band zero-mean stationary Gaussian process, the hazard function has been derived by Vanmarcke (1972) as

$$\eta_X(b) = \frac{1}{\pi} \sqrt{\frac{\lambda_{2,X}}{\lambda_{0,X}}} \left[\frac{1 - \exp \left(-b \delta_X^{1.2} \sqrt{\frac{\pi}{2\lambda_{0,X}}} \right)}{\exp \left(\frac{b^2}{2\lambda_{0,X}} \right) - 1} \right] \quad (15)$$

with

$$\delta_X = \sqrt{1 - \frac{\lambda_{1,X}^2}{\lambda_{0,X} \lambda_{2,X}}} \quad (16)$$

In this equation δ_X is the so-called *bandwidth parameter* of the process $X(t)$ (Vanmarcke 1972, 1975). This parameter measures the variation of the narrowness of the stochastic process $X(t)$. Usually, a stochastic process with $0 \leq \delta_X \leq 0.35$ is called a narrow-band stochastic process. Finally, in the previous equations $\lambda_{i,X}$ ($i = 0, 1, 2$) are the so-called *geometric spectral moments* (GSMs), introduced by Vanmarcke (1972) as the geometric moments of the one-sided PSD of the response process:

$$\lambda_{i,X} \equiv \lambda_{i,X}^G = \int_0^\infty \omega^i G_{XX}(\omega) d\omega \quad (17)$$

In this equation the apex G emphasizes the geometric evaluation of the GSMs. Notice that $\lambda_{0,X}$ coincides with the variance of the zero-mean process $X(t)$, $\lambda_{0,X} \equiv \sigma_X^2 = E\langle X^2(t) \rangle$; $\lambda_{2,X}$ coincides with the variance of the zero-mean process $\dot{X}(t)$, $\lambda_{2,X} \equiv \sigma_{\dot{X}}^2 = E\langle \dot{X}^2(t) \rangle$; while $\lambda_{1,X}$ does not coincide with the cross-covariance of the processes $X(t)$ and $\dot{X}(t)$.

For narrow-band zero-mean nonstationary Gaussian process, the hazard function has been derived by Corotis et al. (1972) as

$$\eta_X(b, t) = \frac{1}{\pi} \sqrt{\frac{\lambda_{2,X}(t)}{\lambda_{0,X}(t)}} \left[\frac{1 - \exp\left(-b \delta_X^{1+d}(t) \sqrt{\frac{\pi}{2\lambda_{0,X}(t)}}\right)}{\exp\left(\frac{b^2}{2\lambda_{0,X}(t)}\right) - 1} \right] \quad (18)$$

where d ($d = 0$ or $d = 0.2$) is an empirical parameter and $\delta_X(t)$ is the bandwidth parameter which in the nonstationary case is time dependent. Because of the non-stationarity of random process, this parameter involves complex functions, and it is defined by Michaelov et al. (1999a, b) as

$$\delta_X(t) = \sqrt{1 - \frac{\text{Re}\{\lambda_{1,X}(t)\}^2}{\lambda_{0,X}(t)\lambda_{2,X}(t)}} \quad (19)$$

The evaluation of the time-dependent quantities $\lambda_{i,X}(t)$ is conceptually more complicated than for stationary processes; indeed for these processes the geometric approach fails for $i = 1$ and $i = 2$ (Di Paola 1985; Di Paola and Petrucci 1990; Muscolino 1991; Michaelov et al. 1999a, b), that is

$$\begin{aligned} \lambda_{i,X}(t) &\neq \lambda_{i,X}^G(t) \\ &= \int_0^\infty \omega^i G_{XX}(\omega, t) d\omega, \quad i = 1, 2 \end{aligned} \quad (20)$$

The physical inconsistency on the evaluation of the geometric GSMs, in the nonstationary case, as the moments of the one-sided EPSD function was pointed out by Corotis et al. (1972). In fact they discovered that for the case of the transient response of an oscillator subjected to stationary Gaussian white noise processes, the second GSM does not exist because it is unbounded. At same time in the stationary case, this GSM, which is the limit of the transient as the time approaches infinity, is finite. The first that considered the problem of spectral characteristics from a nongeometric point of view was Di Paola (1985). The basic idea

of this approach is to establish a time-domain interpretation of the SM. In order to do this, the pre-envelope covariances as the covariances of structural systems subjected to a complex-valued random process (the so-called pre-envelope process) have been introduced (Di Paola and Petrucci 1990). The real part of this process is proportional to the original nonstationary process, while the imaginary part is an auxiliary random process related to the real part in such a way that the complex process exhibits power in the positive frequency range only. Since the use of complex pre-envelope process is not very intuitive, Michaelov et al. (1999a, b) evaluated the pre-envelope covariances as a function of the EPSD of the response and recalled them as *nongeometric spectral moments* (NGSMs). It has to be emphasized that the NGSMs contain more information than the “conventional” covariances. Indeed, the NGSMs have been proved to be more appropriate for describing nonstationary process and can be effectively employed in structural reliability applications (Di Paola 1985; Di Paola and Petrucci 1990; Muscolino 1991; Michaelov et al. 1999a, b).

It has to be emphasized that in the framework of nonstationary analysis of structures, other time-dependent parameters, very useful in describing the time-variant spectral properties of the stochastic process, are (i) the mean frequency, $v_X^+(t)$, which evaluate the variation in time of the mean up-crossing rate of the time axis, and (ii) the central frequency, $\omega_{C,X}(t)$, which scrutinizes the variation of the frequency content of the stochastic process with respect to time. The two functions introduced before can be evaluated as a function of NGSMs and have been defined, respectively, as (Michaelov et al. 1999a, b)

$$v_X^+(t) = \frac{1}{2\pi} \sqrt{\frac{\lambda_{2,X}(t)}{\lambda_{0,X}(t)}}; \quad \omega_{C,X}(t) = \frac{\text{Re}\{\lambda_{1,X}(t)\}}{\lambda_{0,X}(t)} \quad (21)$$

In stationary case the mean frequency, v_X^+ , and the central frequency, $\omega_{C,X}$, are not time dependent. Moreover, in the latter case, because of the $\text{Im}\{\lambda_{1,X}\} = 0$, it follows $\text{Re}\{\lambda_{1,X}\} \equiv \lambda_{1,X}$.

Response of Single-Degree-of-Freedom (SDoF) Oscillators

Fundamental of Deterministic Analysis

The theory of deterministic linear systems plays a fundamental role in the dynamic analysis of structures subjected to stochastic excitations. For this reason in this section the fundamental of deterministic analysis of SDoF subjected to deterministic excitation is synthetically reviewed. Particular care has been devoted to the state-space approach. This approach is the best suited for the development of formulations in the framework of random vibrations. In fact, its adaptability to numerical method of solution of differential equations and its extension to multi-degree-of-freedom (MDoF) systems are very straightforward.

The equation of motion of a linear oscillator with mass, m ; viscous damping, c ; stiffness, k ; and subjected to the excitation $f(t)$ and at rest at initial time of motion, $t = t_0$, can be written as

$$\begin{aligned} m \ddot{u}(t) + c \dot{u}(t) + k u(t) &= f(t); \\ u(t_0) &= 0, \quad \dot{u}(t_0) = 0 \end{aligned} \quad (22)$$

or in canonical form as follows:

$$\begin{aligned} \ddot{u}(t) + 2\xi_0\omega_0 \dot{u}(t) + \omega_0^2 u(t) &= F(t); \\ u(t_0) &= 0, \quad \dot{u}(t_0) = 0 \end{aligned} \quad (23)$$

where $u(t)$ is the displacement response of the mass, $\omega_0 = \sqrt{k/m}$ is the natural circular frequency, $\xi_0 = c/2\sqrt{mk}$ is the damping ratio, and $F(t) = f(t)/m$; a dot over a variable denotes differentiation with respect to time t . In state variables the equation of motion of the oscillator, in canonical form, can be written as a set of two first-order differential equations:

$$\dot{\mathbf{y}}(t) = \mathbf{D}_0 \mathbf{y}(t) + \mathbf{v}_0 F(t); \quad \mathbf{y}(t_0) = \mathbf{0} \quad (24)$$

where

$$\mathbf{y}(t) = \begin{bmatrix} u(t) \\ \dot{u}(t) \end{bmatrix}, \quad \mathbf{D}_0 = \begin{bmatrix} 0 & 1 \\ -\omega_0^2 & -2\xi_0\omega_0 \end{bmatrix}, \quad \mathbf{v}_0 = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \quad (25)$$

Denoting by $\mathbf{y}_p(t)$ the particular solution vector, the solution of Eq. 24 can be evaluated as (Borino and Muscolino 1986)

$$\mathbf{y}(t) = \mathbf{y}_p(t) + \mathbf{\Theta}_0(t - t_0) [\mathbf{y}(t_0) - \mathbf{y}_p(t_0)] \quad (26)$$

where $\mathbf{\Theta}_0(t)$ is the so-called transition matrix:

$$\mathbf{\Theta}_0(t) = \exp(\mathbf{D}_0 t) = \begin{bmatrix} -\omega_0^2 g_0(t) & h_0(t) \\ -\omega_0^2 h_0(t) & \dot{h}_0(t) \end{bmatrix} \quad (27)$$

with

$$\begin{aligned} g_0(t) &= -\frac{1}{\omega_0^2} \exp(-\xi_0\omega_0 t) \left[\cos(\bar{\omega}_0 t) + \frac{\xi_0\omega_0}{\bar{\omega}_0} \sin(\bar{\omega}_0 t) \right]; \\ h_0(t) &= \dot{g}_0(t) = \frac{1}{\omega_0} \exp(-\xi_0\omega_0 t) \sin(\bar{\omega}_0 t); \\ \dot{h}_0(t) &= \exp(-\xi_0\omega_0 t) \left[\cos(\bar{\omega}_0 t) - \frac{\xi_0\omega_0}{\bar{\omega}_0} \sin(\bar{\omega}_0 t) \right] \end{aligned} \quad (28)$$

and $\bar{\omega}_0 = \omega_0 \sqrt{1 - \xi_0^2}$ is the damped natural circular frequency. Notice that the contribution of the last term in the right member of Eq. 26 decreases in the time because the transition matrix satisfies the following condition:

$$\lim_{t \rightarrow \infty} \mathbf{\Theta}_0(t) = \mathbf{0} \quad (29)$$

Alternatively, by applying the so-called *parameter variation method*, the solution of Eq. 24 can be written in integral form as follows:

$$\mathbf{y}(t) = \mathbf{\Theta}_0(t - t_0) \mathbf{y}(t_0) + \int_{t_0}^t \mathbf{\Theta}_0(t - \tau) \mathbf{v} F(\tau) d\tau \quad (30)$$

For quiescent systems, because the relationship $\mathbf{y}(t_0) = \mathbf{0}$ is satisfied, Eqs. 26 and 30 become

$$\begin{aligned} \mathbf{y}(t) &= \mathbf{y}_p(t) - \mathbf{\Theta}_0(t - t_0) \mathbf{y}_p(t_0) \\ &= \int_{t_0}^t \mathbf{\Theta}_0(t - \tau) \mathbf{v} F(\tau) d\tau \end{aligned} \quad (31)$$

Notice that in this case the first element of vector $\mathbf{y}(t)$, written in integral form, coincides with the well-known Duhamel integral. Starting by the integral form solution in state variables,

it is possible to derive a very powerful unconditionally stable numerical procedure for the evaluation of the structural response (see, e.g., Borino and Muscolino 1986).

Stochastic Response

Mathematically strictly speaking, as a consequence of the introduction of the

one-sided PSD, the input process is a complex one. It follows that the response processes, $u(t)$, is a complex function too. After some algebra, for the quiescent oscillator (Eq. 23), the NGSMs can be evaluated, in time domain, as (Di Paola 1985; Di Paola and Petrucci 1990, Muscolino 1991)

$$\begin{aligned}\lambda_{0,uu}(t) &\equiv E\langle u(t)u^*(t) \rangle = \iint\limits_{00}^t h(t-\tau_1)h(t-\tau_2)\bar{R}_{FF}(\tau_1, \tau_2) d\tau_1 d\tau_2; \\ \lambda_{1,uu}(t) &= -i \iint\limits_{00}^t h(t-\tau_1)\dot{h}(t-\tau_2)\bar{R}_{FF}(\tau_1, \tau_2) d\tau_1 d\tau_2; \\ \lambda_{2,uu}(t) &\equiv E\langle \dot{u}(t)\dot{u}^*(t) \rangle = \iint\limits_{00}^t \dot{h}(t-\tau_1)\dot{h}(t-\tau_2)\bar{R}_{FF}(\tau_1, \tau_2) d\tau_1 d\tau_2\end{aligned}\quad (32)$$

where $\bar{R}_{FF}(t_1, t_2)$ is the complex autocorrelation function defined in Eq. 12. Moreover, the presence of the imaginary unit in the second of Eq. 32 inverts the roles of the real and imaginary parts of $\lambda_{1,uu}(t)$ with respect to the variances $\lambda_{0,uu}(t)$ and $\lambda_{2,uu}(t)$; furthermore, while $\lambda_{0,uu}(t)$ and $\lambda_{2,uu}(t)$ are real functions, $\lambda_{1,uu}(t)$ is a complex one. Substituting Eq. 12 into Eq. 32, the following relationships are obtained:

$$\begin{aligned}\lambda_{0,uu}(t) &= \int_0^\infty Z_0^*(\omega, t)Z_0(\omega, t)G_{NN}(\omega)d\omega; \\ \lambda_{1,uu}(t) &= -i \int_0^\infty Z_0^*(\omega, t)\dot{Z}_0(\omega, t)G_{NN}(\omega)d\omega; \\ \lambda_{2,uu}(t) &= \int_0^\infty \dot{Z}_0^*(\omega, t)\dot{Z}_0(\omega, t)G_{NN}(\omega)d\omega\end{aligned}\quad (33)$$

where

$$\begin{aligned}Z_0(\omega, t) &= \int_0^t h(t-\tau)\exp(i\omega\tau)a(\omega, \tau) d\tau; \\ \dot{Z}_0(\omega, t) &= \int_0^t \dot{h}(t-\tau)\exp(i\omega\tau)a(\omega, \tau) d\tau\end{aligned}\quad (34)$$

Notice that the function $Z_0(\omega, t)$ is the so-called *evolutionary frequency response function* of the oscillator (Li and Chen 2009). Remarkably, since the integrals (Eq. 34) are convolution integrals of Duhamel's type, they can be interpreted as the response, in terms of state variables, of the quiescent oscillator, at time $t = 0$, subjected to the deterministic complex function $f(\omega, t) = \exp(i\omega t) a(\omega, t)$. By introducing the state variables, the *evolutionary frequency response vector function* can be defined as

$$\mathbf{Y}_0(\omega, t) = \begin{bmatrix} Z_0(\omega, t) \\ \dot{Z}_0(\omega, t) \end{bmatrix}\quad (35)$$

It follows that relationships (33) can be rewritten in compact form as follows:

$$\begin{aligned}\Sigma_{uu}(t) &= \begin{bmatrix} \lambda_{0,uu}(t) & i\lambda_{1,uu}(t) \\ -i\lambda_{1,uu}^*(t) & \lambda_{2,uu}(t) \end{bmatrix} \\ &\equiv \int_0^\infty G_{NN}(\omega) \mathbf{Y}_0^*(\omega, t)\mathbf{Y}_0^T(\omega, t)d\omega\end{aligned}\quad (36)$$

This matrix coincides with the so-called *pre-envelope covariance matrix* introduced by Di Paola and Petrucci (1990) which is a complex

matrix. As a conclusion, for input processes characterized by one-sided EPSP function, the cross-covariance matrix (Eq. 36) of an oscillator is a complex matrix whose elements are the NGSMs.

Generalizing Eq. 32, it can be easily proved that the complex cross-correlation function matrix of the zero-mean response process, which collects the cross-correlation of the pre-envelope response processes, can be evaluated as

$$\mathbf{R}_{uu}(t_1, t_2) = \int_0^\infty G_{NN}(\omega) \mathbf{Y}_0^*(\omega, t_1) \mathbf{Y}_0^T(\omega, t_2) d\omega \quad (37)$$

Finally, according to the Priestley evolution-ary process model (Priestley 1999), this complex function matrix $\mathbf{R}_{uu}(t_1, t_2)$ can be also rewritten as

$$\mathbf{R}_{uu}(t_1, t_2) = \int_0^\infty \exp[i\omega(t_1 - t_2)] \mathbf{G}_{uu}(\omega, t_1, t_2) d\omega \quad (38)$$

where

$$\mathbf{G}_{uu}(\omega, t_1, t_2) = G_{NN}(\omega) \mathbf{Y}_0^*(\omega, t_1) \mathbf{Y}_0^T(\omega, t_2) \quad (39)$$

Consequently the NGSMs of the oscillator response are the elements of the pre-envelope covariance matrix, given as

$$\Sigma_{uu}(t) \equiv \mathbf{R}_{uu}(t, t) \equiv \int_0^\infty \mathbf{G}_{uu}(\omega, t) d\omega \quad (40)$$

Let us assume now the modulating function $a(\omega, t) = U(t)$. Starting from the nonstationary formulation, it is possible to deduce the formulation in the case of stationary input. This result is obtained by performing the limit as $t \rightarrow \infty$ into Eq. 34:

$$\begin{aligned} \lim_{t \rightarrow \infty} Z_0(\omega, t) &= \int_0^\infty h_0(t - \tau) \exp(i\omega\tau) d\tau = \exp(i\omega t) H_0(\omega); \\ \lim_{t \rightarrow \infty} \dot{Z}_0(\omega, t) &= \int_0^\infty \dot{h}_0(t - \tau) \exp(i\omega\tau) d\tau = i\omega \exp(i\omega t) H_0(\omega) \end{aligned} \quad (41)$$

where $h_0(t)$ and $\dot{h}_0(t)$ are the functions defined in Eq. 28 and $H_0(\omega)$ is the *frequency response function* of the oscillator defined as

$$\begin{aligned} H_0(\omega) &= \int_0^\infty h_0(\tau) \exp(-i\omega\tau) d\tau \\ &= \frac{1}{\omega_0^2 - \omega^2 + i2\xi_0\omega\omega_0} \end{aligned} \quad (42)$$

By substituting Eq. 41 into Eq. 35 and the results into Eq. 36, the following relationship is obtained:

$$\begin{aligned} \Sigma_{uu} &= \int_0^\infty G_{NN}(\omega) \mathbf{H}_0^*(\omega) \mathbf{H}_0^T(\omega) d\omega \\ &\equiv \begin{bmatrix} \lambda_{0,uu} & i\lambda_{1,uu} \\ -i\lambda_{1,uu}^* & \lambda_{2,uu} \end{bmatrix} \end{aligned} \quad (43)$$

where

$$\mathbf{H}_0(\omega) = \begin{bmatrix} H_0(\omega) \\ i\omega H_0(\omega) \end{bmatrix} \quad (44)$$

The elements of this matrix Σ_{uu} are the GSMs, introduced by Vanmarcke (1972), that is

$$\begin{aligned} \lambda_{i,uu} &\equiv \lambda_{i,uu}^G \\ &= \int_0^\infty \omega^i |H_0(\omega)|^2 G_{NN}(\omega) d\omega; \quad i = 0, 1, 2 \end{aligned} \quad (45)$$

Response of Multi-degree-of-Freedom (MDOF) Systems

Fundamental of Deterministic Analysis

Let us consider the equation of motion of a linear quiescent n -degree-of-freedom (n -DoF) classically

damped structural system whose dynamic behavior is governed by the equation of motion:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{f}(t) \quad (46)$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the $(n \times n)$ mass, damping, and stiffness matrices of the structure; $\mathbf{u}(t)$ is the $(n \times 1)$ vector of displacements, having for i th element $u_i(t)$; and $\mathbf{f}(t)$ denotes the external load vector. Under the assumption of classically damped system, the equation of motion can be decoupled by applying the modal analysis. To this aim let us introduce the modal coordinate transformation:

$$\begin{aligned} \mathbf{u}(t) &= \Phi \mathbf{q}(t) = \sum_{j=1}^m \phi_j q_j(t) \Rightarrow u_i(t) \\ &= \sum_{j=1}^m \phi_{ij} q_j(t) \end{aligned} \quad (47)$$

In this equation, $\Phi = [\phi_1 \ \phi_2 \ \dots \ \phi_m]$ is the modal matrix, of order $n \times m$, collecting the m eigenvectors ϕ_j , normalized with respect to the mass matrix $\mathbf{M}$, solutions of the following eigenproblem:

$$\mathbf{K}^{-1}\mathbf{M}\Phi = \Phi\Omega^{-2}; \quad \Phi^T\mathbf{M}\Phi = \mathbf{I}_m \quad (48)$$

In this equation Ω is a diagonal matrix listing the undamped natural circular frequency ω_j , $\mathbf{I}_m$ is the identity matrix of order m , and the apex T means transpose operator. Once the modal matrix Φ is evaluated, by applying the coordinate transformations (47) to Eq. 46, the following set of decoupled second-order differential equations is obtained:

$$\ddot{\mathbf{q}}(t) + \Xi \dot{\mathbf{q}}(t) + \Omega^2 \mathbf{q}(t) = \Phi^T \mathbf{f}(t) \quad (49)$$

in which Ξ is a generalized damping matrix given by

$$\Xi = \Phi^T \mathbf{C} \Phi \quad (50)$$

For classically damped structures the modal damping matrix Ξ is a diagonal matrix listing the

quantities $2\zeta_j\omega_j$, ζ_j being the modal damping ratio. It follows that the j th differential Eq. 49 can be written as

$$\ddot{q}_j(t) + 2\zeta_j\omega_j \dot{q}_j(t) + \omega_j^2 q_j(t) = \phi_j^T \mathbf{f}(t) \quad (51)$$

In the state space, Eq. 51 can be written in the first-order form as

$$\dot{\mathbf{y}}_j(t) = \mathbf{D}_j \mathbf{y}_j(t) + \mathbf{V}_j \mathbf{f}(t) \quad (52)$$

where

$$\begin{aligned} \mathbf{y}_j(t) &= \begin{bmatrix} q_j(t) \\ \dot{q}_j(t) \end{bmatrix}; \quad \mathbf{D}_j = \begin{bmatrix} 0 & 1 \\ -\omega_j^2 & -2\zeta_j\omega_j \end{bmatrix}; \\ \mathbf{V}_j &= \begin{bmatrix} \mathbf{0} \\ \phi_j^T \end{bmatrix} \end{aligned} \quad (53)$$

Stochastic Response for Mono-correlated Stochastic Input Processes

Let us assume now that the forcing term is a mono-correlated zero-mean Gaussian random process vector given by the relationship:

$$\mathbf{f}(t) = \mathbf{b}\bar{F}(t) \quad (54)$$

where $\mathbf{b}$ is the $(n \times 1)$ vector of spatial distribution of loads and $\bar{F}(t)$ is a zero-mean Gaussian nonstationary random process. It follows that the j th differential Eq. 51 can be written as

$$\ddot{q}_j(t) + 2\zeta_j\omega_j \dot{q}_j(t) + \omega_j^2 q_j(t) = p_j \bar{F}(t), \quad j = 1, 2, \dots, m \quad (55)$$

where

$$p_j = \phi_j^T \mathbf{b} \quad (56)$$

After very simple algebra it can be shown that the j th NGSMs, $\lambda_{j,u_i}(t)$ ($i = 0, 1, 2$), of the i th nodal displacement response, $u_i(t)$, are given as a function of modal NGSMs, $p_j \lambda_{j,k\ell}(t)$ ($\ell, k = 1 \dots, m$), by the following relationships:

$$\begin{aligned}
\lambda_{0,u_i u_i}(t) &= \sum_{k=1}^m \sum_{\ell=1}^m p_k p_\ell \phi_{ik} \phi_{i\ell} \lambda_{0,k\ell}(t); \\
\lambda_{1,u_i u_i}(t) &= \sum_{k=1}^m \sum_{\ell=1}^m p_k p_\ell \phi_{ik} \phi_{i\ell} \lambda_{1,k\ell}(t); \quad (57) \\
\lambda_{2,u_i u_i}(t) &= \sum_{k=1}^m \sum_{\ell=1}^m p_k p_\ell \phi_{ik} \phi_{i\ell} \lambda_{2,k\ell}(t)
\end{aligned}$$

It has to be emphasized that the zeroth NGSM, $\lambda_{0,u_i u_i}(t)$, and the second-order NGSM, $\lambda_{2,u_i u_i}(t)$, are real functions that coincide with the variances of the response in terms of displacement and velocity, respectively, while the first-order NGSM, $\lambda_{1,u_i u_i}(t)$, is a complex quantity whose real part can be evaluated as the cross-covariance

between the response process and the response velocity process of the same linear system subjected to a nonstationary input whose stationary counterpart is proportional to its Hilbert transform (Di Paola 1985; Langley 1986; Di Paola and Petrucci 1990; Muscolino 1991). As shown in Eq. 57 the nodal NGSMs can be evaluated as a function of $\lambda_{r,k\ell}(t)$, $r = 0, 1, 2$, which are the so-called time-dependent modal NGSMs “purged” by p_j factors. After some algebra, these quantities, which are complex ones, can be evaluated, in time domain, for quiescent structural systems as (Di Paola 1985; Di Paola and Petrucci 1990; Muscolino 1991)

$$\begin{aligned}
\lambda_{0,k\ell}(t) &= \int_0^t \int_0^t h_k(t-\tau_1) h_\ell(t-\tau_2) \bar{R}_{FF}(\tau_1, \tau_2) d\tau_1 d\tau_2; \\
\lambda_{1,k\ell}(t) &= -i \int_0^t \int_0^t h_k(t-\tau_1) \dot{h}_\ell(t-\tau_2) \bar{R}_{FF}(\tau_1, \tau_2) d\tau_1 d\tau_2; \quad k = 1, 2, \dots, m; \quad \ell = 1, 2, \dots, m; \\
\lambda_{2,k\ell}(t) &= \int_0^t \int_0^t \dot{h}_k(t-\tau_1) \dot{h}_\ell(t-\tau_2) \bar{R}_{FF}(\tau_1, \tau_2) d\tau_1 d\tau_2
\end{aligned} \quad (58)$$

where $\bar{R}_{FF}(t_1, t_2)$ is the complex autocorrelation function defined in Eq. 12. Notice that the presence of the imaginary unit in the second term of the second of Eq. 58 inverts the roles of the real and imaginary parts of $\lambda_{1,k\ell}(t)$ with respect to the cross-covariance $\lambda_{0,k\ell}(t)$ and $\lambda_{2,k\ell}(t)$; furthermore for $k = \ell$ while $\lambda_{0,k\ell}(t)$ and $\lambda_{2,k\ell}(t)$ become real quantities, $\lambda_{1,k\ell}(t)$ remains a complex one.

It can be easily proved that the “purged” NGSMs, given in Eq. 58, can be evaluated as a function of the statistics of the response of a dummy oscillator whose motion is governed by

$$\ddot{z}_j(t) + 2\zeta_j \omega_j \dot{z}_j(t) + \omega_j^2 z_j(t) = \bar{F}(t) \quad (59)$$

where $\bar{F}(t)$ is a complex process whose imaginary part is a process having stationary counterpart proportional to Hilbert transform of the real part of the stationary counterpart of the complex

process itself; it follows that $z_j(t) = q_j(t)/p_j$ is a complex process too. Notice that, with the position $p_j = 1$, Eq. 59 coincides with Eq. 55. Then by substituting the complex function $\bar{R}_{FF}(t_1, t_2)$, defined in Eq. 12, into Eq. 58, after very simple algebra, it is possible to evaluate the “purged” NGSMs as

$$\begin{aligned}
\lambda_{0,k\ell}(t) &= \int_0^\infty Z_k^*(\omega, t) Z_\ell(\omega, t) G_{NN}(\omega) d\omega; \\
\lambda_{1,k\ell}(t) &= -i \int_0^\infty Z_k^*(\omega, t) \dot{Z}_\ell(\omega, t) G_{NN}(\omega) d\omega; \\
\lambda_{2,k\ell}(t) &= \int_0^\infty \dot{Z}_k^*(\omega, t) \dot{Z}_\ell(\omega, t) G_{NN}(\omega) d\omega
\end{aligned} \quad (60)$$

where, for $j = k, \ell$, the following positions have been made:

$$\begin{aligned} Z_j(\omega, t) &= \int_0^t h_j(t - \tau) \exp(i\omega\tau) a(\omega, \tau) d\tau; \\ \dot{Z}_j(\omega, t) &= \int_0^t \dot{h}_j(t - \tau) \exp(i\omega\tau) a(\omega, \tau) d\tau \end{aligned} \quad (61)$$

with

$$h_j(t) = \frac{1}{\bar{\omega}_j} \exp(-\zeta_j \omega_j t) \sin(\bar{\omega}_j t) \quad (62)$$

and $\bar{\omega}_j = \omega_j \sqrt{1 - \zeta_j^2}$ ($j = k, \ell$) is the damped circular frequency of the j th dummy oscillator. Moreover, introducing the state variable, the *modal evolutionary frequency response function vector* is defined as

$$\mathbf{Y}_j(\omega, t) = \begin{bmatrix} Z_j(\omega, t) \\ \dot{Z}_j(\omega, t) \end{bmatrix}; \quad j = k, \ell \quad (63)$$

Then, relationships (33) can be rewritten in compact form as follows:

$$\begin{aligned} \Sigma_{k\ell}(t) &= \begin{bmatrix} \lambda_{0,k\ell}(t) & i\lambda_{1,k\ell}(t) \\ -i\lambda_{1,k\ell}^*(t) & \lambda_{2,k\ell}(t) \end{bmatrix} \\ &\equiv \int_0^\infty G_{NN}(\omega) \mathbf{Y}_k^*(\omega, t) \mathbf{Y}_\ell^T(\omega, t) d\omega \end{aligned} \quad (64)$$

which coincides with the cross-modal *pre-envelope covariance matrix* which is a complex matrix (Di Paola and Petrucci 1990). As a conclusion for input processes characterized by one-sided PSD function, the cross-covariance matrix (Eq. 64) between the k, ℓ th dummy oscillators is a complex matrix whose elements are the “purged” NGSMs. It can be easily proved that the complex cross-correlation function matrix of the zero-mean modal “purged” response process, which collects the cross-correlation of the

pre-envelope response processes, according to the Priestley evolutionary process model (Priestley 1999), can be evaluated as

$$\begin{aligned} \mathbf{R}_{k\ell}(t_1, t_2) &= \int_0^\infty G_{NN}(\omega) \mathbf{Y}_k^*(\omega, t_1) \mathbf{Y}_\ell^T(\omega, t_2) d\omega \\ &\equiv \int_0^\infty \exp[i\omega(t_1 - t_2)] \mathbf{G}_{k\ell}(\omega, t_1, t_2) d\omega \end{aligned} \quad (65)$$

where

$$\mathbf{G}_{k\ell}(\omega, t_1, t_2) = G_{NN}(\omega) \mathbf{Y}_k^*(\omega, t_1) \mathbf{Y}_\ell^T(\omega, t_2) \quad (66)$$

is the cross-modal EPSP function matrix between the k, ℓ th dummy oscillators. By means of the modal transformation (Eq. 47), the nodal autocorrelation and the EPSP function matrices of the displacement response, $u_i(t)$, can be evaluated, after very simple algebra, respectively, as follows:

$$\begin{aligned} \mathbf{R}_{u_i u_i}(t_1, t_2) &= \sum_{k=1}^m \sum_{\ell=1}^m p_k p_\ell \phi_{ik} \phi_{i\ell} \mathbf{R}_{k\ell}(t_1, t_2), \\ \mathbf{G}_{u_i u_i}(\omega, t_1, t_2) &= \sum_{k=1}^m \sum_{\ell=1}^m p_k p_\ell \phi_{ik} \phi_{i\ell} \mathbf{G}_{k\ell}(\omega, t_1, t_2) \end{aligned} \quad (67)$$

Consequently the nodal displacement NGSMs are the elements of the nodal pre-envelope covariance matrix, given as

$$\begin{aligned} \Sigma_{u_i u_i}(t) &\equiv \mathbf{R}_{u_i u_i}(t, t) \equiv \int_0^\infty \mathbf{G}_{u_i u_i}(\omega, t) d\omega \\ &= \sum_{k=1}^m \sum_{\ell=1}^m p_k p_\ell \phi_{ik} \phi_{i\ell} \Sigma_{k\ell}(t) \end{aligned} \quad (68)$$

Let us assume now the modulating function $a(\omega, t) = U(t)$. Starting from the nonstationary formulation, it is possible to deduce the formulation in the case of stationary input. This result

is obtained by performing the limit as $t \rightarrow \infty$ into Eq. 61:

$$\begin{aligned}\lim_{t \rightarrow \infty} Z_j(\omega, t) &= \int_0^{\infty} h_j(t - \tau) \exp(i\omega\tau) d\tau \\ &= \exp(i\omega t) H_j(\omega); \\ \lim_{t \rightarrow \infty} \dot{Z}_j(\omega, t) &= \int_0^{\infty} \dot{h}_j(t - \tau) \exp(i\omega\tau) d\tau \\ &= i\omega \exp(i\omega t) H_j(\omega)\end{aligned}\quad (69)$$

where $h_j(t)$ is the functions defined in Eq. 62 and $H_j(\omega)$ is the *frequency response function* of the j th modal oscillator:

$$\begin{aligned}H_j(\omega) &= \int_0^{\infty} h_j(\tau) \exp(-i\omega\tau) d\tau \\ &= \frac{1}{\omega_j^2 - \omega^2 + i2\zeta_j\omega_j\omega}\end{aligned}\quad (70)$$

By substituting Eq. 69 into Eq. 63 and the results into Eq. 64, the following relationship is obtained:

$$\begin{aligned}\Sigma_{k\ell} &= \int_0^{\infty} G_{NN}(\omega) \mathbf{H}_k^*(\omega) \mathbf{H}_\ell^T(\omega) d\omega \\ &\equiv \begin{bmatrix} \lambda_{0,k\ell} & i\lambda_{1,k\ell} \\ -i\lambda_{1,k\ell}^* & \lambda_{2,k\ell} \end{bmatrix}\end{aligned}\quad (71)$$

where

$$\mathbf{H}_j(\omega) = \begin{bmatrix} H_j(\omega) \\ i\omega H_j(\omega) \end{bmatrix} \quad j = k, \ell \quad (72)$$

The elements of the matrix $\Sigma_{k\ell}$ are the cross GSMs, introduced by Vanmarcke (1972), that is,

$$\begin{aligned}\lambda_{i,k\ell} &\equiv \lambda_{i,k\ell}^G \\ &= \int_0^{\infty} \omega^i H_k^*(\omega) H_\ell(\omega) G_{NN}(\omega) d\omega; \quad i = 0, 1, 2\end{aligned}\quad (73)$$

Stochastic Response for Multi-correlated Stochastic Input Processes

In earthquake engineering it is common to assume that the entire base of a structure is subjected to a uniform ground motion. This hypothesis inherently implies that the ground motion is a result of spatially uniform motion. Thus it is certainly true when the base dimensions of the structure are small relative to the seismic vibration wavelengths. From an analytical point of view, this hypothesis leads to mono-correlated zero-mean Gaussian models of the ground-motion acceleration. It follows that this model of earthquake excitations is undoubtedly advantageous, because it substantially facilitates the stochastic analysis of dynamic problem. Indeed, in this case the stochastic analysis requires the knowledge of only one PSD of the input process.

The assumption of uniform ground motion is inappropriate for structures, such as long span bridges, which require accounting for spatial variability of the support motions. The main sources of ground-motion spatial variability are the loss of coherency of seismic waves with distance, the difference in the arrival times of waves at separate supports, and the difference in soil conditions underneath the supports. In these cases the multi-correlated model of the seismic excitation is more appropriate.

In order to take into account of the spatial variability of earthquake-induced ground motions, let us consider an n -DoF structural system subjected to an N support motion. It follows that the stochastic forcing vector process has to be modeled as a multi-correlated zero-mean Gaussian random vector process:

$$\mathbf{f}(t) = \mathbf{B}\bar{\mathbf{F}}(t) \quad (74)$$

where $\mathbf{B}$ is the $(n \times N)$ matrix of spatial distribution of loads and $\bar{\mathbf{F}}(t)$ is a zero-mean Gaussian nonstationary multi-correlated random vector process of order N . Following the Priestley spectral representation of nonstationary processes (Priestley 1999), this vector can be defined by the *Fourier-Stieltjes integral* as follows (Di Paola and Petrucci 1990):

$$\bar{\mathbf{F}}(t) = \sqrt{2} \int_{-\infty}^{+\infty} \exp(i\omega t) \mathbf{A}(\omega, t) d\mathbf{N}(\omega) \quad (75)$$

where $\mathbf{A}(\omega, t)$ is a slowly varying complex deterministic time-frequency modulating diagonal function matrix, of order $N \times N$, which has to satisfy the condition $\mathbf{A}(\omega, t) \equiv \mathbf{A}^*(-\omega, t)$, while $\mathbf{N}(\omega)$ is an orthogonal vector process satisfying the following conditions:

$$\begin{aligned} E\langle d\mathbf{N}(\omega_1) d\mathbf{N}^{*T}(\omega_2) \rangle \\ = \delta(\omega_1 - \omega_2) \mathbf{G}_{\mathbf{NN}}(\omega_1) d\omega_1 d\omega_2 \end{aligned} \quad (76)$$

This relationship shows that the stationary counterpart of the multi-correlated stochastic process is a vector process, $\mathbf{N}(\omega)$ (of order N), with orthogonal increments. Furthermore, $\mathbf{G}_{\mathbf{NN}}(\omega)$ is an $(N \times N)$ Hermitian matrix function which describes the one-sided PSD function matrix of the so-called “embedded” stationary counterpart vector process, $\mathbf{N}(\omega)$. After some algebra it can be proved that the autocorrelation function matrix of the zero-mean Gaussian nonstationary random vector process $\bar{\mathbf{F}}(t)$ can be obtained as

$$\begin{aligned} \bar{\mathbf{R}}_{\mathbf{FF}}(t_1, t_2) &= E\langle \bar{\mathbf{F}}(t_1) \bar{\mathbf{F}}^{*T}(t_2) \rangle = \int_0^{\infty} \exp[i\omega(t_1 - t_2)] \mathbf{A}(\omega, t_1) \mathbf{G}_{\mathbf{NN}}(\omega) \mathbf{A}^*(\omega, t_2) d\omega \\ &= \int_{-\infty}^{\infty} \exp[i\omega(t_1 - t_2)] \mathbf{G}_{\mathbf{FF}}(\omega, t_1, t_2) d\omega \end{aligned} \quad (77)$$

where

$$\mathbf{G}_{\mathbf{FF}}(\omega, t_1, t_2) = \mathbf{A}(\omega, t_1) \mathbf{G}_{\mathbf{NN}}(\omega) \mathbf{A}^*(\omega, t_2) \quad (78)$$

According to the Priestley evolutionary process model (Priestley 1999), the EPSD function matrix of the nonstationary multi-correlated process $\bar{\mathbf{F}}(t)$ is given as

$$\mathbf{G}_{\mathbf{FF}}(\omega, t) = \mathbf{A}(\omega, t) \mathbf{G}_{\mathbf{NN}}(\omega) \mathbf{A}^*(\omega, t) \quad (79)$$

In the framework of stochastic seismic analysis, the main distinct phenomena that give rise to the spatial variability of earthquake-induced ground motions are (i) the *incoherence effect* associated to loss of coherency of seismic waves due to the differential superpositioning of waves arriving from an extended source, (ii) the *wave-passage effect* due to difference in the arrival times of waves at separate supports, (iii) the *attenuation effect* due to gradual decay of wave amplitudes with distance due to energy

dissipation in the ground medium, and (iv) the *site-response effect* associated to spatially varying of the local soil profiles. These effects are taken into account by the so-called coherency function, $\gamma_{\mathbf{NN},sr}(\omega)$, defined as

$$\gamma_{\mathbf{NN},sr}(\omega) = \frac{G_{\mathbf{NN},sr}(\omega)}{\sqrt{G_{\mathbf{NN},rr}(\omega) G_{\mathbf{NN},ss}(\omega)}} \quad (80)$$

where $G_{\mathbf{NN},sr}(\omega)$ is the s th and r th element of the matrix $\mathbf{G}_{\mathbf{NN}}(\omega)$ that is the one-sided PSD at the s th and the r th supports. The coherency function is usually written as

$$\gamma_{\mathbf{NN},sr}(\omega) = \rho_{sr}(\omega) \exp(-i\omega d_{sr}/c) \quad (81)$$

in which $\exp(-i\omega d_{sr}/c)$ is a measure of the wave-passage delay due to the apparent velocity of waves, c represents the velocity of the seismic waves through the ground (c decreases as the distance between the support points increases or the soil is softer), d_{sr} is the distance between the r th and s th support points, and $\rho_{sr}(\omega)$ is the real frequency-dependent spatial correlation function

between the two support points. Several models of the coherency function have been proposed in literature (see, e.g., Harichandran and Vanmarcke 1986; Zerva 1991). Moreover, the one-sided cross-PSD of ground accelerations in a particular direction between surface points r and s , $G_{\mathbf{NN},sr}(\omega)$, may be written as the product of the coherence function by the target one-sided PSD of ground acceleration $G_0(\omega)$ as follows:

$$G_{\mathbf{NN},sr}(\omega) = \begin{cases} \gamma_{\mathbf{NN},sr}(\omega) G_0(\omega), & \text{for } r \neq s \\ G_0(\omega), & \text{for } r = s \end{cases} \quad (82)$$

Let us evaluate now the NGSMs of the structural response. In the case of multi-correlated excitations, the forcing vector $\mathbf{f}(t)$ assumes the expression (Eq. 74); it follows that the differential equation (49), governing the motion in modal subspace, can be written as

$$\ddot{\mathbf{q}}(t) + \mathbf{\Xi} \dot{\mathbf{q}}(t) + \mathbf{\Omega}^2 \mathbf{q}(t) = \mathbf{P} \bar{\mathbf{F}}(t) \quad (83)$$

where

$$\mathbf{P} = \mathbf{\Phi}^T \mathbf{B} \quad (84)$$

After very tedious algebra it can be shown that the j th NGSMs, $\lambda_{j,u_i u_i}(t)$ ($j = 0, 1, 2$), of the j th nodal displacement response, $u_i(t)$, are given as a function of modal NGSMs, $p_{jv} \lambda_{j,k\ell rs}(t)$ ($\ell, k = 1, \dots, m$; $r, s = 1, \dots, N$), by the following relationships:

$$\begin{aligned} \lambda_{0,u_i u_i}(t) &= \sum_{k=1}^m \sum_{\ell=1}^m \sum_{r=1}^N \sum_{s=1}^N p_{kr} p_{\ell s} \phi_{ik} \phi_{i\ell} \lambda_{0,k\ell rs}(t); \\ \lambda_{1,u_i u_i}(t) &= \sum_{k=1}^m \sum_{\ell=1}^m \sum_{r=1}^N \sum_{s=1}^N p_{kr} p_{\ell s} \phi_{ik} \phi_{i\ell} \lambda_{1,k\ell rs}(t); \\ \lambda_{2,u_i u_i}(t) &= \sum_{k=1}^m \sum_{\ell=1}^m \sum_{r=1}^N \sum_{s=1}^N p_{kr} p_{\ell s} \phi_{ik} \phi_{i\ell} \lambda_{2,k\ell rs}(t) \end{aligned} \quad (85)$$

where p_{jv} is the j th and v th element of the matrix $\mathbf{P}$ ($j = k, \ell$; $v = r, s$). Once again it has to be emphasized that the zeroth NGSM, $\lambda_{0,u_i u_i}(t)$, and the second-order NGSM, $\lambda_{2,u_i u_i}(t)$, are real functions that coincide with the variances of the

response in terms of displacement and velocity, respectively, while the first-order NGSM, $\lambda_{1,u_i u_i}(t)$, is a complex quantity (Di Paola 1985; Langley 1986; Di Paola and Petrucci 1990; Muscolino 1991).

As shown in Eq. 85 the nodal NGSMs can be evaluated as a function of $\lambda_{j,k\ell rs}(t)$, $j = 0, 1, 2$, which are the so-called time-dependent modal NGSMs “purged” by p_{jv} factors. After some algebra, these quantities, which are complex ones, can be evaluated, in frequency domain, for quiescent structural systems, at time $t = 0$, as (Di Paola 1985; Di Paola and Petrucci 1990; Muscolino 1991):

$$\begin{aligned} \lambda_{0,k\ell rs}(t) &= \int_0^\infty Z_{kr}^*(\omega, t) Z_{\ell s}(\omega, t) G_{\mathbf{NN},sr}(\omega) d\omega; \\ \lambda_{1,k\ell rs}(t) &= -i \int_0^\infty Z_{kr}^*(\omega, t) \dot{Z}_{\ell s}(\omega, t) G_{\mathbf{NN},sr}(\omega) d\omega; \\ \lambda_{2,k\ell rs}(t) &= \int_0^\infty \dot{Z}_{kr}^*(\omega, t) \dot{Z}_{\ell s}(\omega, t) G_{\mathbf{NN},sr}(\omega) d\omega \end{aligned} \quad (86)$$

where for $j = k, \ell$, the following positions have been made:

$$\begin{aligned} Z_{jv}(\omega, t) &= \int_0^t h_j(t - \tau) \exp(i\omega\tau) a_{vv}(\omega, \tau) d\tau; \\ \dot{Z}_{jv}(\omega, t) &= \int_0^t \dot{h}_j(t - \tau) \exp(i\omega\tau) a_{vv}(\omega, \tau) d\tau; \\ j &= k, \ell; \quad v = r, s \end{aligned} \quad (87)$$

with $h_j(t)$ the function defined in Eq. 62 and $a_{vv}(\omega, t)$ the v th element of the diagonal matrix $\mathbf{A}(\omega, t)$. Moreover, introducing the state variable, the *modal evolutionary frequency response function vector* is defined as

$$\mathbf{Y}_{jv}(\omega, t) = \begin{bmatrix} Z_{jv}(\omega, t) \\ \dot{Z}_{jv}(\omega, t) \end{bmatrix}; \quad j = k, \ell; \quad v = r, s \quad (88)$$

Stochastic Analysis of Linear Systems, Fig. 1 Hsu and Bernard (1978) model of the uniformly modulated nonstationary excitation: (a) modulating function for different value of the time instant, $t_{\max}$, in

Then relationships (33) can be rewritten in compact form as follows:

$$\begin{aligned} \Sigma_{k\ell rs}(t) &= \begin{bmatrix} \lambda_{0,k\ell rs}(t) & i\lambda_{1,k\ell rs}(t) \\ -i\lambda_{1,k\ell rs}^*(t) & \lambda_{2,k\ell rs}(t) \end{bmatrix} \\ &\equiv \int_0^\infty \mathbf{Y}_{kr}^*(\omega, t) G_{\mathbf{NN},sr}(\omega) \mathbf{Y}_{\ell s}^T(\omega, t) d\omega \end{aligned} \quad (89)$$

where $\Sigma_{k\ell rs}(t)$ coincides with the cross-modal *pre-envelope covariance matrix* (Di Paola and Petrucci 1990). The one-sided PSD $G_{\mathbf{NN},sr}(\omega)$ can be evaluated as a function of the coherence function introduced in Eq. 81. Notice that according to the Priestley evolutionary process model (Priestley 1999), the complex cross-correlation function matrix of the zero-mean modal “purged” response process can be evaluated as

which it takes the maximum value; (b) EPSP function $G_{FF}(\omega, t) = |a(t)|^2 G_{\mathbf{NN}}(\omega)$ with $G_{\mathbf{NN}}(\omega) = 1 \text{ cm}^2/\text{sec}^3$ and $\alpha = 1/5$

$$\begin{aligned} \mathbf{R}_{k\ell rs}(t_1, t_2) &= \int_0^\infty \mathbf{Y}_{kr}^*(\omega, t_1) G_{\mathbf{NN},sr}(\omega) \mathbf{Y}_{\ell s}^T(\omega, t_2) d\omega \\ &\equiv \int_0^\infty \exp[i\omega(t_1 - t_2)] \mathbf{G}_{k\ell rs}(\omega, t_1, t_2) d\omega \end{aligned} \quad (90)$$

where

$$\mathbf{G}_{k\ell rs}(\omega, t_1, t_2) = \mathbf{Y}_{kr}^*(\omega, t_1) G_{\mathbf{NN},sr}(\omega) \mathbf{Y}_{\ell s}^T(\omega, t_2) \quad (91)$$

is the cross-modal EPSP function matrix between the k, ℓ th dummy oscillators at the r th and s th support points. By means of the modal transformation (47), the nodal autocorrelation and the EPSP function matrices of the displacement response, $u_i(t)$, can be evaluated, after very simple algebra, respectively, as follows:

$$\begin{aligned} \mathbf{R}_{u_i u_i}(t_1, t_2) &= \sum_{k=1}^m \sum_{\ell=1}^m \sum_{r=1}^N \sum_{s=1}^N p_{kr} p_{\ell s} \phi_{ik} \phi_{i\ell} \mathbf{R}_{k\ell rs}(t_1, t_2), \\ \mathbf{G}_{u_i u_i}(\omega, t_1, t_2) &= \sum_{k=1}^m \sum_{\ell=1}^m \sum_{r=1}^N \sum_{s=1}^N p_{kr} p_{\ell s} \phi_{ik} \phi_{i\ell} \mathbf{G}_{k\ell rs}(\omega, t_1, t_2) \end{aligned} \quad (92)$$

Stochastic Analysis of Linear Systems, Fig. 2 NGSM functions, $\lambda_{j,uu}(t)$ ($j = 0, 1, 2$) and bandwidth parameter, $\delta_{uu}(t)$, of the transient response of an oscillator ($\omega_0 = 2\pi$ rad/sec, $\xi_0 = 0.05$) in the stationary case

(solid line) and adopting the Hsu and Bernard (1978) model, for different value of the time instant, $t_{\max}$, in which the modulating $a(t)$ function take the maximum value (dashed lines)

Consequently the nodal displacement NGSMs are the elements of the nodal pre-envelope covariance matrix, given as

$$\begin{aligned} \Sigma_{u_i u_i}(t) &\equiv \mathbf{R}_{u_i u_i}(t, t) \equiv \int_0^\infty \mathbf{G}_{u_i u_i}(\omega, t) d\omega \\ &= \sum_{k=1}^m \sum_{\ell=1}^m \sum_{r=1}^N \sum_{s=1}^N p_{kr} p_{\ell s} \phi_{ik} \phi_{i\ell} \Sigma_{k\ell rs}(t) \end{aligned} \quad (93)$$

Calculating Nonstationary Stochastic Responses

In this section, in order to evidence the main differences between the stochastic responses of structural systems subjected to both uniformly and fully nonstationary models of seismic excitations, the spectral characteristics of the response of two SDoF oscillators are evaluated.

Stochastic Analysis of Linear Systems, Fig. 3 NGSMs, $\lambda_{j,u}(t)$ ($j = 0, 1, 2$) and bandwidth parameter, $\delta_u(t)$, of the transient response of an oscillator ($\omega_0 = 8\pi$ rad/sec, $\xi_0 = 0.05$) in the stationary case

(solid line) and adopting the Hsu and Bernard (1978) model, for different value of the time instant, $t_{\max}$, in which the modulating $a(t)$ function take the maximum value (dashed lines)

Comparison Between Steady-State and Nonstationary Responses of SDoF Systems

Let us consider an oscillator, whose differential equation governing the motion is written in canonical form in Eq. 23, forced by the uniformly modulate Gaussian zero-mean nonstationary process $F(t)$, defined as

$$F(t) = a(t) N(t) \quad (94)$$

where $N(t)$ is a Gaussian white noise process, with one-sided PSD $G_{NN}(\omega) = 1 \text{ cm}^2/\text{sec}^3$, and

$a(t)$ is the normalized to one modulating function proposed by Hsu and Bernard (1978):

$$a(t) = \alpha \exp(1)t \exp(-\alpha t) U(t) \quad (95)$$

which takes its maximum value at time, $t_{\max} = 1/\alpha$, and $U(t)$ is the unit step function defined as

$$U(t - t_0) = \begin{cases} 0, & t \leq t_0; \\ 1, & t > t_0 \end{cases} \quad (96)$$

In Fig. 1 the modulating function (95) is depicted for different value of $\alpha = 1/t_{\max}$.

Stochastic Analysis of Linear Systems, Fig. 4 Spanos and Solomos (1983) model of the fully nonstationary excitation model: (a) sections of the normalized to one

modulating function $a(\omega, t)$ at different values of abscissa ω ; (b) EPSD function $G_{FF}(\omega, t) = |a(\omega, t)|^2 G_{NN}(\omega)$ with $G_{NN}(\omega) = 1 \text{ cm}^2/\text{sec}^3$

In the same figure the EPSD function $G_{FF}(\omega, t) = |a(t)|^2 G_{NN}(\omega)$ of the quasi-stationary (separable) Hsu and Bernard (1978) model is also shown assuming $\alpha = 1/5$ and $G_{NN}(\omega) = 1 \text{ cm}^2/\text{sec}^3$.

In Fig. 2 the NGSM, $\lambda_{j,uu}(t)$ ($j = 0, 1, 2$), and bandwidth parameter, $\delta_{uu}(t)$, functions of the response of an oscillator with natural circular frequency $\omega_0 = 2\pi \text{ rad/sec}$ and damping ratio $\xi_0 = 0.05$ for the Hsu and Bernard (1978) model of the uniformly modulated nonstationary excitation are depicted. These NGSMs are compared to the transient NGSMs of the stationary case ($a(t) = U(t)$), for different value of the time instant, $t_{\max}$. In Fig. 3 the comparisons are performed for an oscillator with natural circular frequency $\omega_0 = 8\pi \text{ rad/sec}$ and damping ratio $\xi_0 = 0.05$. These figures shows that when the response approaches to its steady-state condition, defined by the steady-state time $t_{SS} \geq 3/(\xi_0 \omega_0)$, the maximum values of the NGSM functions coincide with the corresponding values of the NGSM for stationary input processes. If this condition is not satisfied, the stationary approximation of input process leads to overestimated results. In fact, for the first oscillator for which the steady-state time is $t_{SS} \approx 9.55 \text{ sec}$, the NGSMs with $t_{\max} < t_{SS}$ possess maximum values lesser than the corresponding stationary case. Similar results

are obtained for the second oscillator for which $t_{SS} \approx 2.39 \text{ sec}$. Moreover, the analysis of the bandwidth parameters shows that if $t_{\max} < t_{SS}$ the parameter $\delta_{uu}(t)$ is narrower than the value obtained in the relative stationary case.

Comparison Between Uniformly and Fully Nonstationary Responses of SDoF Systems

Let us consider now the Spanos and Solomos (1983) model of the fully nonstationary Gaussian zero-mean process. For this model the normalized to one evolutionary modulating function can be written as

$$a(\omega, t) = \varepsilon(\omega) t \exp(-\alpha(\omega) t) U(t) \quad (97)$$

Selecting the following parameters $\varepsilon(\omega) = \omega \sqrt{2}/5 \pi a_{\max}$ and $\alpha(\omega) = 0.15/2 + \varepsilon^2(\omega)/4$, the normalizing to one coefficient is $a_{\max} = 1.34$. The unitary maximum is reached at $\omega = 1.937 \pi \text{ rad/sec}$ and at $t = 6.667 \text{ sec}$. In Fig. 4, the section of the modulating function at different values of abscissa ω is depicted together with the one-sided EPSD function $G_{FF}(\omega, t) = |a(\omega, t)|^2 G_{NN}(\omega)$ with $G_{NN}(\omega) = 1 \text{ cm}^2/\text{sec}^3$. This figure evidences the frequency dependence of this model of nonstationary input process.

Stochastic Analysis of Linear Systems, Fig. 5 NGSMs of the response of an oscillator with $\omega_0 = 2\pi$ rad/sec, $\xi_0 = 0.05$ for the Hsu and Bernard (1978) model (solid line) and for the Spanos and Solomos (1983) model (dashed line)

In Figs. 5 and 6 the NGSMs, $\lambda_{j,uu}(t)$ ($j = 0, 1, 2$), of the two oscillators with natural circular frequency $\omega_0 = 2\pi$ rad/sec and $\omega_0 = 8\pi$ rad/sec and damping ratio $\xi_0 = 0.05$, obtained by means of the two modulating functions before described, are depicted and compared. Analyzing these figures it can be evidenced that the temporal variation of the frequency content of the EPSD function, often neglected for mathematic convenience, has substantial effects on the structural response. In fact the maximum values of the NGSM functions depend on the form of modulating function as well as the dynamic

characteristics of the structural systems. Moreover, in some cases, the quasi-stationary modelling of the modulating function can lead to very unconservative results (see Fig. 5) of the stochastic structural response.

In Figs. 7 and 8 the mean frequencies, $v_{uu}^+(t)$, and the normalized time-varying central frequencies, $\omega_{C,uu}(t)/\omega_0$, defined in Eq. 21, of the response of the two oscillators before analyzed for the Hsu and Bernard (1978) and Spanos and Solomos (1983) modulating functions of the nonstationary zero-mean Gaussian input process, are depicted.

Stochastic Analysis of Linear Systems, Fig. 6 NGSMs of the response of the oscillator with $\omega_0 = 8\pi$ rad/sec, $\xi_0 = 0.05$ for the Hsu and Bernard (1978) model (solid line) and for the Spanos and Solomos (1983) model (dashed line)

Figure 7 shows that for the Hsu and Bernard (1978) modulating function, the mean frequencies, $v_{uu}^+(t)$, get to an asymptotic value very close to the natural frequency of the oscillators. This behavior is not verified for the oscillator with higher natural circular frequency subjected to the Spanos and Solomos (1983) model of the nonstationary input process, where the mean frequency decreases evidencing the frequency dependence of the structural response. Similar results are obtained for the normalized time-varying central frequencies, $\omega_{C,uu}(t)/\omega_0$, depicted in Fig. 8.

Summary

The dynamic behavior of structural systems subjected to uncertain dynamic excitations can be performed through the stochastic analysis, which requires the probabilistic characterization of both input and output processes. The characterization of output processes can be extremely complex, when nonstationary and/or non-Gaussian input processes are involved. However, in several cases the approximate description of the dynamic structural response based on its spectral characteristics may be sufficient.

Stochastic Analysis of Linear Systems,

Fig. 7 Mean frequencies of the response of the oscillator for the Hsu and Bernard (1978) model (solid line) and for the Spanos and Solomos (1983) model (dashed line); (a) oscillator with $\omega_0 = 2\pi$ rad/sec and $\xi_0 = 0.05$; (b) oscillator with $\omega_0 = 8\pi$ rad/sec and $\xi_0 = 0.05$

Stochastic Analysis of Linear Systems, Fig. 8 Time-varying central frequency, normalized by the natural circular frequency, of the oscillator for the Hsu and Bernard (1978) model (solid line) and for the Spanos and Solomos

(1983) model (dashed line); (a) oscillator with $\omega_0 = 2\pi$ rad/sec and $\xi_0 = 0.05$; (b) oscillator with $\omega_0 = 8\pi$ rad/sec and $\xi_0 = 0.05$

In this study a unitary approach to evaluate the spectral characteristics of the structural response, to perform the reliability assessment, of classically damped linear systems subjected to stationary or nonstationary mono-/multi-correlated zero-mean Gaussian excitations, is described.

The main steps of the described approach are (i) the use of modal analysis to decouple the equation of motion; (ii) the determination, in state variable, of the evolutionary frequency response vector functions and of the evolutionary power spectral density function matrix of the structural response; and (iii) the evaluation of the nongeometric spectral moments as well as the spectral characteristics of the stochastic response of linear systems subjected to stationary

or nonstationary mono-/multi-correlated zero-mean Gaussian seismic excitations.

Nonlinearity; Random vibrations

Introduction

The present chapter is devoted to the probabilistic analysis of the random response of nonlinear structural systems exposed to random excitation with special attention to earthquake action. The random system response may be due to random excitation, to random system properties, to random boundary conditions. The nonlinear character of the response is mainly due to the nonlinear materials properties and to the effect of large displacements (the so-called P- Δ effect).

The first pioneering studies on this topic took place in the 1960s and 1970s (VanMarcke et al. 1970; Iwan 1973; Atalik and Utku 1976; Spanos 1976), when equivalent linearization techniques were used, taking advantage of the availability of first digital computers.

The attention is limited herein to systems having deterministic properties, including deterministic boundary conditions, considering those types of nonlinearity that can really occur during earthquakes.

After a brief review of the types of nonlinear behavior that can be expected, the available methods for the analysis of the response are discussed.

They can be classified into analytical and simulation methods. Among the first ones are considered in the following: the Fokker-Planck-Kolmogorov (FPK) equation, the equivalent linearization, the perturbation method, and the

stochastic averaging. The simulation methods based on Monte Carlo techniques are then presented.

Types of Nonlinearity in Earthquake Engineering

During severe earthquakes most structures undergo great amplitude time-varying displacements which can induce inelastic behavior in the structural members.

In the case of reinforced concrete structures, several phenomena take place, like cracking and crushing, together with yielding and strain hardening of steel. Also the bond between steel and concrete may be imperfect, as great shear forces must be exchanged and slippage can occur. Moreover, the reversal of the sign of displacements, due to the structural vibration, leads to the phenomenon of the hysteresis and to the subsequent dissipation of energy.

This apparently undesirable behavior is deliberately taken into account by the modern strategies for aseismic design of reinforced concrete structures, based on the concept of the capacity design, as it allows the reduction of the inertia forces acting upon the structures by means of energy dissipation.

The modeling of the interaction of concrete and steel under severe earthquakes was studied in depth in the past (Park et al. 1972, Takeda et al. 1970, Popov et al. 1972). Among the other aspects, the hysteretic behavior after steel yielding, the stiffness deterioration due to cracking of concrete, the strength deterioration and softening consequent to cumulative severe large deformations, and the pinching behavior due to shear, along with bond deterioration, were investigated.

Simple hysteretic models that can be used in the practice are presented in Fig. 1. Model (a) represents an elastic-perfectly plastic behavior, while model (b) is a variant allowing for strain hardening. Model (c) (Masing 1926) takes into account the stiffness deterioration, using smooth curves, and model (d) is the degrading stiffness model due to Takeda.

The Masing model is also suitable to represent the friction dissipation which takes place in masonry structures under earthquakes.

An interesting and powerful nonlinear model is represented by the Bouc-Wen equation (Bouc 1967; Wen 1976).

The restoring force F is given by

$$F = \alpha k_0 x + (1 - \alpha) Q Z \quad (1)$$

where k_0 is the initial system stiffness, α is the ratio between the post- and the pre-yielding stiffness, x is the displacement, Q is the yield strength, and Z is a nondimensional parameter which takes into account the hysteresis, satisfying the following nonlinear first-order differential equation:

$$q \frac{dZ}{dt} = A \dot{x} - \beta |\dot{x}| Z |Z|^{n-1} - \tau \dot{x} |Z|^n \quad (2)$$

where β , τ , A , and n are the dimensionless parameters which control the shape of the hysteresis loop, q is the yield displacement, and $\dot{x}$ is the velocity.

Typical force-deformation hysteresis loops generated using Eqs. 1 and 2 are shown in Fig. 2. In the examples the dynamical system is acted upon by a sinusoidal motion having amplitude 0.1 m and frequency 1.0 Hz. The other parameters of the model are $q = 0.025$ m, $\beta = \tau = 0.5$, $k_0 = 1$, and $A = 1$. Thus, by changing the different parameters of the Wen's model, many hysteretic behaviors can be obtained such as the Masing type, the elastic-perfectly plastic, and the elastic plastic with hardening.

Analytical Techniques

The solution of the stochastic differential equations that govern the motion of nonlinear dynamical systems has been first achieved by means of analytical techniques. Exact and approximate solutions can be obtained by these techniques depending on the complexity of the problem. The stochastic response of nonlinear single degree of freedom system with elastic behavior and Gaussian external excitation can be generally

Stochastic Analysis of Nonlinear Systems, Fig. 2 Different hysteresis loops from the Bouc-Wen equation

solved exactly through the FPK equation. Nonlinear elastic multi-degree of freedom can be solved exactly via FPK equation only for very restrictive conditions on the stochastic external excitation. Thus, approximate solutions have

been searched for nonlinear multi-degree of freedom systems and for inelastic systems. In the next paragraphs a brief description of the FPK equation and of some approximate methods is provided.

Fokker-Planck-Kolmogorov Equation

Introduction

The theory of stochastic processes began in the nineteenth century when physicists were trying to show that heat in a medium is essentially a random motion of the constituent molecules. At the end of that century, some researches began to adopt more direct mathematical models of random disturbances instead of considering random motion as due to collisions between objects having a random distribution of initial positions and velocities. In this context several physicists, among which Fokker (1914) and Planck (1915), developed partial differential equations, which were versions of what was subsequently called the Fokker-Planck equation, to study the theory of Brownian motion.

The theory of the Fokker-Planck equation was made considerably more general by Kolmogorov (1931). He assumed the process to be continuous with respect to time and Markovian, i.e., a process for which the future probability density conditional on the present and past is actually independent of the past. On introducing further assumptions, Kolmogorov was able to show that the probability density of the process obeys a partial differential equation of the Fokker-Planck type. He also gave another partial differential equation which the future probability density, conditional on the present state, obeys with respect to the present state. The latter equation is called Kolmogorov's first equation, and the Fokker-Planck-type equation is called Kolmogorov's second equation. Sometimes the Fokker-Planck equation is called the Fokker-Planck-Kolmogorov (FPK) equation.

Solution of the Fokker-Planck-Kolmogorov Equation for an SDOF Elastic Nonlinear Second-Order System

Let us consider the nonlinear nonconservative stochastic system

$$m \frac{d^2x}{dt^2} + c \frac{dx}{dt} + \frac{\partial G(x)}{\partial x} = \xi(t) \quad (3)$$

that describes the displacement x of a body with mass m , damping c , and potential energy $G(x)$

subjected to a (scalar) white-noise forcing function $\xi(t)$ with second moment rate b .

By placing $y = m \frac{dx}{dt}$ the system may be rewritten in the state space as a system of first-order differential equations:

$$\begin{aligned} \frac{dx}{dt} &= \frac{y}{m} \\ \frac{dy}{dt} &= -\frac{\partial G(x)}{\partial x} - \frac{c}{m}y + \xi(t) \end{aligned} \quad (4)$$

This is a special case of the system:

$$\begin{aligned} \frac{dx}{dt} &= \frac{\partial H}{\partial y} \\ \frac{dy}{dt} &= -\frac{\partial H}{\partial x} - c \frac{\partial H}{\partial y} + \xi(t) \end{aligned} \quad (5)$$

where the symbol H represents the total energy (potential plus kinetic):

$$H = G(x) + \frac{1}{2m}y^2 \quad (6)$$

The steady-state probability density $p(x,y)$ for the system of Eq. 5 can be determined by solving the appropriate stationary FPK equation:

$$\begin{aligned} \left[-\frac{\partial}{\partial x} \left(\frac{\partial H}{\partial y} p \right) + \frac{\partial}{\partial y} \left(\frac{\partial H}{\partial x} p \right) \right] + \frac{\partial}{\partial y} \left(c \frac{\partial H}{\partial y} p \right) \\ + \frac{1}{2} b \frac{\partial^2 p}{\partial y^2} = 0 \end{aligned} \quad (7)$$

If p is any function of the energy H , the terms in the square brackets vanish, and therefore if it can be found a particular function $p(H)$ which makes the remaining two terms vanish, $p(H)$ is a solution of Eq. 7.

By substituting $p(x, y) = p(H(x, y))$ and assuming null the terms in the square bracket, Eq. 7 becomes

$$\frac{\partial}{\partial y} \left(c \frac{\partial H}{\partial y} p(H) \right) + \frac{1}{2} b \frac{\partial^2}{\partial y^2} p(H) = 0 \quad (8)$$

Stochastic Analysis of Nonlinear Systems,

Fig. 3 Parameters describing a continuous piecewise-linear restoring force

The integration with respect to y yields

$$c \frac{\partial H}{\partial y} p(H) + \frac{1}{2} b \frac{\partial}{\partial y} p(H) = L(x) \quad (9)$$

where $L(x)$ is an arbitrary function.

As boundary conditions for the stationary FPK equation can be assumed, that p is zero at infinity. Thus, the left side of Eq. 9 vanishes when $y \rightarrow \infty$ and hence $L(x) = 0$. Equation 9 simplifies to

$$c \frac{\partial H}{\partial y} p(H) + \frac{1}{2} b \frac{\partial p}{\partial H} \frac{\partial H}{\partial y} = 0 \quad (10)$$

Since $\frac{\partial H}{\partial y}$ cannot be identically null (otherwise H would be independent of y and hence so will be p), then Eq. 10 yields

$$\frac{\partial p}{\partial H} + \frac{2c}{b} p = 0 \quad (11)$$

whose general solution representing the steady-state probability density is

$$p(x, y) = C \exp \left[-\frac{2c}{b} H(x, y) \right] \quad (12)$$

being C a normalizing constant.

For the case of an SDOF system with unit mass and continuous linear piecewise restoring force, a closed form solution of the FPK equation can, thus, be determined. This model can be

used, for instance, to determine the response of cracked reinforced concrete beams with cracks that alternatively open and close (Breccolotti et al. 2008).

In this case the motion of the vibrating system can be described by the equation

$$\ddot{x} + \beta_1 \dot{x} + F_i(x) = f(t) \quad (13)$$

where $F_i(x) = \omega_i^2(x - x_{0i})$ for $x_i \leq x \leq x_{i+1}$, $i = 1, 2, \dots$ (see Fig. 3), ω_i and x_{0i} are positive constants, and $f(t)$ is a Gaussian stochastic process having null mean and uniform power spectrum S_0 over the entire frequency domain.

The following boundary conditions have to be satisfied:

$$w_i(x_{i+1}, \dot{x}, \ddot{x}) = w_{i+1}(x_{i+1}, \dot{x}, \ddot{x}) \quad (14)$$

$$\sum_i \int \int \int w_i(x, \dot{x}, \ddot{x}) dx d\dot{x} d\ddot{x} = 1 \quad (15)$$

$$\omega_i^2(x_{i+1} - x_{0i}) = \omega_{i+1}^2(x_{i+1} - x_{0i+1}) \quad (16)$$

that represent the continuity of the probability density function of the response, the normalizing condition, and the continuity of the piecewise-linear restoring force characteristics, respectively.

It can be demonstrated that the solution of the FPK equation corresponding to this system, representing the stationary probability density function (PDF) of the response, can be written in the form

$$\begin{aligned} w_i(x, \dot{x}) &= C_i \cdot e^{-\left(\frac{\omega_i^2}{s_0} \beta_1 x^2 + \frac{\beta_1}{s_0} \dot{x}^2 - \frac{2s_0 \omega_i^2}{s_0} \beta_1 x\right)} \\ &= C_i \cdot e^{-\frac{\omega_i^2}{s_0} \beta_1 x^2 + \frac{2s_0 \omega_i^2}{s_0} \beta_1 x} \cdot e^{-\frac{\beta_1}{s_0} \dot{x}^2} \\ &= w_{i,x}(x) \cdot w_{i,\dot{x}}(\dot{x}) \end{aligned} \quad (17)$$

It can be noted, as demonstrated by Lin and Cai (1995), that for an SDOF system having nonlinear stiffness, linear damping, and exposed to a Gaussian white-noise excitation, the stationary displacement (x) and the velocity ($\dot{x}$) are independent random variables.

Solution of the Fokker-Planck-Kolmogorov Equation for an nDOF Elastic Nonlinear Second-Order System

Several solutions of the FPK equation for nonlinear elastic systems with n degrees of freedom (nDOF) subjected to random excitation have been developed in the past (Piszczec and Nizioł 1986). Let us consider the following set of n equations for an nDOF system, characterized by elastic nonlinear properties:

$$\ddot{x}_i + \beta_i \dot{x}_i + \frac{1}{m_i} \frac{\partial U}{\partial x_i} = f_i(t) \quad (18)$$

where $f_i(t)$ are independent and uncorrelated white noises with null mean and spectral density S_i and β_i are positive constants.

The term $U(x_1, x_2, \dots)$ represents the potential energy.

This system of differential equations can be solved assuming the validity of the following conditions:

$$\frac{S_i m_i}{2\beta_i} = k \quad i = 1, 2, \dots \quad (19)$$

being k a positive constant. In this case the solution of the FPK equation is

$$\begin{aligned} w(x_1, x_2, \dots, \dot{x}_1, \dot{x}_2, \dots) \\ = C \exp \left[-\frac{1}{k} \left(\frac{1}{2} \sum_{i=1}^n m_i \dot{x}_i^2 + U \right) \right] \end{aligned} \quad (20)$$

This form of the probability density function is known as the Maxwell-Boltzmann distribution, being the expression inside the parentheses the total mechanical energy of the system.

Equivalent Linearization

The very restrictive conditions that make available exact solutions for the stochastic dynamical systems motivated the development of approximate solution techniques. Methods such as the equivalent linearization have been developed to generate first-order approximate solutions. These techniques can also be applied in some cases to single-degree-of-freedom nonlinear oscillator with hysteretic behavior.

The adaptation of the classical equivalent linearization technique of the deterministic theory to systems subjected to random excitations was independently developed by Booton (1953) and Caughey (1953). Later on other researchers have extended the method to encompass approximate solutions of the stationary random response of multi-degree-of-freedom nonlinear oscillators. In this case the mathematical equation that describes the response of the system is

$$M\ddot{\underline{x}} + C\dot{\underline{x}} + K\underline{x} + \underline{f}(\underline{x}, \dot{\underline{x}}) = \underline{G} \quad (21)$$

where M , C , and K are the constant mass, damping, and stiffness square matrices with dimension n , $\underline{f}(\underline{x}, \dot{\underline{x}})$ is an n -vector function of the dependent variable $\underline{x}$ and its derivative, and

$$\underline{G}^T = (g_1, \dots, g_n) \quad (22)$$

with n stationary Gaussian processes g_i .

The principle of the method is the replacement of the nonlinear dynamical system described by Eq. 21 by an auxiliary linear system for which the exact analytic solution is known. The replacement is made so as to be optimum with respect to some measure of the difference between the original and the auxiliary system.

Stochastic Analysis of Nonlinear Systems,

Fig. 4 Bilinear hysteretic restoring force

This optimum auxiliary linear system, which will be called *equivalent*, is defined as

$$M\ddot{\underline{x}} + (C + C_e)\dot{\underline{x}} + (K + K_e)\underline{x} = \underline{G} \quad (23)$$

where C_e and K_e are t -independent matrices. These matrices must be such that the difference $\underline{d}$ between systems of Eqs. 21 and 23, defined by

$$\underline{d} = \underline{f}(\underline{x}, \dot{\underline{x}}) - C_e\dot{\underline{x}} - K_e\underline{x}, \quad (24)$$

is minimized for every $\underline{x}$ which belongs to the class of solutions of the system (23).

Since the excitation $\underline{G}$ of the linear system is Gaussian, it is well known that the response $\underline{x}$ will be Gaussian as well. Therefore, the matrices C_e and K_e must be such that the difference $\underline{d}$ is minimized for every stationary Gaussian random vector $\underline{x}$.

The equivalent linearization technique is thus composed of the following steps:

1. Identification of a class of approximate solution functions and the parameters defining each member of the class.
2. Selection of the norm of the difference vector $\underline{d}$.
3. Selection of the averaging operator G .
4. Determination of the matrices C_e and K_e of the equivalent linear system in terms of the identification parameters of $\underline{x}$.

5. Solution of the equivalent linear system to obtain equations for the specification of the identification parameters of $\underline{x}$.

The application of the method can be conveniently shown by analyzing the hysteretic stochastic dynamical single DOF system described by the following differential equation (Iwan and Lutes 1968):

$$\ddot{x} + 2\beta_0\omega_0\dot{x} + \omega_0^2\varphi(x) = \frac{n(t)}{m} \quad (25)$$

where m denotes the mass, ω_0 is the undamped natural circular frequency for small-amplitude vibrations, β_0 is the fraction of critical damping for small-amplitude vibrations, and $\varphi(x)$ is the bilinear hysteretic restoring force, shown in Fig. 4, having a unit slope for small amplitudes and a second slope α . The excitation $n(t)$ is a stationary random function with a uniform power spectral density S_0 and a Gaussian probability distribution.

The equivalent linear system

$$\ddot{x} + 2\beta_{eq}\omega_{eq}\dot{x} + \omega_{eq}^2x = \frac{n(t)}{m} \quad (26)$$

may be identified by choosing the parameters ω_{eq} and β_{eq} so as to minimize the mean-squared

difference between the nonlinear inelastic equation of motion (25) and the linear equation (26).

For the case of bilinear hysteretic oscillator with “small” nonlinearity, a solution for the parameters ω_{eq} and β_{eq} has been found by Caughey (1960) under the following assumptions:

1. The response of the nonlinear system is contained within a narrow frequency band.
2. The probability density of the amplitude of this narrowband response follows the Rayleigh distribution.

These assumptions lead to the following expressions for ω_{eq} and β_{eq} :

$$\left(\frac{\omega_{eq}}{\omega_0}\right)^2 = 1 - \left[\frac{8(1-\alpha)}{\pi}\right] \int_1^\infty \left(2^{-3} + \frac{1}{\lambda z}\right) (z-1)^{\frac{1}{2}} e^{-\frac{2}{z}} dz \quad (27)$$

and

$$\beta_{eq} = \beta_0 \left(\frac{\omega_0}{\omega_{eq}}\right) + \left(\frac{\omega_0}{\omega_{eq}}\right)^2 \frac{(1-\alpha)}{\sqrt{\pi\lambda}} \operatorname{erfc}\left(\lambda^{-\frac{1}{2}}\right) \quad (28)$$

where

$$\lambda = \frac{2\sigma_x^2}{Y^2}$$

In general Eq. 27 must be evaluated numerically. However, when $\lambda \gg 1$, the asymptotic expansion shown in Eq. 29 can be used:

$$\left(\frac{\omega_{eq}}{\omega_0}\right)^2 = \alpha + \left[\frac{8(1-\alpha)}{\pi}\right] \left(0.6043\lambda^{-\frac{3}{4}} - 0.2451\lambda^{-\frac{5}{4}} - 0.1295\lambda^{-\frac{7}{4}}\right) \quad (29)$$

After finding ω_{eq} and β_{eq} , the RMS levels of response of the equivalent linear system can be obtained from

$$\sigma_x^2 = \omega_{eq}^2 \sigma_x^2 = \frac{\pi S_0}{4m^2 \beta_{eq} \omega_{eq}} \quad (30)$$

Perturbation Method

The random response of slightly nonlinear vibrating systems can also be obtained by applying the classical perturbation method (Crandall 1963). The method is based on the assumption that the nonlinearity is small enough to allow the solution of the stochastic differential equation of motion to be expressed as a power series. If the following SDOF system is considered

$$\ddot{x} + 2\zeta\omega_0\dot{x} + \omega_0^2 x + \varepsilon\eta(x, \dot{x}) - f(t) = 0 \quad (31)$$

where η is a nonlinear function and ε is a sufficiently small parameter, the solution can be expressed as a power series in ε :

$$x(t) = x_0(t) + \varepsilon x_1(t) + \varepsilon^2 x_2(t) + \dots \quad (32)$$

Substituting Eq. 32 into Eq. 31 and grouping the different terms having the same power of ε , a set of linear equation in $x_0, x_1, x_2, \dots$ can be obtained. If the external excitation $f(t)$ is weakly stationary, the steady-state response to Eq. 31 can be constructed from the following solutions of the set of linear equations:

$$\begin{aligned} x_0(t) &= \int_{-\infty}^{\infty} f(t-\tau)h(\tau)d\tau \\ x_1(t) &= \int_{-\infty}^{\infty} \eta[x_0(\tau), \dot{x}_0(\tau)]h(\tau)d\tau \\ x_2(t) &= \int_{-\infty}^{\infty} \eta[x_1(\tau), \dot{x}_1(\tau)]h(\tau)d\tau \\ &\dots \end{aligned} \quad (33)$$

being h the impulse response function corresponding to $\varepsilon = 0$.

Stochastic Averaging

The method of stochastic averaging, firstly introduced by Landau and Stratonovich (1962), has proved to be a very useful tool for deriving approximate solutions to problems involving the dynamical response of lightly damped systems to broadband random excitation. It is based on the principle that the rate of change with respect to time of the oscillator's total energy is equal to the power input due to random excitation, minus the power dissipation due to the damping mechanism.

In lightly damped structures the slowly varying energy can be treated as a constant over an appropriate period of oscillation, and oscillatory terms can be approximated by their time averages over one period of oscillation. Furthermore, under broadband random excitation, the relaxation time of the oscillator response is much greater than the correlation time of the excitation. Thus, it is possible to model the power input due to the excitation as a nonzero mean component plus an additional, fluctuating component with the character of white noise.

Thanks to these properties, the method can also be applied to strongly nonlinear stiffness oscillators and to certain nonlinearities of the hysteretic kind.

The essence of the standard stochastic averaging method is embodied in a limit theorem due to Stratonovich (1963) and Khasminskii (1966):

$$\dot{X} = \varepsilon^2 f(X, t) + \varepsilon g(X, t, Y(t)) \quad (34)$$

where $X(t)$ is an n -vector stochastic process, usually representing the response, and $Y(t)$ is an m -vector stochastic excitation process. If the elements of $Y(t)$ are broadband processes, with zero means, and the vectors f and g satisfy certain requirements (which are almost invariably met in practice), then it can be shown that $X(t)$ may be uniformly approximated over a time interval of order $O(\varepsilon^{-1})$ by an n -dimensional Markov process, which satisfies the Ito equation:

$$dX = \varepsilon^2 m(X)dt + \varepsilon \sigma(X)dW \quad (35)$$

The symbol $W(t)$ denotes an n -vector of independent Wiener (or Brownian) processes, with unit variance, and m and σ are, respectively, the “drift vector” and the “diffusion matrix.”

If ε is small, then the elements of $X(t)$ must be slowly varying, with respect to time. The equations of motion which occur in random vibration problems can be written in state space form, involving displacement and velocity response variables. However, these variables are usually rapidly fluctuating with respect to time. Evidently a transformation of variables is required to cast the equations of motion into the form of Eq. 34.

It has been shown that the stochastic averaging method is applicable to an oscillator with bilinear restoring force-displacement characteristic when the energy dissipation due to hysteresis is relatively low. In this case, after a preliminary averaging operation, the equation of motion could be cast into the standard form of Eq. 34, enabling the stationary response distribution to be determined together with statistics such as the standard deviation of the displacement and the average yielding rate.

Nevertheless, the standard stochastic averaging technique cannot be used for examining the effect of strongly nonlinear restoring forces since, to $O(\varepsilon^2)$, this effect vanishes. In these cases it is possible to combine the equivalent linearization method with stochastic averaging and treat the equivalent frequency as amplitude dependent.

An alternative approach to the analysis of nonlinear oscillators based on a consideration of the energy envelope has been developed by Roberts and Spanos (1986).

Consider an oscillator with the following equation of motion:

$$\ddot{x} + \varepsilon^2 h(x, \dot{x}) + G(x) = \varepsilon z(t) \quad (36)$$

with ε assumed small enough to ensure that $x(t)$ is $O(\varepsilon^0)$. The symbol $G(x)$ denotes an arbitrary nonlinear stiffness term, while the energy envelope $V(t)$ may be defined as the sum of the kinetic and the potential energy:

$$V(t) = \frac{\dot{x}^2}{2} + U(x) \quad (37)$$

and

$$U(x) = \int_0^x G(\xi) d\xi \quad (38)$$

For the special case where the damping is linear $\varepsilon^2 h(x, \dot{x}) = 2\zeta\omega_0\dot{x}$ and the nonlinear stiffness has the power-law form

$$G(x) = k|x|^v \text{sgn}(x), \quad (39)$$

it is possible to obtain analytical solution for the transition density function $p(V, t|V_1, t_1)$ of $V(t)$. By introducing the nondimensional energy variable

$$\chi(t) = \frac{V(t)}{\gamma k \sigma^{v+1}}, \quad (40)$$

the following transition density $p(\chi, t|\chi_1, t_1) = p(\chi, \tau|\chi_1)$ can be found:

$$p(\chi, \tau|\chi_1) = \frac{1}{(1-q)} \left(\frac{\chi}{\chi_1 q} \right)^{\frac{\rho}{2}} \exp \left\{ -\frac{\chi + q\chi_1}{1-q} \right\} I_{\rho} \left\{ \frac{2\sqrt{\chi\chi_1 q}}{1-q} \right\} \quad (41)$$

being

$$\rho = \frac{1}{\alpha} - 1 \quad (42)$$

$$q = e^{-2\alpha\zeta\omega_0 t} \quad (43)$$

and with $I_{\rho}(\cdot)$ as the modified ρ - order Bessel function of the first kind.

Path Integral Solution

The FPK equation that describes the evolution of the response's probability density (PD) of a nonlinear system excited by an external white noise can be solved numerically by path integral (PI) solution procedures. In essence the PI method is a stepwise calculation of the joint probability density function of a set of state space variables describing a white-noise-excited nonlinear dynamic system. Among the first efforts to develop the PI method into numerical tools are those of Wehner and Wolfer (1983), Sun and Hsu (1990), and Naess and Johnsen (1993).

The PI method has been proved to provide extremely accurate results for the tail behavior of the joint probability density function of the state space vector and thus for the estimation of extreme responses of nonlinear dynamical systems excited by forces, external or parametric, that can be approximated as white noise, filtered

white-noise processes, and combined normal and Poisson white noise (Pirrotta and Santoro 2011).

The PI method is based on the fact that the state space vector, Y_t say, obtained as a solution of a stochastic differential equation is a Markov vector process. This makes it possible to use a time stepping procedure to obtain the joint probability density function $p(y, t)$ of Y_t as a function of time t by exploiting the fundamental equation:

$$p(y, t) = \int_{-\infty}^{\infty} p(y, t|y', t') p(y', t') dy' \quad (44)$$

where $p(y, t|y', t')$ denotes the conditional probability density function of Y_t given that $Y_{t'} = y'$. For small time increments $\Delta t = t - t'$, $p(y, t|y', t')$ will be referred to as the short-time transition probability density function. It can be demonstrated that for a numerical solution of a stochastic differential equation, the short-time transition probability density function can always be given as an analytical, closed-form expression. Hence, if an initial probability density function, $p_0(y) = p(y, t = 0)$, is given, then Eq. 44 can be invoked repeatedly to produce the time evolution of $p(y, t)$. If the stochastic differential equation has an invariant measure there exists a stationary probability density function $p_s(y)$, then, eventually, assuming that $p_0(y) \neq p_s(y)$, $p(y, t)$ will approach this stationary probability density function. The number of times Eq. 44 has to be repeatedly used to reach the stationary situation depends, of course, on the dynamic system and on the specified initial probability density function $p_0(y)$.

Monte Carlo Simulation Methods

Generality

The probabilistic structure and the statistical moments of the response of any type of nonlinear mechanical systems can be evaluated using simulation techniques, like the Monte Carlo method. This method operates in the time domain by repeating a great number of times deterministic

analyses, each one consisting in a step-by-step nonlinear analysis of the structure subjected to an earthquake record.

In order to evaluate properly the statistics of the response, each earthquake record must belong to the same “family,” in the sense that all the records must be compatible with the same power spectral density (PSD) function.

The major advantage of Monte Carlo simulation is that it can deal with almost any type of nonlinearity, maybe using the same commercially available packages that are used for the deterministic analyses. Its only disadvantage is that it is time-consuming, as many analyses are requested in order to have reliable estimates of the statistical properties of the response.

The number of needed runs may be many thousands, even if 300–400 analyses can give acceptable results in practical applications.

Probably the most important and delicate part of Monte Carlo simulation is the generation of realizations of the stochastic process or field that represents the earthquake.

In principle the earthquakes may be modeled as nonstationary non-Gaussian random fields, even if the null-mean Gaussian approximation is considered acceptable by most authors.

If the analyzed system is a building, it is reasonable, due to the reduced area of ground that it occupies, to model the process as one-dimensional. If the hypothesis that the earthquake induces ground acceleration in one direction only may be accepted, the process is univariate.

In the case of structures that have a notable extension over the ground, like long span bridges, the earthquake input is not the same in different part of the system and the process must be considered as multidimensional. If only one-direction component of the ground acceleration is considered, it is also univariate. Otherwise it is multivariate.

Univariate One-Dimensional Stochastic Processes

The basic method to generate a realization of a univariate, one-dimensional (1V-1D) stationary stochastic process $f_0(t)$ with zero mean and one-sided PSD function $G_{f_0}(\omega)$ was proposed by Shinozuka (Shinozuka 1972).

The process may be simulated by the series

$$f(t) = \sqrt{2} \sum_{n=0}^{N-1} A_n \cdot \cos(\omega_n t + \Phi_n) \quad (45)$$

where

$$A_n = \sqrt{G_{f_0}(\omega_n) \Delta\omega}, \quad n = 0, 1, 2, \dots, N-1 \quad (46)$$

$$\omega_n = n\Delta\omega, \quad (47)$$

$$\Delta\omega = \frac{\omega_u}{N} \quad (48)$$

ω_u is the upper cutoff frequency and the phase angle Φ_n is the realization of a random variable uniformly distributed over the interval $[0, 2\pi]$.

Shinozuka and Deodatis (1991) showed that it must be

$$A_0 = 0 \text{ and } S_{f_0}(\omega_0 = 0) = 0 \quad (49)$$

to ensure that the realization of the process is ergodic.

Univariate Multidimensional Stochastic Processes

For the sake of simplicity, let us consider the special case of a univariate two-dimensional stochastic process (1V-2D), which may represent the random field of the one-direction ground acceleration interesting a great-extension structure frozen in time.

The process $f_0(x_1, x_2)$, having cross-PSD $G_{f_0}(k_{1n_1}, k_{2n_2})$, can be simulated by the series

$$f(x_1, x_2) = \sqrt{2} \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} \left[A_{n_1 n_2} \cos(k_{1n_1} x_1 + k_{2n_2} x_2 + \Phi_{n_1 n_2}^{(1)}) + \tilde{A}_{n_1 n_2} \cos(k_{1n_1} x_1 - k_{2n_2} x_2 + \Phi_{n_1 n_2}^{(2)}) \right] \quad (50)$$

where

$$G_{f_0}(k_1, k_2), \tilde{A}_{n_1 n_2} = \sqrt{G_{f_0}(k_{1n_1}, -k_{2n_2}) \Delta k_1 \Delta k_2} \quad (51)$$

$$k_{1n_1} = n_1 \Delta k_1, \quad k_{2n_2} = n_2 \Delta k_2, \quad (52)$$

$$\Delta k_1 = \frac{k_{1u}}{N_1}, \quad \Delta k_2 = \frac{k_{2u}}{N_2} \quad (53)$$

$$n_1 = 0, 1, 2, \dots, N_1 - 1, \quad n_2 = 0, 1, 2, \dots, N_2 - 1 \quad (54)$$

and

$$A_{0n_2} = A_{n_1 0} \text{ for } n_1 = 0, 1, 2, \dots, N_1 - 1 \text{ and } n_2 = 0, 1, 2, \dots, N_2 - 1 \quad (55)$$

$$\tilde{A}_{0n_2} = \tilde{A}_{n_1 0} \text{ for } n_1 = 0, 1, 2, \dots, N_1 - 1 \text{ and } n_2 = 0, 1, 2, \dots, N_2 - 1 \quad (56)$$

k_{1u} and k_{2u} are the upper cutoff wave numbers and the phase angles $\Phi_{n_1 n_2}^{(1)}$ and $\Phi_{n_1 n_2}^{(2)}$ are the realization of two statistically independent random variables uniformly distributed over the interval $[0, 2\pi]$.

The extension to the case of 1D-3V process $f_0(x_1, x_2, t)$, including also the time variability, is straightforward.

Earthquake Power Spectra

A well-known PSD of the ground motion available in literature is the so-called Kanai-Tajimi spectrum. It is based on the hypothesis that the ground acceleration during earthquakes may be considered as a filtered band-limited white-noise process expressed by the following function:

$$G(\omega) = \frac{[1 + 4\xi_g^2 \cdot (\omega/\omega_g)^2]}{[1 - (\omega/\omega_g)^2]^2 + 4\xi_g^2 \cdot (\omega/\omega_g)^2} G_0 \quad (57)$$

Stochastic Analysis of Nonlinear Systems, Fig. 5 Kanai-Tajimi power spectrum

where G_0 is the constant value of the spectrum of the white-noise process and ω_g and ξ_g are the predominant ground frequency and the ground damping.

The values of $\omega_g = 4\pi$ and $\xi_g = 0.60$ have been suggested as representative of earthquakes on firm ground.

The typical aspect of the Kanai-Tajimi PSD is shown in Fig. 5.

Anyway in most cases it is better to derive the PSD from the response spectrum.

For this purpose let us consider the following SDOF deterministic dynamical system:

$$\ddot{x}(t) + 2\xi\omega\dot{x}(t) + \omega x(t) = f_0(t) \quad (58)$$

acted upon by a 1V-1D stationary stochastic process $f_0(t)$ which represents the ground acceleration. If the process is Gaussian, its probabilistic structure is fully represented by its PSD G_{f_0} .

The random dynamic analysis of the system in the frequency domain allows finding the PSD of the response $x(t)$, which is the system displacement:

$$G_x(\omega) = G_{f_0}(\omega) |H(\omega)|^2 \quad (59)$$

The variance of the response is represented by the area under the PSD function:

$$\sigma_x^2 = \int_0^\infty G_{f_0}(\omega) |H(\omega)|^2 d\omega \quad (60)$$

where $|H(\omega)|^2$ is the squared frequency-domain transfer function between loading and system response:

$$|H(\omega)|^2 = \frac{1}{(\omega_n^2 - \omega^2)^2 + 4\xi^2 \omega_n^2 \omega^2} \quad (61)$$

with ω_n the natural frequency of the system.

The variance of the pseudo-acceleration response is

$$\begin{aligned} \sigma_{\ddot{x}}^2 &= \omega_n^4 \sigma_x^2 = \omega_n^4 \int_0^\infty G_{f_0}(\omega) |H(\omega)|^2 d\omega \\ &\approx G_{f_0}(\omega_n) \omega_n \left(\frac{\pi}{4\xi} - 1 \right) \end{aligned} \quad (62)$$

The ordinates $\ddot{x}_{s,p}$ of the acceleration response spectrum are the maxima of the response $\ddot{x}(t)$ of an oscillator whose frequency ω varies from 0 to some stipulated maximum value. The parameter “s” is the duration of the strong motion and “p” is the non-exceedance probability of the maxima.

The solution of the equation

$$\ddot{x}_{s,p} = r_{s,p} \sigma_{\ddot{x}} \quad (63)$$

implies the evaluation of the peak factor $r_{s,p}$ by solving the corresponding “first-passage” problem.

First of all, it must be reminded that the moment of order i of the generic one-sided PSD $S(\omega)$ is

$$\lambda_i = \int_0^\infty \omega^i S(\omega) d\omega \quad (64)$$

while a measure where the spectral mass is concentrated along the frequency axis is

$$\Omega = \sqrt{\lambda_2/\lambda_0} \quad (65)$$

parameter that resembles the root mean square of a random variable.

A measure of the spread of the PSD function is

$$\delta = \sqrt{1 - \lambda_1^2/\lambda_0\lambda_2} \quad (66)$$

Given the above, an approximate expression for the peak factor $r_{s,p}$ is given by

$$r_{s,p} = \sqrt{2 \log \left\{ 2n \left[1 - \exp \left(-\delta_{\ddot{x}}(s) \sqrt{\pi \log 2n} \right) \right] \right\}} \quad (67)$$

where

$$n = \frac{\Omega_{\ddot{x}}(s) s_0 / 2\pi}{-\log p} \quad (68)$$

$$s_0 = s \cdot \exp \left[-2 \left\{ \sigma_{\ddot{x}}^2(s) / \sigma_{\ddot{x}}^2(s/2) - 1 \right\} \right] \quad (69)$$

$\Omega_{\ddot{x}}(s)$ and $\delta_{\ddot{x}}(s)$ are the spectral moments of the response.

Then the PSD function is

$$\begin{aligned} G_{f_0}(\omega_n) &\approx \frac{1}{\omega_n \left(\frac{\pi}{4\xi_s} - 1 \right)} \\ &\sqrt{\frac{\omega_n^2 S_v(\omega_n)_{s,p}^2}{r_{s,p}^2} - \int_0^{\omega_n} G_{f_0}(\omega) d\omega} \end{aligned} \quad (70)$$

where ξ_s is the time-dependent damping for the duration s

and S_v is the velocity response spectrum.

As the PSD $G_{f_0}(\omega)$ appears on both sides of Eq. 65, an iterative computational procedure must be used.

Summary

The present chapter is devoted to the probabilistic analysis of the random response of nonlinear structural systems exposed to the random excitation due to earthquakes. The system response is nonlinear due to the nonlinear character of the

material properties and to the effects of large structural displacements.

The attention is focused on systems having deterministic properties, including deterministic boundary conditions, taking into account those types of nonlinearity that can really occur during earthquakes.

After a brief review of the types of nonlinear behaviors that can be expected, some available methods for the analysis of the response are discussed.

They can be classified into analytical and simulation methods. Among the first ones are presented: the Fokker-Planck-Kolmogorov (FPK) equation, the equivalent linearization, the perturbation method, and the stochastic averaging. The simulation methods based on Monte Carlo techniques are then presented.

Stochastic Finite Elements

Carsten Proppe

Institut für Technische Mechanik, Karlsruhe
Institute of Technology, Karlsruhe, Germany

Introduction

The finite element method (FEM) has become the dominant computational method in structural engineering. In general, the input parameters in the standard FEM assume deterministic values. In earthquake engineering, at least the excitation is often random. However, considerable uncertainties might be involved not only in the excitation of a structure but also in its material and geometric properties. A rational treatment of these uncertainties needs a mathematical concept similar to that underlying the standard FEM. Thus, FEM as a numerical method for solving boundary value problems has to be extended to stochastic boundary value problems. The extension of the FEM to stochastic boundary value problems is called stochastic finite element method (SFEM).

The first developments of the SFEM can be traced back at least to Cornell (1970), who studied soil settlement problems, and to Shinozuka (Astill et al. 1972), who combined FEM with Monte Carlo simulation for reliability analysis of structures with random excitation, random material properties, or random geometric properties. He introduced random fields and discretized them based on spectral representation theory

(Shinozuka 1971) of wide-sense homogeneous random fields.

The expression SFEM came in use in the early 1980s (Contreras 1980; Baecher and Ingra 1981). Der Kiureghian and Ke (1988) defined SFEM as “a finite element method which accounts for uncertainties in the geometry or material properties of a structure, as well as the applied loads” where “the uncertainties are usually spatially distributed over the region of the structure and should be modelled as random or stochastic fields.” The distinguishing feature of an SFEM is that it involves the discretization of the random field and the computation of solution statistics.

Discretization methods for random fields replace the random field by a finite set of random variables. They can be broadly classified into two groups: direct discretization schemes and series expansion techniques. Direct discretization schemes either assign the values of the random field at a given set of nodes to the finite set of random variables (point discretization schemes) or compute the values from local averages of the random field over a spatial domain (local averaging schemes).

Possible sets of nodes for point discretization schemes are the nodes of the finite element mesh (Hisada and Nakagiri 1981; Liu et al. 1986), the centroids of the finite elements (Der Kiureghian and Ke 1988), or the Gauss points used by the integration rules of the finite elements (Brenner and Bucher 1995). If the set of nodes for the point discretization scheme of the random field corresponds to the set of nodes of the finite elements, the shape functions for the representation of the random field may differ from those for the displacements (Liu et al. 1986). Point discretization schemes yield a positive definite correlation matrix that is easily computed. The distribution function of the random variables is the same as for the random field. Nearly all schemes can be applied to Gaussian as well as non-Gaussian random fields. The point discretization schemes that do not use different shape functions have the disadvantage that the FE mesh depends on the correlation structure of the random field and that the shape and size of all these elements should be the same. In general, the discretization produces a

huge number of random variables and leads to inefficient numerical procedures.

In contrast, local averaging schemes may yield accurate results even on rather coarse FE meshes. They can be based directly on averages of the random parameter field (Vanmarcke and Grigoriu 1984) or on integrals computed over the domain of a finite element, e.g., for the determination of the element stiffness matrix (Deodatis 1991). However, direct averaging yields random variables whose distribution functions are difficult to obtain (except for Gaussian random fields) and the approximation of non-rectangular elements may lead to a nonpositive definite covariance matrix (Matthies et al. 1997), and averaging based on element integration introduces again a dependence of the FE mesh on the correlation structure.

Series expansion techniques represent the random field by a series involving countably infinite random variables and a complete set of deterministic functions. The discretization is obtained by truncation of the series expansion. Lawrence (Lawrence 1987) considers a series expansion with an a priori set of orthogonal deterministic base functions that are multiplied by random variables. In the Karhunen-Loève (KL) expansion, the set of orthogonal base functions is obtained as eigenfunctions of a homogeneous Fredholm integral equation of second kind that involves the covariance kernel of the random field. The KL expansion is optimal in the sense that it reduces the mean-square error resulting of its truncation. In principle, it can be applied to homogeneous as well as inhomogeneous random fields and to Gaussian as well as non-Gaussian random fields. However, in practical cases, the KL expansion is applied to Gaussian random fields almost exclusively because the random variables in the expansion are then independent and standard normally distributed. In general, the eigenfunctions have to be computed numerically and the accuracy of the numerical solution influences the accuracy of the random field representation. For strongly correlated random fields with smooth covariance kernel, few terms of the series expansion are sufficient to represent the random field.

However, according to Stefanou and Papadrakakis (2007), homogeneity and ergodicity of sample functions generated by the KL expansion are questionable. The spectral representation method approximates a homogeneous Gaussian random field by a superposition of harmonics with fixed frequencies and random amplitudes or random frequencies and amplitudes. Due to the central limit theorem, the generated samples are Gaussian, if a sufficient number of harmonics (at least 128, according to Stefanou (2009)) are superposed.

In some cases, non-Gaussian random fields can be represented by nonlinear memoryless transformations of Gaussian random fields (Yamazaki and Shinozuka 1988). The memoryless transformation introduces a compatibility condition between the marginal distribution function and the autocorrelation function of the non-Gaussian random field. If this condition is not satisfied, only an approximation of the non-Gaussian random field by a nonlinearly transformed Gaussian random field is possible. Iterative procedures have been proposed (Deodatis and Micaletti 2001; Yamazaki and Shinozuka 1988) that calibrate the power spectral density of the Gaussian random field in order to approximately match the marginal distribution function and the autocorrelation function of the non-Gaussian random field. The underlying Gaussian random field can then be discretized by any of the methods described above.

A series expansion of a non-Gaussian random field in terms of independent random variables is obtained by projection on a set of orthogonal polynomials. This method is known as polynomial chaos expansion and is discussed extensively in Ghanem and Spanos (1991), where Hermite polynomials and Gaussian random variables are considered. In Xiu and Karniadakis (2002), other families of orthogonal polynomials and corresponding distributions of the random variables are discussed. The polynomial chaos expansion is convergent in mean-square sense. Field and Grigoriu (2004) critically discuss polynomial chaos expansions and show that the accuracy of the PC approximation is not always improved as additional terms are retained and

that the polynomial chaos expansion might be computationally demanding due to the large number of expansion coefficients that have to be computed.

Once the random field involved in the stochastic boundary value problem has been discretized, a solution method has to be adopted in order to solve the boundary value problem numerically. The choice of the solution method depends on the required statistical information of the solution. If only the first two statistical moments of the solution are of interest (*second moment analysis*), the perturbation method can be applied. However, if a *full probabilistic analysis* is necessary, Galerkin schemes can be utilized or one has to resort to Monte Carlo simulations eventually in combination with a von Neumann series expansion.

The perturbation method starts with a Taylor series expansion of the solution, the external loading, and the stochastic stiffness matrix in terms of the random variables introduced by the discretization of the random parameter field. The unknown coefficients in the expansion of the solution are obtained by equating terms of equal order in the expansion. From this, approximations of the first two statistical moments can be obtained. The perturbation method is computationally more efficient than direct Monte Carlo simulation. However, higher-order approximations will increase the computational effort dramatically, and therefore accurate results are obtained for small coefficients of variation only.

In the spectral SFEM, the random parameter fields are discretized by a KL or a polynomial chaos expansion, the solution is expanded with Hermite polynomials, and a Galerkin approach is applied to solve for the unknown expansion coefficients. The theoretical foundation has been laid in Deb et al. (2001) and Babuška et al. (2005), where local and global polynomial chaos expansions for linear elliptic boundary value problems with stochastic coefficients were investigated and where a priori error estimates have been proved for a fixed number of terms of the KL expansion.

Instead of a Galerkin projection, several authors employed collocation schemes for the

determination of the unknown coefficients in the approximation scheme (Acharjee and Zabarar 2007; Babuška et al. 2007; Baroth et al. 2007; Huang et al. 2007). This leads to nonintrusive algorithms that allow to combine the solution procedure with repetitive runs of a finite element (FE) solver for deterministic problems. A nonintrusive algorithm based on least squares regression has been presented recently in Berveiller et al. (2006).

In the following, discretization methods for the random parameter field are illustrated, and a mathematical theory for the approximate solution of stochastic elliptic boundary value problems involving a discretized random parameter field that is represented as a superposition of independent random variables is outlined. In the random domain, global and local polynomial chaos expansions are employed. The relation between local approximations of the solution and Monte Carlo simulation is considered, and reliability assessment is briefly discussed. Finally, an example serves to illustrate the different solution procedures.

Discretization of Random Fields

Let D be a convex bounded open set in $\mathbb{R}^n$ and $(\Omega, \mathcal{F}, P)$ be a complete probability space, where Ω is the set of outcomes, $\mathcal{F}$ the σ -field of events, and $P : \mathcal{F} \rightarrow [0 : 1]$ a probability measure. A function $\alpha : D \times \Omega \rightarrow \mathbb{R}^m$ is a *random field*, if $\alpha(x, \omega)$ is a random variable for any $x \in D$. In the following, we consider scalar valued random fields ($m = 1$).

The finite dimensional distribution of order q of α at $x_1, x_2, \dots, x_q \in D$ is the probability of the set $\cap_{i=1}^q \{\alpha(x_i, \omega) \leq \alpha_i\}$. The random field is *homogeneous* (in strict sense), if the finite dimensional distributions are invariant under a space shift and thus depend only on the space lag.

Suppose that the random field α is square integrable on $D \times \Omega$ and denote by $E[X] = \int_{\Omega} x dP$ the expectation of the random variable $X(\omega)$. Then, the mean, correlation, and covariance are given by $E[\alpha(x, \omega)]$, $R(x, y) = E$

$[\alpha(x, \omega)\alpha(y, \omega)]$, and $C(x, y) = E[(\alpha(x, \omega) - E[\alpha(x, \omega)])(\alpha(y, \omega) - E[\alpha(y, \omega)])]$, respectively. A random field is *homogeneous* (in weak sense), if the mean is constant and the correlation depends only on the space lag $y - x$.

Bochner's theorem allows to introduce the spectral distribution $S(v)$ of a weakly homogeneous random field with continuous correlation function by

$$R(x) = \int_{\mathbb{R}^n} \exp(ix \cdot v) dS(v). \quad (1)$$

If S is absolutely continuous, the Radon-Nikodym derivative $s(v)$ is called *spectral density function*: $dS(v) = s(v) dv$.

Spectral Representation

If α is a weakly homogeneous mean-square continuous random field, it can be represented by

$$\alpha(x, \omega) = \int_{\mathbb{R}^n} \exp(ix \cdot v) dW(v), \quad (2)$$

where the random field $W(v)$ has mean zero and satisfies $E[dW(v) dW(\mu)^*] = \delta(v - \mu) dS(v)$. The asterisk denotes complex conjugation and δ is the Dirac δ -distribution.

This distribution can be used to approximately represent a homogeneous Gaussian random field by a superposition of harmonics. For a real-valued random field, one obtains the representation

$$\alpha(x, \omega) = \int_{\mathbb{R}^n} (\cos(v \cdot x) dU(v) + \sin(v \cdot x) dV(v)), \quad (3)$$

where $E[dU(v)^2] = E[dV(v)^2] = dS(v)$. Starting from a partition of the wave number domain, the increments $dU(v)$ and $dV(v)$ are approximated by

$$\begin{aligned} \Delta U(v_i) &= \sqrt{2\Delta S} \cos \phi_i; \\ \Delta V(v_i) &= \sqrt{2\Delta S} \sin \phi_i; \\ \Delta S &= S(v_{i+1}) - S(v_i) \end{aligned} \quad (4)$$

where ϕ_i are random variables uniformly distributed on $[0, 2\pi]$. A representation involving a finite number of random variables is thus

$$\sum_{i=1}^M \sqrt{2\Delta S} \cos(v_i \cdot x + \phi_i). \quad (5)$$

As a consequence of the central limit theorem, it converges for $M \rightarrow \infty$ to a Gaussian random field with the same mean value and autocorrelation structure as the target Gaussian random field.

Karhunen-Loève Expansion

Due to the properties of the covariance function, the operator $T : L^2(D) \rightarrow L^2(D)$,

$$T_u = \int_D C(x, y) u(y) dy, \quad (6)$$

is compact and self-adjoint and thus admits a spectrum of decreasing nonnegative eigenvalues $\{\lambda_i\}_{i=1}^\infty$. The corresponding eigenfunctions $\{\phi_i(x)\}_{i=1}^\infty$ are orthonormal in $L^2(D)$. The random variables given by

$$\xi_i(\omega) = \frac{1}{\sqrt{\lambda_i}} \int_D (\alpha(x, \omega) - E[\alpha](x)) \phi_i(x) dx \quad (7)$$

are uncorrelated (but in general not independent), have zero mean and unit variance, and allow to represent the random field by the KL expansion

$$\alpha(x, \omega) = E[\alpha](x) + \sum_{i=1}^\infty \sqrt{\lambda_i} \xi_i(\omega) \phi_i(x) \quad (8)$$

that converges in $L^2(D \times \Omega)$ (Loève 1977). Conditions for stronger convergence properties are given in Babuška et al. (2005). The KL expansion is usually truncated by retaining only the first M terms. In order to keep the computational effort small, a fast decay of the spectrum of Eq. 6 is important. It is shown in Todor and Schwab (2006) that fast eigenvalue decay corresponds to smoothness of the covariance function. Moreover, for a decreasing correlation length, the number M of retained terms increases if the accuracy of

the approximation is kept constant. The KL expansion reduces to the spectral representation method for homogeneous random fields defined over an infinite domain (Huang et al. 2001).

For a prescribed, uniformly bounded random field $\alpha(x, \omega)$, the random variables $\xi_i(\omega)$ in Eq. 8 would be dependent non-Gaussian random variables whose joint distribution function is very difficult to identify. If, on the other hand, independent but bounded distributions are prescribed for $\xi_i(\omega)$, the random field $\alpha(x, \omega)$ is not necessarily bounded for $N \rightarrow \infty$. Thus, one is left with Gaussian distributions for $\xi_i(\omega)$ and $\alpha(x, \omega)$, with transformations of Gaussian random fields or with some situations, where nonnegative distributions for $\xi_i(\omega)$ lead to meaningful (e.g., Erlang) distributions for $\alpha(x, \omega)$.

The KL expansion is optimal in the sense that the error measured in $L^2(D \times \Omega)$ resulting from a truncation after M terms is smaller than for any other linear combination of M functions. It is a representation for homogeneous as well as nonhomogeneous random fields. However,

several authors (Grigoriu 2006; Stefanou and Papadrakakis 2007; Sudret and Der Kiureghian 2000) observed problems regarding the homogeneity of samples generated from the truncated expansion.

Kriging

Application of Kriging to the discretization of random fields has been introduced by Li and Der Kiureghian (1993). The random field $\alpha(x, \omega)$ is approximated by a linear function of M nodal values $\alpha_i(\omega) = \alpha(x_i, \omega)$

$$\tilde{\alpha}(x, \omega) = \phi_0(x) + \sum_{i=1}^M \alpha_i(\omega) \phi_i(x). \quad (9)$$

The functions $\phi_i(x)$, $i = 0, \dots, M$ are determined by minimizing in each point x the variance of the error $\alpha(x, \omega) - \tilde{\alpha}(x, \omega)$ under the condition that $\tilde{\alpha}(x, \omega)$ is an unbiased estimator of $\alpha(x, \omega)$. This yields

$$\begin{aligned} E[\alpha(x, \omega)] &= \phi_0(x) + \sum_{i=1}^M E[\alpha_i(\omega)] \phi_i(x), \\ \sum_{i=1}^M \phi_i(x) \text{Cov}[\alpha_i(\omega) \alpha_j(x)] &= \text{Cov}[\alpha(x, \omega) \alpha_j(\omega)], \quad j = 1, 2, \dots, M, \end{aligned} \quad (10)$$

with the covariance operator

$$\text{Cov}[X, Y] = E[(X - E[X])(Y - E[Y])]. \quad (11)$$

Li and Der Kiureghian (1993) introduced a spectral decomposition of the nodal covariance matrix. They showed that the maximum error of the KL expansion is not always smaller than the error of Kriging for a given number of retained terms. The point-wise variance error estimator of the KL expansion for a given order of truncation is smaller than the error of Kriging in the interior of the discretization domain but larger at the boundaries. Note however that the

KL expansion provides the lowest mean error over the domain.

Polynomial Chaos Expansion

In contrast to the KL expansion, the polynomial chaos expansion does not need an a priori knowledge of the covariance structure of the random field. A functional representation of the random field in terms of a vector of basic random variables ξ ,

$$\alpha(x, \omega) = f(x, \xi), \quad (12)$$

is necessary. Such a representation is given for the solution field of a stochastic boundary value

problem, if the random parameter field has been discretized.

A nonlinear expansion of the functional $f(x, \xi)$ is obtained by projecting it on a set of polynomials $\{\Gamma_p\}$ the basic random variables ξ . The space spanned by $\{\Gamma_p\}$ is called the p th homogeneous chaos. The polynomial Γ_p , called the polynomial chaos of order p , is a polynomial of order p that is orthogonal to all polynomials with order less than p .

Assuming symmetry of the polynomials, which is always possible (Ghanem and Spanos 1991), the random field can be approximated by

$$\begin{aligned} \tilde{\alpha}(x, \omega) = & \phi_0(x) + \sum_{i_1=1}^N \phi_{i_1}(x) \Gamma_1(\xi_{i_1}) \\ & + \sum_{i_1=1}^N \sum_{i_2=1}^{i_1} \phi_{i_1 i_2}(x) \Gamma_2(\xi_{i_1}, \xi_{i_2}) \\ & + \sum_{i_1=1}^N \sum_{i_2=1}^{i_1} \sum_{i_3=1}^{i_2} \phi_{i_1 i_2 i_3}(x) \Gamma_3(\xi_{i_1}, \xi_{i_2}, \xi_{i_3}) + \dots \end{aligned} \quad (13)$$

or more briefly by

$$\tilde{\alpha}(x, \omega) = \sum_{i=1}^M \Phi_i(x) \Psi_i(\xi). \quad (14)$$

The expansion is convergent in the mean-square sense. For Gaussian random variables, the polynomial chaos expansion is described in

more detail in Ghanem and Spanos (1991). Xiu and Karniadakis (2002) extended the approach to general families of orthogonal polynomials, the Wiener-Askey chaos.

Field and Grigoriu (2004) pointed out some limitations of polynomial chaos approximations. They demonstrated that the convergence rate of polynomial chaos approximations may be slow, that the accuracy of the polynomial chaos approximation is not always improved by adding terms, that higher-order moments may be inaccurate, and that the polynomial chaos approximations of homogeneous non-Gaussian processes may not be homogeneous.

Transformation Techniques for Non-Gaussian Random Fields

Transformation techniques for non-Gaussian random fields seek to represent the non-Gaussian random field as a nonlinear transformation of a Gaussian random field:

$$\alpha(x, \omega) = F^{-1}(\Phi(g(x, \omega))), \quad (15)$$

where Φ is the standard Gaussian cumulative distribution function, F is the non-Gaussian marginal cumulative distribution function of $\alpha(x, \omega)$, and $g(x, \omega)$ is the underlying Gaussian random field.

The transformation imposes a correlation structure to $\alpha(x, \omega)$, namely,

$$R(\xi) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F^{-1}(\Phi(u)) F^{-1}(\Phi(v)) \phi(u, v, R_g(\xi)) du dv, \quad (16)$$

where $\phi(u, v, R_g(\xi))$ denotes the joint Gaussian probability density function. If the correlation structure of $\alpha(x, \omega)$ does not match the prescribed values, one has to resort to nonlinear transformations that match the target marginal distribution and/or the correlation structure approximately (Grigoriu 1998).

The nonlinear transformation technique can be combined with any series expansion schemes described above for the underlying Gaussian

random field. It allows to calculate analytically many important quantities, such as crossing rates and extreme value distributions.

Phoon et al. (2002, 2005) used the KL expansion for the simulation together with an iterative mapping scheme to fit the target marginal distribution function of non-Gaussian random fields. The method allows to simulate homogeneous as well as nonhomogeneous random fields.

Stochastic Linear Elliptic Boundary Value Problems

Consider the following model problem with stochastic operator and deterministic input on $\bar{D} \times \Omega$: find $\bar{D} \times \Omega \rightarrow \mathbb{R}$, such that P -almost surely

$$\begin{aligned} -\nabla \cdot \alpha(x, \omega) \nabla u(x, \omega) &= f(x) \quad \text{on } D, \\ u(x, \omega) &= 0 \quad \text{on } \partial D. \end{aligned} \quad (17)$$

It is assumed that the deterministic input function $f(x)$ is square integrable and that the random field $\alpha: D \times \Omega \rightarrow \mathbb{R}$ is bounded and coercive, i.e., there exists positive constants $a_{\min}, a_{\max}$, such that

$$P(\omega \in \Omega : a_{\min} < \alpha(x, \omega) < a_{\max} \quad \forall x \in D) = 1 \quad (18)$$

and that the random field has a continuous and square-integrable covariance function.

We are interested in the probability that a functional $F(u)$ of the solution $u(x, \omega)$ exceeds a threshold F_0 , i.e., we want to evaluate the integral

$$P_F = \int_{\Omega} \chi_{(F_0, \infty)}(F(u(x, \omega))) dP(\omega), \quad (19)$$

where $\chi_I(\cdot)$, the indicator function, assumes the value 1 in the interval I and vanishes elsewhere.

The variational formulation of the stochastic boundary value problem necessitates the introduction of the Sobolev space $H_0^1(D)$ of functions having generalized derivatives in $L^2(D)$ and vanishing on the boundary ∂D with norm $\|u\|_{H_0^1(D)} = \left(\int_D |\nabla u|^2 dx \right)^{1/2}$, the space $L_P^2(\Omega)$ of square-integrable random variables, and the tensor product space $H_0^1(D) \otimes L_P^2(\Omega)$ of $H_0^1(D)$ -valued random fields with finite second order moments, equipped with the inner product

$$(u, v)_{H_0^1(D) \otimes L^2(\Omega)} = \int_{\Omega} \int_D \nabla u(x, \omega) \cdot \nabla v(x, \omega) dx dP(\omega). \quad (20)$$

The variational formulation of the stochastic linear elliptic boundary value problem Eq. 17 then

reads: find $u \in H_0^1(D) \otimes L_P^2(\Omega)$, such that for all $v \in H_0^1(D) \otimes L_P^2(\Omega)$,

$$\int_{\Omega} \int_D \alpha(x, \omega) \nabla u \cdot \nabla v dx dP(\omega) = \int_{\Omega} \int_D f(x) v(x, \omega) dx dP(\omega). \quad (21)$$

The assumptions on the random field $\alpha(x, \omega)$ guarantee the continuity and coercivity of the bilinear form in Eq. 21, and thus, the existence and uniqueness of a solution to Eq. 21 follows from the Lax-Milgram lemma.

Numerical Solution of the Stochastic Boundary Value Problem

In a first step, the random parameter field is discretized and replaced by a finite sum of random variables. Assume that a suitable approximation is given by a linear combination of continuous and independent random variables $\xi_i(\omega)$ with zero mean and unit variance,

$$\alpha_M(x, \omega) = E[\alpha](x) + \sum_{i=1}^M \xi_i(\omega) \phi_i(x), \quad (22)$$

where $\Gamma_i = \xi_i(\Omega)$ are bounded intervals in $\mathbb{R}$.

Under these assumptions, the stochastic variational problem involving the random field $\alpha_M(x, \omega)$ has the following deterministic equivalent: find $u \in H_0^1(D) \otimes L_P^2(\Gamma)$, such that

$$\begin{aligned} \int_{\Gamma} \int_D \alpha_M(x, y) \nabla_x u(x, y) \cdot \nabla_x v(x, y) dx p(y) dy \\ = \int_{\Gamma} \int_D f(x) v(x, y) dx p(y) dy, \end{aligned} \quad (23)$$

for all $v \in H_0^1(D) \otimes L_P^2(\Gamma)$, where $p \in L^\infty(\Gamma)$ is the joint probability density functions of the random variables $\xi_i(\omega)$, $i = 1, 2, \dots, M$; see Babuška et al. (2005). Here, $\Gamma = \prod_{i=1}^M \Gamma_i \subset \mathbb{R}^M$. This variational formulation is now discretized on finite dimensional approximation spaces. For $H_0^1(D)$, a family of standard finite element approximation spaces $X_h \subset H_0^1(D)$ of continuous piecewise linear functions in a regular

triangulation T_h of D with mesh parameter h is considered. Following Deb et al. (2001), discontinuous finite elements are applied on the domain Γ , which is partitioned into elements $\gamma = \prod_{i=1}^M (a_i^\gamma, b_i^\gamma)$, with $(a_i, b_i) \subset \Gamma_i$. Elements of $Y_k^q \subset L_p^2(\Gamma)$ are functions that are polynomials of degree at most q (i.e., $y_1^{q_1} y_2^{q_2} \dots y_M^{q_M} \in Y_k^q$ if $q_1 + q_2 + \dots + q_M \leq q$) when restricted to each element $\gamma \subset \Gamma$. The parameter $k = (k_1, k_2, \dots, k_M)$, with $k_i = \max_{\gamma \in \Gamma} |b_i^\gamma - a_i^\gamma|$, represents the mesh parameter. If the partition consists of a single element only and the degree q is varied, global approximations are obtained.

Denote with $N_i(x)$, $i = 1 \dots N$ a basis of X_h and with $\psi_k(y)$, $k = 1 \dots P$, a basis of Y_k^q . The solution $u(x, y)$ is approximated on $X_h \otimes Y_k^q$ by

$$\sum_{i=1}^N \sum_{k=1}^P u_{ik} N_i(x) \psi_k(y). \quad (24)$$

In order to determine the unknown coefficients u_{ik} , this representation is inserted into Eq. 23 together with test functions $v(x, y) = N_j(x) \psi_l(y)$, $j = 1, 2, \dots, N$, $l = 1, 2, \dots, P$, yielding

$$\begin{aligned} \sum_{j=1}^P \int_{\Gamma} (K^{(0)} + \sum_{s=1}^M K^{(s)} y_s) \psi_j(y) \psi_l(y) p(y) dy u_j \\ = \int_{\Gamma} \psi_l(y) p(y) dy, \end{aligned} \quad (25)$$

where

$$\begin{aligned} K_{ij}^{(0)} &= \int_D Ex \nabla N_i(x) \cdot \nabla N_j(x) dx, \\ K_{ij}^{(s)} &= \int_D \phi_s(x) \nabla N_i(x) \cdot \nabla N_j(x) dx, \\ f_i &= \int_D f(x) N_i(x) dx, \quad i, j = 1, 2, \dots, N, \end{aligned} \quad (26)$$

and u_j is the $N \times 1$ dimensional matrix obtained from u_{ij} for fixed value of j . In structural mechanics, the matrices $K^{(s)}$, $s = 0, 1, \dots, M$ can be

interpreted as finite element stiffness matrices with a spatial variation of Young's modulus.

If the basis $\{\psi_k\}_{k=1}^P$ consists of discontinuous finite element base functions, the system of equations Eq. 25 decouples and can be treated separately for each element γ . Moreover, due to the presence of terms in one single variable y_s , $s = 1, 2, \dots, M$ on the left-hand side of Eq. 25, it is possible to construct the basis $\{\psi_k\}_{k=1}^P$ in a way that the problem decouples into problems that have the same size as the deterministic FE problem (Babuška et al. 2005). To see this, consider the polynomial basis $\{\psi_i^\gamma\}_{i=1}^{P_\gamma}$ in one element γ only. This basis can be constructed by multiplying polynomials in one single variable y_s , $s = 1, 2, \dots, M$. Let $P(y)$ be the monomial basis $(1, y, y^2, \dots, y^q)^T$. We want to find a transformation matrix $S_\gamma^{(s)}$, such that the transformed basis $\psi_\gamma^{(s)}(y) = S_\gamma^{(s)} P(y)$ satisfies

$$\begin{aligned} \int_{a_s^\gamma}^{b_s^\gamma} \psi_i^{(s)}(y) \psi_j^{(s)}(y) p_s(y) dy &= \delta_{ij} \text{ and} \\ \int_{a_s^\gamma}^{b_s^\gamma} \psi_i^{(s)}(y) \psi_j^{(s)}(y) y_s p_s(y) dy &= \lambda_i^{(s)} \delta_{ij}. \end{aligned} \quad (27)$$

Defining the matrices $A_\gamma^{(s)}$ and $B_\gamma^{(s)}$ by

$$\begin{aligned} A_{\gamma ij}^{(s)} &= \int_{a_s^\gamma}^{b_s^\gamma} P_i(y) P_j(y) y p_s(y) dy \\ B_{\gamma ij}^{(s)} &= \int_{a_s^\gamma}^{b_s^\gamma} P_i(y) P_j(y) p_s(y) dy, \end{aligned} \quad (28)$$

it is easily seen that $\lambda_i^{(s)}$ are the eigenvalues and $S_\gamma^{(s)}$ is the matrix of the eigenvectors of the generalized eigenvalue problem

$$A_\gamma^{(s)} S_\gamma^{(s)T} = B_\gamma^{(s)} S_\gamma^{(s)T} \Lambda, \text{ with } S_\gamma^{(s)} B_\gamma^{(s)} S_\gamma^{(s)T} = I. \quad (29)$$

Now, by introducing multiindices $j = (j_1, j_2, \dots, j_M)$ for the basis function $\psi_{ji} = \prod_{s=1}^M \psi_{j_s}^{(s)}(y_s)$ on each element γ , we find from Eq. 25

$$\left(K_\gamma^{(0)} + \sum_{s=1}^M K_\gamma^{(s)} \right) u_j = f_\gamma \int_\gamma \psi_{ji}(y) p(y) dy, \quad 1 \leq j_i \leq q + 1, \quad i = 1, 2, \dots, M \quad (30)$$

due to the orthogonality properties Eq. 27 of this basis.

As can be seen from this equation, the parallelization of the algorithm for computing the local chaos approximations is easily possible due to the fact that:

1. The approximations on each element γ are independent.
2. The linear systems for the expansion coefficients decouple due to the choice of biorthogonal polynomials instead of Hermite polynomials.

As a consequence, any degree of parallelization (from coarse grained to fine grained) is possible, depending on the number of processors at disposal. Note, however, that the introduction of biorthogonal polynomials is possible only if the random variables ξ_i are independent and that approximations with biorthogonal polynomials require in general an upper limit q for the polynomial degree in each single variable y_s , $s = 1, \dots, M$, i.e., $y_1^{q_1} y_2^{q_2} \dots y_M^{q_M}$ is an approximation function, if $q_s \leq q$, $s = 1, 2, \dots, M$. For the same level q , this truncation leads to much more expansion coefficients than requiring $q_1 + q_2 + \dots + q_M \leq q$, especially if M is large.

Relationship with Monte Carlo Simulation

There is a close correspondence between Monte Carlo simulation and local polynomial approximations. The equations for Monte Carlo simulation can be obtained if instead of the Galerkin approximation, a collocation method is applied with respect to Γ , leading to

$$\left(\mathbf{K}^{(0)} + \sum_{s=1}^M \mathbf{K}^{(s)} y_s^j \right) u(y^j) = f, j = 1, 2, \dots, N, \quad (31)$$

with N sampling points y^j , $j = 1, 2, \dots, N$, where finite element solutions are obtained.

If the vectors $u(y^j)$ are computed by means of Eq. 31, it is not obvious how to interpolate the solution in probability space for other values of y . A simple interpretation in terms of a local approximation would be a partition of Γ into N subdomains, where each subdomain contains the nearest neighbors of the sampling point y_j . In each subdomain, $u(y)$ is then approximated by a constant value, namely, the value of the sampling point associated with the subdomain. If the number of sampling points tends to infinity, the error of the approximation vanishes.

This approach can be related to Latin hypercube sampling, if the number of subdomains γ is very high and the approximations are not computed for every subdomain of the partition. For computing n samples according to the Latin hypercube sampling method, Γ is partitioned into n^N subdomains of equal size. Then, the $n \times N$ matrix Π containing random permutations of $1, \dots, n$ and an $n \times N$ matrix G of independent and uniformly over $[0, 1]$ distributed random numbers are constructed, and the sampling plan $S = (\Pi - R)/n$ is established. Mapping the elements of the sampling plan to Γ via $\xi_{ij} = P_G^{-1}(S_{ij})$, $i = 1, \dots, n$, $j = 1, \dots, N$, where $P_G^{-1}(\cdot)$ is the inverse of the standard Gaussian distribution, one computes the solution only in those subdomains, in which the sample $\xi_i = (\xi_{i1}, \dots, \xi_{iN})$, $i = 1, \dots, n$ falls. In this way, a hybrid method, i.e., a combination of sampling techniques with approximation techniques, is obtained that leads to a considerable reduction of the sampling variance.

Evaluation of Response Quantities

Once the algebraic problem is solved and the approximation coefficients have been determined, an expression of the displacement field that depends on the input random variables has been obtained. This expression can be considered as a response surface. This response surface has local character (Proppe 2008) and depends on the size and location of the elements γ , if a partition of Γ is adopted.

Approximations for the moments of $u(x, \omega)$ can be computed by evaluating this expression

with respect to the input random variables. Computation of approximations for the distribution of $u(x, \omega)$ or the failure probability Eq. 19 is a more complex task, and resort to Monte Carlo simulation via the obtained expression for $u(x, \omega)$ seems to be the easiest way to accomplish it.

For solving reliability problems, it is very helpful to consider the approximation for the displacements as a local response surface, which leads to a functional relationship between the input random variables and $u(x, \omega)$. It is then possible to compute the most probable point of failure (MPP), i.e., the point ξ with $F(u(x, \xi)) = F_0$ with lowest Euclidean norm, and to refine the grid at its vicinity. In this way, it is possible to solve the reliability problem with a high degree of accuracy in an adaptive manner.

The MPP may also be useful for the evaluation of the integral in Eq. 19 by means of variance-reduced Monte Carlo simulation (importance sampling). To this end, a sampling density $\tilde{p}(y)$ is introduced by shifting the original probability density function $p(y)$ of the random variables ξ_i , $i = 1, \dots, M$, to the previously obtained MPP, and Eq. 19 is approximated by

$$P_F \approx \sum_{j=1}^N \chi(F_{0,\infty})(F(u(x, y^j))) \frac{p(y^j)}{\tilde{p}(y^j)} \tilde{p}(y^j), \quad (32)$$

where the sampling points y^j , $j = 1, 2, \dots, M$ are generated according to $\tilde{p}(y)$ and $u(x, y^j)$ is computed from the approximation on the element that contains y^j .

The accuracy of the MPP is influenced by the FE mesh, the truncation level M of the random parameter field, the partition of Γ , and the choice of the ansatz functions both in spatial and random domain. These parameters can be gradually adapted such that the MPP is computed with a prescribed accuracy.

Example

In order to illustrate the stochastic finite element techniques, consider a clamped thin square plate under uniform in-plane tension (cf. Ghanem and

Stochastic Finite Elements, Fig. 1 Thin square plate under uniform in-plane tension

Spanos 1991 and Fig. 1). The product of Young's modulus and the thickness of the plate is assumed to be an isotropic Gaussian random field with covariance function

$$C(x_1, y_1; x_2, y_2) = \sigma \exp\left(-\frac{|x_1 - x_2|}{l_c} - \frac{|y_1 - y_2|}{l_c}\right), \quad (33)$$

standard deviation $\sigma = 0.2$, correlation length $l_c = 1$, and unit mean value. The Poisson's ratio is 0.3. The plate has unit length and the external excitation is deterministic and of unit magnitude. The longitudinal displacement of one of the free corners is considered in the following.

Approximation of Higher-Order Moments: Skewness and Kurtosis

The random field has been represented by two random variables ($M = 2$). Figures 2 and 3 display the approximations obtained with polynomials up to third order for the skewness and the kurtosis of the displacement of the free corner with increasing number of intervals of equal probability. Reference values have been obtained by Monte Carlo simulation with $30 \cdot 10^6$ samples. For one interval, the result corresponds to a global approximation. It can be seen that global approximations are rather inexact for the skewness and kurtosis and that it is sufficient to split the intervals into two parts in order to improve the results significantly.

Hybrid Method

Figures 4 and 5 display relative (with respect to the estimated values) 95 % confidence intervals

Stochastic Finite Elements,

Stochastic Finite Elements,

Fig. 6 Accuracy of estimates for the MPP

for the estimation of the skewness and kurtosis obtained from Latin hypercube sampling and Latin hypercube sampling combined with linear approximation in the sampling intervals. A three-term ($M = 3$) representation of the random field by truncated Gaussian random variables has been employed. For a low to moderate number of intervals, the confidence intervals obtained by the hybrid method are narrower than those of the standard Latin hypercube sampling.

Reliability Assessment

For most reliability approximation techniques, it is necessary to compute the MPP. In order to obtain this point, a constrained optimization problem has to be solved. This implies expensive function calls (e.g., FE solutions) for the

computation of the displacements. These computations can be bypassed, if the approximations obtained from the numerical solution of the stochastic boundary value problem are employed as response surfaces. Figure 6 compares the relative error (i.e., the relative Euclidean distance) between the “true” MPP computed with FE calls and approximations obtained with local and global response surfaces of the displacement. The random field has been represented by four random variables ($M = 4$). The functional $F(u)$ is the value of the displacement field at the free corner and the threshold value F_0 has been set to 2.0. In order to obtain local approximations, an approximation of the MPP has been computed with a linear global approximation, and an interval of length 1σ has been inserted at that point for

Stochastic Finite Elements,

Fig. 7 Prediction of the failure probability

the coordinate with largest partial derivative of the longitudinal displacement for the free corner at the MPP. Linear polynomials have been applied for local approximations. From Fig. 6, one can see that this method yields very accurate approximations for the MPP, while for global approximations, polynomials of third degree are necessary in order to achieve a comparable accuracy.

From this fact, a corresponding approximation quality of the failure probability can be deduced, if variance-reduced sampling techniques which rely on the MPP together with the abovementioned response surface techniques are employed. This can be clearly seen from Fig. 7, where the probability of failure obtained with various approximation techniques has been plotted over the threshold value F_0 . Importance sampling at the predicted MPP with 30 batches of 10,000 samples has been employed for each failure probability estimate. For global approximations, again polynomials of third degree are necessary in order to obtain accurate predictions. On the other hand, local approximations with linear polynomials lead already to quite accurate results, if only the principle direction is partitioned.

In Fig. 8, the relative error of the failure probability for $F_0 = 2.3$ is displayed over the corresponding number of deterministic FE runs.

This allows to compare the efficiency of local and global approximations. From Fig. 8, it is evident that local approximations have considerable advantages over global approximations. This behavior is even more pronounced for smaller values of F_0 .

Finally, for $F_0 = 2.7$ (corresponding to a probability of failure of 8.2×10^{-5}) and a tolerance of 2 % for the Euclidean norm of the MPP, the procedure described in section “[Relationship with Monte Carlo Simulation](#)” yields $M = 4$ and a partition of Γ into 48 elements leading to an overall effort of 768 deterministic FE runs for the reliability estimation problem. This is considerably lower than 10^4 runs for importance sampling and 10^5 runs for a direct Monte Carlo simulation.

Concluding Remarks

For the SFE solution of stochastic boundary value problems, a mathematical theory is available that is in many aspects comparable to its deterministic counterpart, the finite element method. However, for random fields with short correlation lengths (requiring a high number M of random variables), the solution methods become inefficient, due to the series expansion of the solution. This is also true for most other SFE approximations, be they global or local, and recourse to efficient sampling

Stochastic Finite Elements,

Fig. 8 Efficiency of global and local approximation techniques for the prediction of the failure probability

techniques combined with efficient model reduction might be the only way to circumvent this problem.

A fundamental question that still has to be addressed in detail concerns the error of the solution due to the discretization of the random parameter field. Beyond this aspect of verification, the validation of the random field model itself, either from experimental data or from information pertaining to the microscale, remains an important issue (cf. the critique of the SFE method raised, e.g., in Ostoja-Starzewski 2011).

Earthquake ground motion simulation; Nonstationary stochastic process; Stochastic models; Strong ground motion simulation; Synthetic accelerograms

Introduction

Strong earthquake ground motion records are fundamental in engineering applications. Ground motion time series are used in ► [response-history dynamic analysis](#) of structural or geotechnical systems. In such analysis, the validity of predicted responses depends on the validity of the input excitations. Ground motion records are also used to develop ground motion prediction equations (GMPEs) for intensity measures such as spectral accelerations that are used in ► [response-spectrum dynamic analysis](#). Despite the thousands of available strong ground motion records, there remains a shortage of records for large-magnitude earthquakes at short distances or in specific regions, as well as records that sample specific combinations of source, path, and site characteristics. The limited number of recordings has become problematic in the emerging field of

► [performance-based earthquake engineering](#) (PBEE), which considers the entire spectrum of structural response, from linear to grossly nonlinear and even collapse, and thereby requires ground motions with various levels of intensity for various earthquake design scenarios (e.g., a design scenario can be defined by the earthquake magnitude, distance, and site conditions). To obtain the desired ground motions for the purposes of PBEE, it is common engineering practice to scale or modify acceleration time series that were recorded during previous earthquakes to represent certain ground motion characteristics for the design of structural or geotechnical systems. However, scaling and modification methods can significantly alter other ground motion characteristics and result in unrealistic earthquake ground motion time series. Synthetic ground motions can be used instead to replace or supplement recorded motions when scarcity of previously recorded motions becomes a problem, provided they accurately capture characteristics of real earthquake ground motions and their natural variability.

Synthetic ground motions can be based on deterministic or stochastic simulations. A determinist model is one in which variables are uniquely determined, and the model performs the same way for a given set of initial conditions. Conversely, in a stochastic model, randomness is present and variables are not described by unique values, but rather by probability distributions. In earthquake engineering, deterministic ground motion simulation is commonly referred to as “physics-based” ground motion simulation. These simulation models synthesize the earthquake source by defining a source model (e.g., kinematic or dynamic rupture models) and describe the seismic wave travel path by defining a material model (e.g., seismic velocity model); then, they utilize numerical methods (e.g., finite element or finite difference methods) to estimate the solution to the wave propagation equation. In other words, these models explicitly incorporate the physics of the propagation of seismic waves. They produce realistic synthetic ground motions at low frequencies (typically $<1\text{ Hz}$). But they are computationally intensive due to the fine

discretization of the medium and require a thorough knowledge of the environment (i.e., earthquake source, crustal structure, material properties, basin and local site effects); this information is not available for many regions or is not accessible to engineers for well-studied regions. On the other hand, stochastic simulation models are simple and powerful tools that incorporate what is known about ground motion, source, path, and site characteristics into simple functional forms, and as a result are widely used to simulate earthquake ground motions. There is a specific entry dedicated to ► [physics-based ground motion simulation](#) in this encyclopedia by Taborda and Roten that provides more details on deterministic ground motion simulation models. Here, we focus on stochastic ground motion simulation.

A word of caution may be in order here about the terminology “physics-based.” The use of this term for deterministic models is mostly out of convenience and should not imply that stochastic models are not based on physics. In fact, some experts disagree with this terminology because many stochastic models are valid representations of the physics of earthquakes, and although they do not necessarily solve the mathematical problem of wave propagation, they integrate the physical characteristics of the earthquake source, path effects, and site effects implicitly through their formulations and parameters.

Both deterministic and stochastic simulations can be used for response-history dynamic analysis, but only stochastic simulations can be utilized for stochastic dynamic (i.e., random vibration) analysis, because the latter analysis method requires a random process model of the earthquake ground motion. Synthetic ground motions are particularly useful for nonlinear dynamic analysis due to the scarcity of recorded motions for large-magnitude earthquakes that are capable of causing nonlinear responses. Two approaches are available for nonlinear dynamic analysis of structures subjected to earthquakes: (1) nonlinear response-history analysis by the use of a selected set of ground motion time series and (2) nonlinear stochastic dynamic analysis by the use of a stochastic representation of the ground motion.

Well-developed methods and tools are available for nonlinear response-history analysis; a set of recorded or synthetic ground motions or a collection of both can be used for this type of analysis. Nonlinear stochastic methods are not as developed, but research in that direction is continuing (e.g., Au and Beck 2003; Der Kiureghian and Fujimura 2009). Several stochastic ground motion simulation models exist that can satisfy the requirements of these nonlinear stochastic methods. These methods typically require the input excitation to be represented in a discrete form and in terms of a finite number of random variables. For example, in Der Kiureghian and Fujimura (2009), it is necessary to represent the input excitation in the following form

$\mu(t) + \sum_{i=1}^n s_i(t)u_i$, where $\mu(t)$ is the deterministic mean of the random process, n is the discretization of the time series and provides a measure of the resolution, and u_i and $s_i(t)$ are, respectively, representatives of standard normal random variables and deterministic basis functions of time.

Regardless of the method of simulation, the resulting synthetic time series should properly represent the main characteristics of real earthquake ground motions. For most engineering applications, the intensity, duration, and frequency content of the input ground motion are the characteristics that control the response of structural and geotechnical systems. In addition to the duration of motion, which results from variation of the ground motion intensity over time, variation of the frequency content of the motion is also an important characteristic that influences the response, particularly in nonlinear analysis. Consequently, two important characteristics of real earthquake ground motions that separate them from a simple stochastic process (e.g., a ► white-noise signal) are temporal and spectral nonstationarities. Temporal nonstationarity refers to the nonstationarity of ground motion in the time domain (i.e., variation of intensity with time). Spectral nonstationarity refers to the nonstationarity of ground motion in the frequency domain (i.e., variation of frequency

content with time). Whereas most simulation methods account for temporal nonstationarity, which controls most common intensity measures and duration of motion, many ignore the spectral nonstationarity, which can be very important in nonlinear dynamic analysis.

Many synthetic ground motion models exist, but not all represent the natural variability of real earthquake ground motions. Some models underestimate the natural variability of ground motions because they underestimate the variability in their model parameters. On the other hand, if correlations between the model parameters are not taken into account or are underestimated, the variability of the resulting ground motions can be overestimated compared to real earthquake ground motions. In probabilistic analysis, it is important to capture the natural variability of ground motions in the simulations to accurately quantify the variation of response due to the variation in input excitation.

In summary, stochastic ground motion simulations have many applications. They can be used in linear and nonlinear response-history dynamic analysis as well as in stochastic dynamic analysis, or they can be used to develop GMPEs for various intensity measures. Stochastic models are generally simpler, more widely used, and more accurate at high frequencies than deterministic (physics-based) models. A good stochastic ground motion model must represent the temporal and spectral nonstationary characteristics of real earthquake ground motions and must properly represent their natural variability. More details on stochastic ground motion models, their classification, formulation, parameters, and practicality are given below. Discussions on adjustment of models for special situations including multicomponent, near-fault, and multi-station simulations are also provided.

Classification of Ground Motion Simulation Models

There are two main categories of models for generating synthetic ground motions, source-based models and site-based models.

Source-based models explicitly describe the fault rupture process at the source, the propagation of the resulting seismic waves through the ground medium, and the effects of local site conditions on the seismic waves to generate a time series at a specific site. Site-based models describe the ground motion time series as it is observed at a specific site by fitting a stochastic process to previously recorded motions with known earthquake and site characteristics; in this way, they implicitly account for the source, path, and site effects. Due to their need for empirical recordings of ground motions, site-based models are sometimes referred to as empirical models, but note that this terminology is not strictly correct because many source-based models also use data to empirically identify their parameters.

Source-Based Models

Source-based models can be deterministic or stochastic. An early review of source-based models is presented by Zerva (1988). Deterministic (physics-based) simulations were briefly described in the Introduction and have their own entry in this encyclopedia. They can produce realistic accelerograms at low frequencies (typically <1 Hz) but often need to be adjusted for high frequencies by combining with a stochastic component, resulting in hybrid models. For many years, source-based simulations have been utilized to develop GMPEs for locations where earthquakes are rare and the collection of recorded ground motions is sparse, for example, in the stable continental regions of the Central and Eastern United States (e.g., Somerville et al. 2001); research is continuing to improve these simulations and the resulting GMPEs.

One family of widely used synthetic ground motions are the source-based stochastic simulations based on the work of David Boore and a number of other researchers in the past several decades (e.g., Boore 2003; Beresnev and Atkinson 1998; Motazedian and Atkinson 2005; Boore 2009). This simulation method roots in the work of McGuire and Hanks (1980), which identifies the Fourier amplitude spectrum (FAS) of a ground motion considering the source, path, and

site effects and then combines it with a random phase spectrum. This method assumes ground motion to be a band-limited white Gaussian noise with finite duration. The white-noise is then adjusted to have the following FAS:

$$Y(M_0, f, R) = S(M_0, f) \times P(R, f) \times G(f) \times I(f)$$

where $S(M_0, f)$ is the source spectrum with f denoting the frequency and M_0 representing the seismic moment; R is the distance from the earthquake source to the site and $P(R, f)$ accounts for the wave propagation effects, including the geometrical attenuation with distance, which is usually described by a three-segmented function, and the energy dissipation (combining intrinsic and scattering attenuation); $G(f)$ accounts for the effects of local site conditions, including near-surface amplification and reduction of high frequencies that result from the path-independent loss of energy; and finally, $I(f)$ is the indicator of the instrument or the type of motion (i.e., acceleration, velocity, or displacement). More details are provided in Boore (2003).

This method was first developed to model far-field ground motions where the earthquake source can be considered as a point (Boore 1983), resulting in “point-source stochastic models.” For simulation of ground motions closer to the earthquake source, the method was improved to consider the rupture progress on a finite fault (Beresnev and Atkinson 1998), resulting in “finite-fault stochastic models.” In finite-fault modeling, the fault is discretized into many subfaults, and each subfault is treated as a point-source. The ground motion from each subfault is modeled using the point-source stochastic model with the amplitude spectrum described in the above equation. The total ground motion at a site is the superposition of the contributions of all subfaults with a proper time lag considering the difference from the triggering time of the subfault and from the travel time between the subfault and the site. Using finite-fault modeling, the synthetic motion is able to capture some near-fault characteristics of ground motion, such as rupture directivity and hanging-wall effect.

Most improvements in source-based stochastic modeling focus on enhancing the source spectrum, $S(M_0, f)$. The originally used source spectrum was according to the ω -square model with single corner frequency (Aki 1967)

$$S(M_0, f) = \frac{CM_0}{1 + \left(\frac{f}{f_c}\right)^2}$$

where C is a constant related to the radiation pattern and f_c is the corner frequency inversely controlled by the dimension of the source. By applying the above equation in finite-fault modeling, however, the sum of acceleration amplitude spectrum at high-frequency range ($f > f_c$) strongly depends on the discretization scheme of the fault. The proper subfault size is required to be within 5–15 km in order to obtain a reliable synthesis (Beresnev and Atkinson 1998). To solve this problem, Motazedian and Atkinson (2005) made a conceptual improvement by introducing a “dynamic corner frequency” in the source spectrum

$$S_{ij}(f) = \frac{CM_{0ij}H_{ij}}{1 + \left(\frac{f}{f_{cij}}\right)^2}$$

where f_{cij} is the dynamic corner frequency for the ij -th subfault and H_{ij} is the scaling factor to compensate the high-frequency spectral loss from using a dynamic corner frequency.

The dynamic corner frequency of the ij -th subfault depends on the cumulative number of subfaults ruptured by the time the subfault is triggered. Therefore, each subfault will have a different corner frequency in the source spectrum. Generally, a subfault that is triggered in the early part of the rupture will have a higher corner frequency than a subfault triggered in the late part. This describes the difference in the frequency contents of the generated motions from different subfaults. The most significant advantage of using a dynamic corner frequency is that the high-frequency spectral amplitude is no longer dependent on the size of the subfault; thus a subfault can be as small as 1 km, which allows the finite-fault modeling to be used for

small- or intermediate-magnitude events. One of the latest improvements to the source-based stochastic simulation is the work of Boore (2009) that allows selection of different functions for calculating the scaling factor H_{ij} .

Source-based stochastic models are simple and practical compared to deterministic (physics-based) models. Availability of source codes for these models has increased their use in recent years. For example, EXSIM_dmb is a simulation software that is developed by Boore and can be downloaded from his website (http://www.daveboore.com/software_online.html), and EXSIM_beta is a simulation software that is developed by Motazedian and can be found on his website (<http://http-server.carleton.ca/~dariush/>); both EXSIM_dmb and EXSIM_beta are based on stochastic finite-fault modeling with dynamic corner frequency. One of the disadvantages of source-based stochastic models is that they assume stationarity of the frequency content with time, which is usually not the case in real earthquake ground motions as will be discussed in more detail in the next section. Also, care should be taken in using these models for probabilistic analyses because they usually underestimate the variability in ground motions by fixing their parameters instead of assigning a probability distribution to them.

In general, source-based models tend to heavily employ seismological principles to describe the source mechanism and wave travel path and depend on physical parameters that vary significantly from region to region. This limits their use in regions where seismological data are lacking. This is more critical for deterministic (physics-based) models than it is for stochastic models that use simpler parameters and models for the source, path, and site effects. In the current practice, most engineers prefer using methods of scaling and spectrum matching of recorded motions instead of incorporating source-based models. This is partly due to the lack of understanding the seismological principles underlying these models and the fact that these models require a thorough knowledge of the source, wave path, and site characteristics, which typically are not available to a design engineer.

In this regard, source-based stochastic models have an advantage compared to deterministic (physics-based) models; but the user is still required to make certain assumptions depending on the region in order to define the models for the source $S(M_0, f)$, path $P(R, f)$, and site $G(f)$. More recently developed site-based stochastic models can be more useful in engineering applications because their relatively simple formulations facilitate time-efficient simulations (similar to source-based stochastic models) and their parameters are expressed directly in terms of earthquake and site characteristics such as magnitude and distance that describe a design scenario and are readily available to a design engineer.

Site-Based Models

Site-based models are stochastic and represent the earthquake ground motion time series by a stochastic process. A large number of site-based stochastic ground motion models have been developed. Formal reviews are presented by several authors including Liu (1970), Shinozuka and Deodatis (1988), and Conte and Peng (1997). The papers by Rezaeian and Der Kiureghian (2008, 2010, and 2012) provide reviews and are representative of the more recent work. As previously mentioned, a good synthetic ground motion model must represent both the temporal and the spectral nonstationary characteristics of earthquake ground motions. Whereas temporal nonstationarity can be easily modeled in site-based stochastic simulations by time-modulating a stationary ► [stochastic process](#), spectral nonstationarity is not as easy to model. Nevertheless, this spectral nonstationarity is of particular importance in nonlinear dynamic analysis because of the moving resonance effect of nonlinear structures (i.e., when the natural period of a structure varies during the ground shaking period due to inelastic behavior and gets closer to the varying frequency content of the ground motion) and should not be ignored. In general, for a stochastic model to be of practical use in earthquake engineering, it should be parsimonious, i.e., it must have as few parameters as possible. Preferably, the model parameters should provide physical insight into the characteristics

of the motion. Furthermore, the model should refrain from complicated analysis, involving extensive processing of recorded motions for parameter identification.

Site-based stochastic ground motion simulation models can be classified into four categories:

Filtered white-noise processes

Processes obtained by passing a white-noise signal through a filter. These models are appealing due to the efficient digital simulation of sample functions for a filtered white-noise process (i.e., generating realizations). Many models of this type use subsequent modulation in time to achieve temporal nonstationarity, but these processes have essentially time-invariant frequency content. This type of simulation can be improved by varying the filter parameters in time to achieve nonstationarity of the frequency content (e.g., Rezaeian and Der Kiureghian 2008).

Filtered Poisson processes

Processes obtained by passing a train of Poisson pulses through a linear filter. Through modulation in time, these processes can possess both temporal and spectral nonstationarities (e.g., Lin 1986). However, matching with recorded ground motions is difficult.

Auto-regressive-moving-average (ARMA) models

By allowing the model parameters to vary with time, these models (e.g., Conte et al. 1992) can have both temporal and spectral nonstationarities. However, it is difficult to relate the model parameters to any physical aspects of the ground motion.

Time-varying spectral representation

Instead of working in the time domain, as is done in the previous three categories, these models work in the frequency domain and use various forms of spectral representation (e.g., Conte and Peng 1997). The focus in these models is in developing a time-varying spectral representation by matching to a target recorded ground motion. These models require extensive processing of the target motion. Virtually all these models assume the ground motion to be a zero-mean Gaussian process.

$$a(t) = q(t, \alpha) \times f(t, \lambda)$$

where $a(t)$ is the acceleration time series with t denoting time; $q(t, \alpha)$ is a deterministic nonnegative time-modulating function with α representing a vector of parameters; and $f(t, \lambda)$ is a filtered white-noise process with λ representing a vector of parameters. Several models have been proposed for the $q(t, \alpha)$ modulating function, e.g.,

- The piecewise function by Housner and Jennings (1964)
- The double exponential function proposed by Shinozuka and Sato (1967)
- The gamma function proposed by Saragoni and Hart (1974)

These models or their modified versions have been used by many other modelers. In general, a time-modulating function gradually increases from zero to achieve a nearly constant intensity that represents the “strong shaking” phase of an earthquake ground motion and then gradually decays back to zero (see Fig. 1). The parameters α control the intensity and shape of the function. Although it is not a common practice, two or more modulating functions can be combined to simulate ground motions that have more than a single strong shaking phase, a feature possibly caused by multiple sub-events.

The conventional “filtered white-noise” process $f(t, \lambda)$ is the stationary response of a linear time-invariant filter subjected to a white-noise process. White-noise $w(t)$ is a stationary random process in time that has a zero mean and a constant spectral density for all frequencies. The response of a linear filter to a white-noise process may be calculated by using the Duhamel convolution integral, and hence the general formulation of a filtered white-noise process can be written in the following form:

$$f(t, \lambda) = \int_{-\infty}^t h(t - \tau, \lambda) w(\tau) d\tau$$

where $h(t, \lambda)$ denotes the impulse response function or IRF of a linear filter and the parameters λ can be the natural frequency and damping of the

Simulating a Single Ground Motion Time Series Using a Site-Based Stochastic Model

Model Formulation

Regardless of the specific formulation, every site-based model is essentially a stochastic process with a certain number of parameters. As an example, the general formulation for a site-based stochastic model based on the filtered white-noise process is given below (Rezaeian and Der Kiureghian 2008)

Stochastic Ground Motion Simulation, Fig. 1 Development of a fully nonstationary stochastic process according to Rezaeian and Der Kiureghian (2008)

filter or other parameters that shape the filter response. Different filters are used and various tricks are incorporated by modelers to make the resulting process “fully nonstationary” and representative of real earthquake ground motions. One approach taken by Rezaeian and Der Kiureghian (2008) is illustrated in Fig. 1, where the filtered white-noise process is normalized by its standard deviation $\sigma_f(t)$ to separate the temporal from the spectral characteristics; and the filter parameters are functions of time, $\lambda(t)$, to achieve spectral nonstationarity. Like all other models that use a time-modulating function, temporal nonstationarity is achieved by $q(t, \alpha)$. In this figure, the nonstationary characteristics of ground motions are demonstrated using the trace of an example stochastic process.

Model Parameters

Given a target accelerogram (i.e., a recorded ground motion), the model parameters α and

$\lambda(t)$ are identified by fitting certain characteristics of the stochastic process to those of the target accelerogram. The approaches to parameterization and model fitting are entirely different from model to model. Currently, there are no standards on the exact characteristics that modelers should match to identify their parameters for a target motion. However, all these different characteristics are designed to capture the intensity, duration, and frequency content of the ground motion at certain points in time or in frequency. In some models, this is done over the entire duration of the recorded ground motion and its entire frequency spectrum; in this case, the parameters are identified using the following generalized formulation:

$$\hat{\mathbf{p}} = \underset{\mathbf{p}}{\operatorname{argmin}} \int_0^{t_n} \left[f_{obj}(\text{recorded}) - f_{obj}(\text{simulation}) \right] dt$$

where $\mathbf{p}$ is a vector of model parameters and t_n denotes the entire duration of the recorded ground

motion. Linear or nonlinear optimization methods are used to minimize the difference between an objective function for the recorded motion, $f_{obj}(\text{recorded})$, and the same function for the simulation, $f_{obj}(\text{simulation})$, resulting in the vector of identified parameters $\hat{\mathbf{p}}$ for that particular recorded motion. The misfit of the objective functions can be characterized by their difference, as is shown in the above equation, or by their absolute difference, or by their square root difference. Many objective functions are used in the literature by various modelers. Objective functions such as the expected cumulative energy of the process or the variance of the process can be used to identify the parameters of the time-modulating function; objective functions such as the zero-level up-crossing rate can be used to identify the frequency parameters (e.g., Yeh and Wen 1990; Rezaeian and Der Kiureghian 2008).

Once a set of model parameters has been identified, $\hat{\mathbf{p}}$, the model formulation is used to simulate realizations of the ground motion. These realizations are all different due to the stochasticity of the model (e.g., the white-noise process in the above example), but they all have the same model parameters and expected characteristics similar to those of the target motion. In this way, the target accelerogram may be regarded as a single realization of the ground motion process for a specified set of model parameters, while the simulated motions may be regarded as other random samples of the process for the same set of model parameters.

Post-Processing for Long Spectral Periods (Low Frequency)

In general, site-based stochastic ground motion models fail to match the response spectrum associated with the target accelerogram in the long spectral period range and tend to overestimate the structural response (typically beyond 2–4 s depending on the model). This is because a stochastic model developed for an acceleration process cannot guarantee zero velocity and displacement residuals (final values at the end of the record) upon integration of a sample realization. This shortcoming of site-based models has been recognized by some modelers who “post-process” the simulations by extending

baseline correction methods or high-pass filtering methods used for recorded accelerograms to simulated motions in order to overcome this disadvantage (e.g., Papadimitriou 1990; Liao and Zerva 2006). For example, Rezaeian and Der Kiureghian (2008) use a high-pass filter representing a critically damped oscillator to post-process the stochastically simulated ground motion to obtain zero velocity and displacement residuals and appropriate response spectral values for periods as long as 5–10 s. An example of a simulated ground motion before and after post-processing is shown in Fig. 2. Even though the difference between the acceleration processes is insignificant, the integration over time results in unacceptably high nonzero velocity and displacement residuals as well as high spectral intensities at long periods before post-processing. After the post-processing, the residuals are zero and the spectral content is lower at long periods.

Simulating a Suite of Ground Motions for a Specified Design Scenario

Here, a design scenario refers to a set of earthquake and site characteristics such as earthquake magnitude, source-to-site distance, and soil conditions of the site. In the broader context of PBEE, an ensemble of ground motions that represents all possible ground shakings for a specified design scenario is of interest, not just ground motion simulations with characteristics similar to those of a previously observed motion. A good stochastic ground motion model must properly represent the natural variability of real earthquake ground motions. It also must be practical for use by a practicing engineer.

Variability

The variability among an ensemble of simulated ground motions for a specified design scenario comes from two sources: (1) the randomness of ground motions for a specified set of model parameters (the stochasticity mentioned in the discussion of the model parameters) and (2) the randomness of the model parameters for a specified design scenario. The former is due to the stochastic nature

Stochastic Ground Motion Simulation, Fig. 2 An example stochastic simulation before and after post-processing using a high-pass filter with a cutoff frequency of 0.2 Hz

of the model and it is achieved when fitting to and simulating a target accelerogram. The latter is referred to as “parametric uncertainty.” Both should be modeled properly to reproduce in the synthetic motions the variability present in real earthquake ground motions.

The underestimation of parametric uncertainty results in the underestimation of the natural variability of ground motions. This has been a major problem in the current practice of seismic hazard analysis and the generation of synthetic ground motions. A few exceptions are some recent site-based models (e.g., Rezaeian and Der Kiureghian 2010), where model parameters are fitted to a database of ground motions and are randomized at the time of simulation to achieve variability similar to the sample database. Most source-based models account for the variability in ground motions by manually varying the source parameters; whether the realizations follow the “true” underlying probability distribution for each parameter is the question in these models.

To properly account for parametric uncertainty, a good model needs to randomly generate parameters according to their underlying probability distributions and also to account for the correlations between the parameters. Probability distributions for parameters and their correlations can be estimated empirically or based on the

physical meaning of a parameter. If correlations between the parameters are ignored, the variability in the resulting ensemble of ground motions may be overestimated because the parameter realizations are not well constrained.

Practicality

There is a need for generating synthetic motions that correspond to a specified design scenario, but most site-based stochastic models limit their scope to generating synthetic motions similar to a target recorded ground motion. In such models, no attempt is made to select a different but appropriate set of model parameters for the specified design scenario. Moreover, for a model to be practical and to be used in the engineering community, it should be expressed in terms of variables that are readily available to a design engineer.

In practice, GMPEs are widely used because they predict measures of ground motion intensity in terms of common earthquake and site characteristics that define a design scenario to a practicing engineer. Typical intensity measures modeled by GMPEs are peak ground motion values (i.e., peak ground acceleration, velocity, and displacement) and elastic response spectra at specified oscillator periods and damping ratios. A few GMPEs for inelastic response spectra have also been developed. These GMPEs are useful for

linear response-spectrum analysis or crude nonlinear analysis, but not for response-history analysis, as they do not predict ground motion time series. Such simplified analysis methods have proven to be adequate for simple code-based design purposes, but not for PBEE. Stochastic ground motion models can complement GMPEs by generating ground motion time series in terms of similar earthquake and site characteristics used by GMPEs. This is done by developing predictive relations for the model parameters in terms of commonly used earthquake and site characteristics.

To adjust a stochastic model for practical use, the model parameters are identified for a database of recorded ground motions. Then, through regression analyses and empirical modeling methods, predictive relations for each parameter in terms of earthquake and site characteristics are developed to relieve the design engineer from the task of predicting the parameter values for a design scenario (e.g., Sabetta and Pugliese 1996; Stafford et al. 2009; Rezaeian and Der Kiureghian 2010). A generic form of predictive relations for a model parameter p is given below

$$\Phi^{-1}[F_P(p)] = \mu(\text{Earthquake, Site, } \boldsymbol{\beta}) + e$$

where Φ^{-1} denotes the inverse of the standard normal cumulative distribution function, F_P denotes the marginal cumulative distribution function estimated for parameter p , μ is the conditional mean of $\Phi^{-1}[F_P(p)]$ given the earthquake and site characteristics of interest, and $\boldsymbol{\beta}$ is the vector of regression coefficients. The regression error e is a zero-mean normally distributed random variable with standard deviation σ representing the uncertainty of the parameter. The earthquake and site characteristics are typically the earthquake magnitude, source-to-site distance, faulting mechanism, and various proxies to describe the site soil conditions such as V_{S30} (i.e., the time-averaged shear wave velocity in the top 30 m of soil). These regression variables change depending on the region and the parameter under consideration.

Given the predictive relations as described above, one can calculate the mean of each model parameter given a set of earthquake and site

characteristics. The error can then be randomized to generate the realizations of the model parameter. To generate the realizations of multiple parameters, correlations between the parameters should be taken into account in the simulation.

Extensions of Site-Based Stochastic Models

Multiple-Component Simulation

Earthquake ground motions are multidimensional. Neglecting the rotational components, three translational components are usually expressed in two orthogonal horizontal directions and one vertical direction. For proper dynamic analysis of complex structural and geotechnical systems, for example, asymmetric structures that are vulnerable to torsion or structural components that are sensitive to vertical ground shaking, it is important to simulate multicomponent ground motion time series. The vast majority of stochastic models are restricted to simulating a single horizontal ground motion component, but the research to simulate multiple components is continuing and under development (e.g., bidirectional ground motion simulation by Rezaeian and Der Kiureghian (2012)).

When modeling and simulating multiple ground motion components, differences as well as similarities and dependencies between the components must be taken into account. Because the ground motion components are generated from the same earthquake source and from seismic waves that travel through the same ground medium, high correlations between model parameters of the components are expected. Correlations and coherencies between the components can be estimated empirically by analyzing a large number of recorded ground motion components.

For stochastic ground motions, in addition to cross-correlations between the model parameters, dependencies between the stochastic components (e.g., the seed white-noise processes) should also be taken into account. This is a difficult task, but Penzien and Watabe (1975) showed that there is a unique set of orthogonal axes, referred to as “principal axes,” along which the three translational

components of ground motion may be considered uncorrelated. These are the major, intermediate, and minor principal axes along which the ground motion components have intensities in decreasing order and the stochastic processes (e.g., the seed white-noise processes) are statistically independent. Although the stochastic processes can be assumed statistically independent, there can still be high correlations between the model parameters of the two ground motion components (see Rezaeian and Der Kiureghian 2012). Based on examination of few real accelerograms, Penzien and Watabe (1975) suggested that the major principal axis usually points in the general direction of the epicenter, the intermediate principal axis is horizontal and perpendicular to the major principal axis, and the minor principal axis is almost vertical. The concept of principal axes has been the basis for many subsequent studies on multicomponent stochastic modeling of ground motions, but more studies are required to confirm the direction of the principal components. If simulation is done along the horizontal principal axes, an orthogonal pair of acceleration time series $a_1(t)$ and $a_2(t)$ can easily be rotated to the horizontal direction of interest using a rotation matrix

$$\begin{bmatrix} a_{1,\theta}(t) \\ a_{2,\theta}(t) \end{bmatrix} = \begin{bmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{bmatrix} \begin{bmatrix} a_1(t) \\ a_2(t) \end{bmatrix}$$

where $a_{1,\theta}(t)$ and $a_{2,\theta}(t)$ are the counterclockwise rotations by angle θ .

Near-Fault Simulation

Ground motions close to fault ruptures (within about 30 km), i.e., ► **near-fault** ground motions, can have distinct characteristics such as the directivity effect in the fault-normal direction and the fling step in the fault-parallel direction. These characteristics can have a strong influence on the structural response and are usually modeled separately and then added to a site-based stochastic ground motion simulation.

A site near a fault may experience forward directivity, which occurs when the fault rupture propagates toward the site with a velocity almost equal to the shear wave velocity. The resulting ground motion time series is characterized by the

presence of a two-sided, long-period, large-amplitude velocity pulse that typically shows as a long-period pulse in the response spectrum and may impose extreme demands on structures. Because near-fault recordings that contain directivity pulses are relatively scarce and because scaling and modification methods cannot create a pulse in a record that does not initially contain a pulse, simulated near-fault ground motions are needed. But only a few stochastic models currently exist that simulate the forward directivity effect (e.g., Mavroeidis and Papageorgiou 2003; Dabaghi et al. 2011). This is usually done by modeling a long-period velocity pulse that is a function of the earthquake design scenario, including the relative location of the site to the fault rupture. The simulated velocity pulse is added to the derivative of the simulated acceleration time series resulting in a simulated pulse-like near-fault ground motion.

Not all near-fault ground motions contain a pulse. For example, backward directivity occurs when the fault rupture propagates away from the site. The resulting ground motion tends to be of low intensity and long duration. A valid near-fault ground motion model should take into account both the pulse-like and non-pulse-like cases.

The fling step is caused by the permanent displacement of the fault and is usually characterized by a one-sided velocity pulse in the fault-parallel direction. Modeling of the fling step is not as well developed in stochastic ground motion modeling, but its effect on structural response is not as extreme as the forward directivity effect. The fling step is difficult to model because information is usually lost in the typical processing of recorded ground motions.

Spatial Simulation (Multiple Stations)

Most stochastic ground motion models are developed for single-station simulations. To simulate ground motions from a single earthquake event at multiple stations that are located close to each other, the spatial coherency between records should be taken into account. This coherency usually depends on the frequency content of the ground motions and separation distance between the stations and can be estimated from the power spectral density functions of recorded motions.

Several models exist in the literature that can be used to adjust a ground motion time series for spatial variation (e.g., Liao and Zerva 2006; Konakli and Der Kiureghian 2012, Konakli et al. 2014). These models can be applied to a stochastic simulation of ground motion at a single station to generate consistent simulations at nearby stations.

Validation of Ground Motion Simulation Models

Although many stochastic ground motion simulation models exist, no standard validation techniques are available. There are almost as many validation approaches undertaken as there are simulation models. Comparisons against empirical data and trusted models in engineering practice aid in identifying the limitations of the proposed simulation models and may encourage implementation of simulations in practice. The next step in the field of ground motion simulation that has been gaining attention in recent years is development of standard techniques for ground motion simulation validation for use in various engineering applications (see, e.g., the efforts of the Southern California Earthquake Center ground motion simulation validation technical activity group http://collaborate.scec.org/gmsv/Main_Page).

Summary

Stochastic ground motion simulations are used to replace or supplement recorded earthquake ground motions when recorded motions are sparse. Stochastic ground motion models are categorized into source-based and site-based models. Definitions and examples for each category are given. Source-based simulations explicitly model the source spectrum, path, and site effects. Site-based stochastic models are classified into four groups depending on their formulations. Regardless of the formulation, the model must exhibit the characteristics of real earthquake ground motions including temporal and spectral nonstationarities. Site-based models simulate a

recorded accelerogram by identifying the model parameters through optimization and fitting into certain target characteristics of real earthquake ground motions. The parameters are then used in the formulation of the stochastic process. Post-processing is usually required for site-based stochastic models to ensure zero residuals and proper modeling of long-period spectral values. Simulating a suite of ground motions for a specified design scenario is discussed, where the natural variability of ground motions must be modeled properly by accounting for parametric uncertainty and correlations between the model parameters. Practicality of a model is also discussed, where the model parameters are expressed in terms of earthquake and site characteristics that define a design scenario and are readily available to a design engineer. Finally, adjusting site-based stochastic ground motion simulations for special cases including multicomponent, near-fault, and multi-station simulations is discussed. Currently, many research efforts are directed toward developing ground motion simulation validation procedures for various engineering applications.

Introduction

In recent years, Structural Health Monitoring (SHM) of engineering structures has become an important area of research. This is a broad term which by large also deals with the online detection and identification of structural damage and therefore holds a critical significance for the case of large-scale civil structures where a failure incidence is connected not only to high cost losses but potentially to human loss in the worst-case scenario.

Vibration-based methods are today the fastest growing research area in the SHM field (Fassois and Kopsaftopoulos 2013). However, while such methods are already used for industrial mechanical structures, these are still far from being successfully implemented in large-scale civil structures such as high-rise buildings and bridges. The main reason for this discrepancy is the fact that these structures do not operate in the controlled environment of an industry or a laboratory facility but rather they are affected by a number of uncontrollable environmental conditions, such as temperature, temperature spatial gradients due to solar irradiation, temporal temperature gradient due to thermal capacity, humidity, and others (Sohn 2007). The shortcomings of vibration-based SHM methods have been recognized already in one of the first review papers on the subject (Doebling et al. 1998) exposing the advantages and capabilities of several methodologies in this area.

For the aforementioned reason, one is faced with the problem of identifying a dynamic model that is able to represent a given structure for an extended spectrum of operational conditions – if not its entire life cycle. Toward this end, the combined vibrational response and environmental data, which are normally available in current SHM systems, have to be utilized along with appropriate models that can account for the variability of structural dynamics due to environmental conditions. The approach detailed herein treats this issue through a functional representation that introduces this dependence into the model's parameters.

Structures Operating Under Varying Conditions and Their Responses

A linear viscously damped structure may be described by the following lumped parameter, time-varying ordinary differential equation:

$$\mathbf{M}(t)\ddot{\mathbf{x}}(t) + \mathbf{C}(t)\dot{\mathbf{x}}(t) + \mathbf{K}(t)\mathbf{x}(t) = \mathbf{u}(t), \quad \text{for } t \in [t_0, t_f] \quad (1)$$

where t designates analog time with t_0 denoting the start and t_f the end of the structure's lifetime or inspection interval, $\mathbf{x}(t)$ the structural displacements response vector, $\mathbf{u}(t)$ the applied excitation forces vector, and $\mathbf{M}(t)$, $\mathbf{C}(t)$, $\mathbf{K}(t)$ the mass, damping, and stiffness matrices of the structure, respectively.

The variability of structural response may be usually attributed to a small number of parameters related with either inherent properties of the structure or exogenous random variables, e.g., environmental and loading conditions, geometry, mass distribution, and so on. Gathering these L parameters in a single vector $\boldsymbol{\xi}(t) = [\xi_1(t), \xi_2(t), \dots, \xi_L(t)]^T$ the previous model may be rewritten as

$$\mathbf{M}(\boldsymbol{\xi}(t))\ddot{\mathbf{x}}(t) + \mathbf{C}(\boldsymbol{\xi}(t))\dot{\mathbf{x}}(t) + \mathbf{K}(\boldsymbol{\xi}(t))\mathbf{x}(t) = \mathbf{u}(t) \quad (2)$$

Focusing on environmental conditions and assuming that they are characterized by slow (compared to the structural dynamics) variation, the previous model may be rewritten as

$$\mathbf{M}(\boldsymbol{\xi})\ddot{\mathbf{x}}(t) + \mathbf{C}(\boldsymbol{\xi})\dot{\mathbf{x}}(t) + \mathbf{K}(\boldsymbol{\xi})\mathbf{x}(t) = \mathbf{u}(t), \quad \text{for } t \in [t_a, t_b] \subset [t_0, t_f] \quad (3)$$

The latter may be considered as a local time-invariant model which represents the structure when monitored during a small time interval. Within this interval the input parameter vector,

ξ and as a consequence the mechanical properties of the structure, may be considered to be “fixed” to constant values. Then, the input parameter vector ξ may be considered as a realization of the random vector Ξ with joint probability density function (pdf) $f_{\Xi}(\xi)$. In this way the initial linear time-varying (LTV) model of Eq. 1 may be written as a linear time-invariant (LTI) model:

$$\mathbf{M}(\Xi)\ddot{\mathbf{x}}(t) + \mathbf{C}(\Xi)\dot{\mathbf{x}}(t) + \mathbf{K}(\Xi)\mathbf{x}(t) = \mathbf{u}(t), \quad \text{with } \Xi(\omega) \in \Omega \quad (4)$$

which is however characterized by parameters that are depending on the input variable vector Ξ . In the equation above, Ω designates the event space of the random vector Ξ , and ω an elementary event of this space.

The above continuous-time model obviously has a discrete-time counterpart, which for the simpler single-input single-output case may be approximated by a scalar difference equation of the following form (Andersen 1997):

$$\begin{aligned} x(t) + a_1(\Xi)x[t-1] + \dots + a_{n_a}(\Xi)x[t-n_a] \\ = b_0(\Xi)u[t] + b_1(\Xi)u[t-1] + \dots \\ + b_{n_b}(\Xi)u[t-n_b], \quad \text{for } t = 1, \dots, N \end{aligned} \quad (5)$$

in which t designates normalized discrete time (absolute time normalized by the sampling period T_s), N the signals' length in samples, $x[t]$, $u[t]$ the discretized versions of the observed vibration response and excitation force, respectively, $a_i(\Xi)$, $b_i(\Xi)$ the model parameters depending on Ξ , and finally n_a , n_b the equation orders.

Structural identification is an inverse problem which concerns the estimation of an appropriate mathematical representation of the structural dynamics based on vibrational measurements. In the case of ambient loading, the excitation may not be measured with accuracy, and thus, the input sequence $u[t]$ in the theoretical model of Eq. 5 has to be replaced by an unknown excitation

sequence $e[t]$. The latter is typically considered to be a normally independently distributed (NID) sequence, that is, a white noise process, with zero mean and constant variance σ_e^2 . Therefore, the analytical model of Eq. 5 is approximated by a model of the following form:

$$\begin{aligned} x(t) + a_1(\Xi)x[t-1] + \dots + a_{n_a}(\Xi)x[t-n_a] \\ \underbrace{= e[t] + c_1(\Xi)e[t-1] + \dots + c_{n_c}(\Xi)e[t-n_c]}_{\text{MA part}}, \\ e[t] \sim \text{NID}(0, \sigma_e^2), \quad \text{for } t = 1, \dots, N \end{aligned} \quad (6)$$

which has the form of a conventional ARMA model (Ljung 1999), with the important difference that it is characterized by stochastic parameters which depend on the input variable vector Ξ . These parameters may actually be represented by a deterministic mapping describing their relation with the input random variables. Specifically, assuming that the ARMA model parameters $a_i(\Xi)$ and $c_i(\Xi)$ have finite variance, they admit the following representation (Soize and Ghanem 2004):

$$\begin{aligned} a_i(\Xi) &= \sum_{j=1}^{\infty} a_{i,j} \varphi_{\mathbf{d}(j)}(\Xi) \quad (i = 1, \dots, n_a), \\ c_i(\Xi) &= \sum_{j=1}^{\infty} c_{i,j} \varphi_{\mathbf{d}(j)}(\Xi) \quad (i = 1, \dots, n_c) \end{aligned} \quad (7)$$

with $a_{i,j}$ and $c_{i,j}$ designating unknown deterministic coefficients of projection onto the probability space of Ξ and $\varphi_{\mathbf{d}(j)}$ are multivariate basis functions that are orthonormal with respect to the joint pdf of Ξ , that is,

$$E[\varphi_{\alpha}(\Xi)\varphi_{\beta}(\Xi)] = \begin{cases} 1, & \text{for } \alpha=\beta \\ 0, & \text{otherwise} \end{cases} \quad (8)$$

and $\mathbf{d}(j)$ is the multi-indices of the multivariate basis. Each probability density function may be

associated with a well-known family of orthogonal polynomials. For instance, a normal distribution is associated with Hermite polynomials while a uniform distribution with Legendre. A list of the most common probability density functions along with the corresponding orthogonal polynomials and the relations for their construction may be found in Xiu and Karniadakis (2002). For the case of independent random variables Ξ_j the expansion of Eq. 7 is called polynomial chaos (PC) expansion (Blatman and Sudret 2010), and the resulting models may be referred to as PC-ARMA models.

Of course, for purposes of practicality, the infinite series of PC expansion of Eq. 7 must be truncated by selecting an appropriate functional subspace consisting of a finite number of terms. A usual approach lies in the selection of a functional subspace consisting of polynomial basis functions with total maximum degree P , that is, $|d(j)| = \sum_{\ell=1}^L d(j, \ell) \leq P$ for all j . In this case the dimensionality of the functional subspace is equal to

$$p = \frac{(L + P)!}{L!P!} \quad (9)$$

where L is the number of random variables and P the maximum basis total degree. For instance, for a random input vector of dimension equal to three ($L = 3$) and maximum degree equal to two ($P = 2$), the multi-indices vectors are:

	l		
	1	2	3
$d(1)$	0	0	0
$d(2)$	1	0	0
$d(3)$	0	1	0
$d(4)$	0	0	1
$d(5)$	2	0	0
$d(6)$	0	2	0
$d(7)$	0	0	2
$d(8)$	1	1	0
$d(9)$	1	0	1
$d(10)$	0	1	1

In this way, the resulting PC-ARMA model is fully parametrized in terms of a finite number

of deterministic coefficients of projection $a_{i,j}$ and $c_{i,j}$ while a specific PC-ARMA model structure is fully defined by the model orders n_a, n_c , and the basis total degree P .

At this point it should be noted that similar models have been used for the structural identification and damage detection issues in a number of recent studies (Functionally Pooled ARX models; see Kopsaftopoulos and Fassois 2013 and the references therein) and automatic control within the Linear Parameter Varying (LPV) models framework (Tóth 2010, Zhao et al. 2012).

PC-ARMA Model Identification

The complete PC-ARMA structural identification problem may be stated as follows: Given a set of dynamic vibration response signals obtained from the structure under study for various measured environmental conditions, select the PC-ARMA model structure and estimate the corresponding model parameters that best fit the available records. The issues of PC-ARMA model parameter estimation and model structure selection are discussed in the following sections.

Model Parameter Estimation

As already mentioned, the estimation of a PC-ARMA model refers to the determination of the coefficients of projection assembled in the parameter vector

$$\theta = [a_{1,1} a_{1,2} \cdots a_{n_a,p} c_{1,1} c_{1,2} \cdots c_{n_c,p}]^T$$

or a subset of θ selected by the procedure described in the next section. Its estimation is based on the availability of structural vibration response data and measurements of the environmental conditions of interest. In order to identify a stochastic model that will be able to describe the structure's dynamics for the wide range of its operational spectrum, data from a sufficient number of operating conditions should be available.

Considering K such datasets have been acquired during an equal number of experiments conducted under different input random vector realizations

$\xi_k = [\xi_{1k} \xi_{2k} \dots \xi_{Lk}]^T$, for $k = 1, 2, \dots, K$. Based on the validity of the assumptions described in the previous section, it is considered that the recorded

vibration response signals $\mathbf{x}_k^N = \{x_k[1], x_k[2], \dots, x_k[N]\}^T$ follow the PC-ARMA model of Eqs. 6 and 7:

$$\begin{aligned} x_k[t] &+ \sum_{j=1}^p a_{1,j} \varphi_{\mathbf{d}(j)}(\xi_k) x_k[t-1] + \dots + \sum_{j=1}^p a_{n_a,j} \varphi_{\mathbf{d}(j)}(\xi_k) x_k[t-n_a] \\ &= e_k[t] + \sum_{j=1}^p c_{1,j} \varphi_{\mathbf{d}(j)}(\xi_k) e_k[t-1] + \dots + \sum_{j=1}^p c_{n_c,j} \varphi_{\mathbf{d}(j)}(\xi_k) e_k[t-n_c], \end{aligned} \quad (9a)$$

for $t = 1, \dots, N$, and $k = 1, \dots, K$

$$e_k \sim \text{NID} \left(0, \sigma_{e_k}^2 \right) \quad (9b)$$

$$E\{e_i[t]e_j[t-\tau]\} = \begin{cases} \sigma_{e_i}^2 \delta_{i,\tau} & \text{for } i=j \\ 0 & \text{for } i \neq j \end{cases} \quad (9c)$$

with $\delta_{i,j}$ designating the Kronecker delta function. In the relationships above, the uncorrelatedness of the residual series between different vibration response records has been added to the model assumptions.

The estimation of the PC-ARMA model parameter vector θ may be based on the minimization of the Prediction Error (PE) criterion. The PE criterion consists of the sum of squares of the model's one-step-ahead prediction errors for the complete set of datasets. As it may be easily shown, the one-step-ahead prediction errors

coincide with the model's residual sequence $e_k[t]$ (Ljung 1999), and thus, θ has to be estimated through the following minimization problem:

$$\begin{aligned} \theta &= \arg \min_{\theta} \left\{ \sum_{k=1}^K \sum_{t=1}^N \frac{(x_k[t] - \hat{x}_k[t|t-1])^2}{\gamma_k^2} \right\} \\ &= \arg \min_{\theta} \left\{ \sum_{k=1}^K \sum_{t=1}^N \frac{\hat{e}_k[t]^2}{\gamma_k^2} \right\} \end{aligned} \quad (10)$$

with $\hat{x}_k[t|t-1]$ denoting the model's one-step-ahead prediction, γ_k user defined weights, and argmin minimizing argument with respect to the indicated quantity. Toward this end, Eq. 9 may be rewritten in a regression type form as

$$\begin{aligned} x_k[t] &= - \sum_{i=1}^{n_a} \sum_{j=1}^p a_{i,j} \varphi_{\mathbf{d}(j)}(\xi_k) x_k[t-i] + \sum_{i=1}^{n_c} \sum_{j=1}^p c_{i,j} \varphi_{\mathbf{d}(j)}(\xi_k) e_k[t-i] + e_k[t] \\ &= \underbrace{\begin{bmatrix} -\varphi_{\mathbf{d}(1)}(\xi_k) x_k[t-1] \\ -\varphi_{\mathbf{d}(2)}(\xi_k) x_k[t-1] \\ \vdots \\ -\varphi_{\mathbf{d}(p-1)}(\xi_k) x_k[t-n_a] \\ -\varphi_{\mathbf{d}(p)}(\xi_k) x_k[t-n_a] \\ \varphi_{\mathbf{d}(1)}(\xi_k) e_k[t-1] \\ \varphi_{\mathbf{d}(2)}(\xi_k) e_k[t-1] \\ \vdots \\ \varphi_{\mathbf{d}(p-1)}(\xi_k) e_k[t-n_c] \\ \varphi_{\mathbf{d}(p)}(\xi_k) e_k[t-n_c] \end{bmatrix}}_{\varphi[\xi_k, t]^T} \cdot \underbrace{\begin{bmatrix} a_{1,1} \\ a_{1,2} \\ \vdots \\ a_{n_a,p-1} \\ a_{n_a,p} \\ c_{1,1} \\ c_{1,2} \\ \vdots \\ c_{n_c,p-1} \\ c_{n_c,p} \end{bmatrix}}_{\theta} + \hat{e}_k[t] \end{aligned} \quad (11)$$

or by stacking all time instants in a single vector

$$\underbrace{\begin{bmatrix} x_k[1] \\ x_k[2] \\ \vdots \\ x_k[N] \end{bmatrix}}_{x_k^N} = \underbrace{\begin{bmatrix} \varphi[\xi_k, 1]^T \\ \varphi[\xi_k, 2]^T \\ \vdots \\ \varphi[\xi_k, N]^T \end{bmatrix}}_{\Phi(\xi_k)} \cdot \underbrace{\begin{bmatrix} a_{1,1} \\ a_{1,2} \\ \vdots \\ a_{n_{a,p-1}} \\ a_{n_{a,p-1}} \\ c_{1,1} \\ c_{1,2} \\ \vdots \\ c_{n_{c,p-1}} \\ c_{n_{c,p}} \end{bmatrix}}_{\theta} + \underbrace{\begin{bmatrix} e_k[1] \\ e_k[2] \\ \vdots \\ e_k[N] \end{bmatrix}}_{e_k^N} \quad (12)$$

Finally, by pooling all the available datasets, the following regression model is obtained:

$$\underbrace{\begin{bmatrix} x_1^N \\ x_2^N \\ \vdots \\ x_K^N \end{bmatrix}}_X = \underbrace{\begin{bmatrix} \Phi(\xi_1) \\ \Phi(\xi_2) \\ \vdots \\ \Phi(\xi_K) \end{bmatrix}}_{\Phi(\xi)} \cdot \theta + \underbrace{\begin{bmatrix} e_1^N \\ e_2^N \\ \vdots \\ e_K^N \end{bmatrix}}_E \quad (13)$$

where $\Phi(\xi)$ is the regression matrix. Thus, the minimization problem of Eq. 7 may be rewritten as follows:

$$\theta = \arg \min_{\theta} \{E^T \cdot \Gamma \cdot E\} \quad (14)$$

where $\Gamma = I_N \otimes \gamma$ with $\gamma = [\gamma_1 \cdots \gamma_K]^T$ denoting the vector of weights, I_N the $N \times N$ identity matrix, and $\otimes$ the Kronecker product.

Due to the nonlinear dependence of the a priori, unknown residual sequence E on the parameter vector θ , the last equation leads to a nonlinear-weighted least squares problem, which has to be tackled by nonlinear optimization methods. However, nonlinear least squares techniques are sensitive to the initial parameter values and if no accurate estimates are available, the minimization procedure is very likely to converge to a local minimum. In order to avoid potential inaccurate convergence problems associated with arbitrary initial estimates, initial values for the coefficients of projection may be obtained by identifying conventional ARMA models for each of the K data

sets and expanding their parameters onto the PC basis (Zhao et al. 2012).

However, in the simpler PC-AR case, the regression model of Eq. 13 is linear, and thus, θ may be estimated by the linear weighted least squares (WLS) estimator:

$$\hat{\theta} = (\Phi(\xi)^T \cdot \Gamma \cdot \Phi(\xi))^{-1} (\Phi(\xi)^T \cdot \Gamma \cdot Y) \quad (15)$$

The simplest and obvious choice for the weights γ_k is to set them equal to unity, with this selection leading to the ordinary least squares (OLS) estimator. However, it has been shown for the similar FP-ARX models (Kopsaftopoulos and Fassois 2006) that the weights that lead to consistent and asymptotically efficient estimates are those equal to the standard deviation of the residual sequence, that is,

$$\gamma_k = \sigma_{e_k}, \quad \text{for } k = 1, 2, \dots, K \quad (16)$$

Due to the fact that the true residual standard deviation is typically unknown, it has to be replaced by an appropriate estimate, typically obtained via the OLS estimation which is used as a first stage. The WLS estimator may then be realized in an iterative manner till convergence of the PE criterion is achieved.

Model Structure Selection

Model structure selection is the optimization procedure during which models corresponding to various candidate “structures” are estimated and weighted according to an appropriately selected fitness criterion. Model “fitness” may be considered in terms of various criteria, such as the residual sum of squares (RSS)

$$\text{RSS} = \sum_{k=1}^K \sum_{t=1}^N e_k[t]^2 \quad (17a)$$

or the equivalent mean squared error (MSE)

$$\text{MSE} = \frac{\text{RSS}}{NK} \quad (17b)$$

However, the limitation of using such criteria is that they may monotonically decrease with

increasing model structure and as a result may lead to overfitting. For this reason, caution has to be exercised and a compromise has to be made between model accuracy and model structure complexity.

The model structure selection procedure for a PC-ARMA model concerns the determination of the set of 3 integers (n_a, n_c, P) for obtaining the best fitting model, and a combinatorial approach, that is, estimating PC-ARMA models for various integer sets, may be used. However, a simpler approach that may lead to sparse PC basis by selecting only a subset of the initial PC functional subspace may be described as follows (Poulimenos and Fassois 2006):

Phase I. AR/MA orders selection. In order to “decouple” the selection of the model orders (n_a, n_c) from that of functional subspaces, their interaction has to be minimized. For this reason a high-degree P and the complete set of PC basis functions may be initially adopted. When employing these, AR/MA model order selection may be achieved through trial-and-error techniques based on the values of the fitness function.

Phase II. PC basis subspace selection. The aim of this phase is the optimization of the PC functional subspace, in the sense of reducing model complexity without significantly reducing model accuracy. This may be accomplished by dropping, one at a time, the PC basis functions whose removal does not cause significant loss of the criterion employed.

A flowchart of the complete PC-ARMA identification procedure is given in Fig. 1.

Validation

Once a PC-ARMA model has been obtained, it must be validated with respect to the assumptions behind the identification method. A standard validation procedure in the simple ARMA case involves the testing of Gaussianity and, in particular, the whiteness of the identified model’s one-step-ahead prediction error sequence. In the PC-ARMA case this assumption has to be validated for each of the recorded datasets, while the

Stochastic Structural Identification from Vibrational and Environmental Data, Fig. 1 Flowchart of the PC-ARMA model identification procedure

additional assumption of cross-uncorrelatedness between the datasets has to be validated.

The validation procedure of the estimated PC-ARMA model may be based on the typical

Stochastic Structural Identification from Vibrational and Environmental Data, Fig. 2 The complete stochastic structural identification framework based on PC-ARMA models

cross-validation principle which presumes the separation of the processed signal into an estimation set and a smaller validation set of data (Ljung 1999).

Summary of the Method

- Step 1.** Collect K datasets of vibration response and environmental variables measurements from the structure under study for a range of operating conditions.
- Step 2.** Fit a probability density function to the environmental variables based on the available data and select the corresponding family of PC basis functions.
- Step 3.** Select a high total degree for the PC basis P ; estimate PC-ARMA models of various orders (e.g., considering common AR/MA order, from $n_a = n_c = n_{\min}$ up to $n_a = n_c = n_{\max}$); and select the final orders based on the “fitness” criterion (e.g., MSE).
- Step 4.** Estimate PC-ARMA (n_a, n_c) models by rejecting each time a number of PC basis function from the complete PC subspace. Reject the functions whose removal does not imply significant reduction of the “fitness” criterion value.

The complete stochastic structural identification framework based on PC-ARMA models is illustrated in the abstract schematic representation of Fig. 2. It is noted that the estimated PC-ARMA model parameters may be used for the calculation of the structure’s modal characteristics, such as the modal frequencies and damping ratios, as a function of the input variable vector Ξ for the entire event space Ω .

Numerical Case Study

The modeling of a 3-DOF system (Fig. 3) is presently considered for demonstrating the workings of the PC-ARMA identification framework. The mechanical properties of the system are:

$$m_1 = 10^2, \quad m_2 = 10^{1.5}, \quad m_3 = 10 \text{ (kg)}$$

$$k_1 = 10^6, \quad k_2 = 10^{5.5}, \quad k_3 = 10^5 \text{ (N/m)}$$

$$c_1 = 100, \quad c_2 = 10, \quad c_3 = 10, \text{ (N/ms}^{-1}\text{)}$$

The system is considered to operate under varying conditions of temperature and humidity.

Stochastic Structural Identification from Vibrational and Environmental Data, Fig. 3 Three degree of freedom system and its properties

The system's stiffness coefficients are considered to be linearly depended on the temperature through the following relationship:

$$k'_i = k_i[1 - (T - T_{\text{ref}})k_T]$$

with $k_T = 5 \times 10^{-3}$ denoting the thermal coefficient and $T_{\text{ref}} = 20^\circ\text{C}$ the reference temperature, while humidity is modeled as mass increment due to trapped humidity. For the sake of simplicity, in this test case study, it is assumed that the temperature is uniform with no spatial gradients or temporal variations within each experiment, while the mass load is evenly distributed over the system.

In order to identify an inverse model for this system under various operating conditions, the system's response (acceleration of mass m_3) is simulated for various operating condition scenarios. Specifically, 50 samples of the added mass and temperature variables are drawn, by means of the Latin hypercube sampling (LHS) method, from their theoretical pdfs which are considered to correspond to a log-normal distribution with mean value equal to 1 and variance equal to 0.25 for the mass load, that is, $\Xi_1 \sim \ln N(1, 0.25)$, and a normal distribution with mean value equal to

15 and variance equal to 25 for the temperature, that is, $\Xi_2 \sim N(15, 25)$. The 50 samples of the input variables are shown in Fig. 4.

In a real-world structural identification application, where no information is available regarding the true pdfs of the input random vector, someone could use maximum likelihood estimation fitting of the environmental condition data values to a parametric distribution. The results of such a fitting of the data onto pdfs are shown in Fig. 5. Based on this fitting and after transforming the pdf of the mass load into a normal distribution by using the natural logarithm, the Hermite polynomials may be selected for the construction of the multivariate PC basis functions.

For each set of these "environmental" conditions, a white noise realization of the excitation force $u(t) \sim N(0, 10^4)$ is used for the excitation of the system. System's response is obtained by using the Runge-Kutta algorithm for 1,800 points with sampling frequency equal to 64 Hz. After discarding the first 1,000 samples in order to avoid transient effects, the rest of the data are separated into an estimation set consisting of 500 samples and a validation set of 300 samples.

Stochastic Structural Identification from Vibrational and Environmental Data, Fig. 4 Input variable values for the 50 simulation experiments conducted

Stochastic Structural Identification from Vibrational and Environmental Data, Fig. 5 The empirical density and distribution functions calculated based on the 50 realizations of the input variables, compared to the

corresponding probability density and cumulative distribution functions estimated by the maximum likelihood method

The estimation dataset (50 sets $\times$ 500 samples) is used for the identification of the system through simple PC-AR models in what follows. PC-AR model structure selection is based on the

MSE criterion and the procedure described in section 2.2. The maximum total degree of the PC multivariate basis is initially selected equal to 5, which using Eq. 9 with $P = 5$, and

Stochastic Structural Identification from Vibrational and Environmental Data, Fig. 6 PC-AR model structure selection results: (a) MSE criterion values for WLS-based estimated PC-AR models with $n_a = 2, 3,$

$\dots, 20$ and $P = 5$, and (b) MSE criterion values obtained from a PC-AR(6) model by dropping, one at a time, the PC basis functions of the initial subspace

$L = 2$ gives a total number of 21 candidate basis functions. These functions are firstly used for the AR order selection by estimating PC-AR models of various orders ($n_a = 2, 3, \dots, 20$) by means of the WLS estimator. The results illustrated in Fig. 6a show an AR order equal to six as appropriate for capturing the dynamics of the simulated system. At the second stage of the structure selection procedure, a sparse PC basis is sought. As shown in Fig. 6b, this comes down to a basis of only 4 basis functions which are given in Table 1. It may be observed that the basis indicates a linear relationship of the PC-AR model parameters with respect to temperature and quadratic with respect to humidity (mass load).

	<i>l</i>	
	1	2
<i>d</i> (1)	0	0
<i>d</i> (2)	1	0
<i>d</i> (3)	0	1
<i>d</i> (4)	2	0

The estimated PC-AR(6) model is successfully validated by calculating the one-step-ahead prediction errors for the validation dataset (50 sets $\times$ 300 samples). Indicative results for the autocorrelation function of the resulting

Stochastic Structural Identification from Vibrational and Environmental Data,

Fig. 7 PC-AR(6) model validation results. (a) The autocorrelation function for the prediction error sequence of the validation set (simulation experiment 2; time lags 100; 95 % confidence limits) and (b) the covariance matrix of the prediction error matrix E

prediction error sequence corresponding to the second simulation experiment are shown in Fig. 7a, while also the assumption of uncorrelatedness between the various prediction error sequences may be qualitatively validated by visually inspecting the residual covariance matrix which is shown in Fig. 7b.

Finally, the estimated coefficients of projection may be used for calculating the PC-AR(6)-based estimates of the system natural frequencies and thus for constructing a surface that shows the dependence of the natural frequencies of the 3-DOF system on the two input random variables. The results are plotted against the theoretical curves in Fig. 8. It may be observed that there is a good agreement between the theoretical and the estimated natural frequencies with the highest errors, which are below 1 Hz, occurring at extreme values of the input variables which were not included in the estimation set.

Summary

Mechanical properties, and thus the dynamic behavior of an engineering structure, are significantly affected by environmental and operational conditions. A complete identification procedure has to lead to a consistent representation of the structural dynamics for a great percentage, if not the whole, range of the structure's operational spectrum. This may be achieved either by a multi-model approach, that is, estimating local models for every new set of environmental conditions data or using functional models that incorporate into their parameters the structure's dependency on a set of random input variables which correspond to the measured environmental conditions. In this way, after the estimation (training) of the functional model on a given set of measurements, its parameters may be extrapolated for any new set of environmental conditions. Presently, the functional models used are of the

Stochastic Structural Identification from Vibrational and Environmental Data, Fig. 8 PC-AR(6)-based natural frequency estimates compared to the theoretical

curves. The natural frequencies are plotted versus the input variables, that is added mass and temperature

ARMA form with parameters that are expanded on polynomial chaos basis. The latter has the important feature of being orthogonal to the probability density function of the input variable vector, providing in this way the best convergence rate with increasing functional subspace.

Introduction

The catastrophic earthquakes that struck several countries over the last 20 years brought to light the susceptibility of the existing building stock (Fig. 1). Old-type reinforced concrete (R/C) structures are characterized by insufficient reinforcement detailing (lack of stirrups for ensuring a certain ductility level, indirect supports, insufficient anchorages of bars), nonuniform distribution of stiffness and/or mass along the height of the building, insufficient foundation system, poor

quality of materials, and various other weaknesses such as increased loading due to change of use and corrosion of reinforcement.

The majority of multistory R/C buildings in southern Europe were built in the first half of the twentieth century. Structures were designed for gravity loads only by implementing the allowable stress design philosophy which did not allow any control of the mode of failure and the corresponding deformation capacity of the individual members. Taking Greece as an example, the first seismic code was introduced in 1959, and R/C walls were introduced in construction in the 1960s (often without extending up to the foundation of the building). The modern seismic codes were introduced more than 20 years later, in the mid-1980s. The multistory R/C buildings of the 1950s represent the cutting edge of the construction technology for gravity load-designed frame buildings. Information regarding the material, detailing, and geometrical characteristics of representative low- to medium-rise (up to 8 stories) R/C buildings real structures found in the urban areas built between the 1920s and 1960s is presented in Table 1 (Thermou and Palaioxorinou 2013). The lack of a continuous vertical load path along the height of the buildings is a common feature of the buildings of that era. There is no typical floor since the dimensions of the columns and beams change from story to story. Often in-plan column layout does not follow a grid pattern, hence leading to indirect supports. Representative typical floor plan layouts are presented in Fig. 2.

The result of these systematic deficiencies of existing buildings is a decreased level of seismic protection, increased seismic vulnerability, and hence extensive damage expected in future seismic excitations. This is a rather alarming issue considering the socioeconomic impact of severely damaged buildings or collapses in future strong ground motions. The recommended solution for this category of buildings, which comprises the vast majority of the existing stock, is retrofitting (strengthening) with a view to upgrading their seismic capacity and meeting the current standards for seismically designed structures. Adopting global intervention (GI)

methods (e.g., R/C jacketing, R/C infill walls) leads to the modification of strength and stiffness (Fig. 3). They are used in systems with a high flexibility to sway, in torsionally unbalanced systems, or where strengthening of the existing building is required (e.g., increase of base shear strength in buildings with an open first story,

Fig. 1). GI methods cannot be used separately from local intervention (LI) methods since they are used to accommodate premature failure modes (Thermou et al. 2012a). LI methods as, for example, the intervention methods with composite materials are considered not to alter the stiffness or flexural strength of the retrofitted

Strengthened Structural Members and Structures: Analytical Assessment, Fig. 2 Representative ground floor plan layouts of the R/C multistory buildings in Greece of the (a) 1920s, (b) 1950s, and (c) 1960s

Strengthened Structural Members and Structures: Analytical Assessment, Fig. 3 Retrofitting strategy: stiffness, strength, and ductility increase (Thermou and Elnashai 2006)

members, but only affect their post-yielding deformation capacity through confinement and by suppressing premature modes of failure (e.g., brittle shear or lap splice failure).

The decision on the extent of the interventions (i.e., which floors, which elements of the floor, and which design parameters are going to be modified) and its impact on the modification of selected global response indices may be assessed through analytical modeling of the strengthened structure. This implies that there should sufficient information relative to the effectiveness of the intervention methods adopted at member level. The addition of a new concrete layer (e.g., flexural strengthening of beams) or a new R/C member (e.g., R/C jacketing, R/C infill walls) in various retrofit techniques entails issues related to the connection between existing and newly cast concrete. The response of the composite member, and subsequently of the whole structure, depends largely on the response characteristics of the interface, since slip takes place and shear transfer mechanisms are mobilized. Estimating response indices such as stiffness and strength in a reliable manner requires the development of analytical models that will consider the phenomena that take place along interfaces due to slip and their interaction.

This contribution aims to present the framework for the analytical assessment of strengthened structures when the intervention methods adopted result in composite members with multiple monolithic phases. The slippage introduced

due to the discontinuity in the normal strain along the interfaces is rather determinant for the response at member level. One of the objectives is to highlight the role of the interface characteristics and present the parameters that influence the interconnection between the existing and new member. The shear transfer mechanisms mobilized due to relative slippage of the contact interfaces are presented in the following, and their interaction is discussed. Information is also provided for the influence of cyclic loading on the shear resistance mechanisms. The fundamentals for the development of analytical models which take into account slip at the interfaces are discussed. The interrelation between the effects that the changes at local level may have on global level is identified as a key issue in the assessment of strengthened structures. Moreover, the alternative simplified design approach suggested by codes, where the monolithic factors are utilized as to indirectly account for the adverse effect of slippage on response, is presented. The last section of this entry focuses on the alternative analytical design approaches that could be followed for one of the most popular global intervention techniques, the R/C jacketing technique.

Implications of the Addition of New Concrete Layers or New Elements

The response of a composite beam, as the one shown in Fig. 4, depends on the degree of

Strengthened Structural Members and Structures: Analytical Assessment,

Fig. 4 Strain distribution profiles for (a) no connection; (b) perfect and (c) partial connection between beam A and beam B. (d) Shear flow along the interface

interconnection between beam A and beam B. In one extreme case, the case of zero friction (no connection), beam B could slide relative to beam A without mobilizing any kind of shear resistance (Fig. 4a). In an ideal situation, the composite members (beam A and beam B) would behave as monolithic (perfect connection, Fig. 4b). In real conditions, partial connection between the two bodies is expected, which implies that relative slip, s , between the two bodies is allowed, thus mobilizing the shear transfer mechanisms at the interface (Fig. 4c). The discontinuity in the strain profile corresponds to the slip, s , at the horizontal interfaces (Fig. 4c). Curvature, which is the slope of the strain profile on the cross section, is the same between the various slipping parts. This is a common assumption in the analysis of composite (layered) beams (e.g., glulam timber beams, composite steel beams, etc.). The shear flow, T , at the interface is estimated by

$$T = \frac{V \cdot S}{I} \quad (1)$$

where S is the first moment of area, I is the moment of inertia of the composite cross section, and V is the shear force on the member.

Flexural enhancement of beams with the addition of a new reinforced concrete layer in the tension zone follows the principles presented for the composite beam of Fig. 4. The same approach can also be followed in the case of composite

cross sections where an outer shell is placed around the core of the cross section, as in the case of R/C jacketing of an existing column, or when an infill wall is added to an existing bay by incorporating the existing columns.

The preparation of the interface and the interconnection measures taken between existing and new member play a key role in the interfacial force transfer and relative slip occurring along the contact surface. The bond between the monolithic phases of the composite member can be enhanced by roughening of the substrate surface, addition of dowels placed through holes driven on the substrate surface, and when applicable (e.g., R/C jacketing technique) welding of the new longitudinal bars to the existing ones through deformed reinforcing bars bent into a U-shape. Moreover, experimental evidence has shown that differential shrinkage and stiffness of new-to-old concrete interfaces, as well as the compressive strength of the added concrete to an existing concrete substrate, influence the response of composite system where concrete-to-concrete interfaces exist (e.g., Choi et al. 1999). For example, in the experimental study conducted by Júlio et al. (2006), it was found that the increase of the concrete compressive strength of the new layer compared to that of the existing one leads to an enhancement of the compressive strength of the interface, i.e., taking into account the compressive strength of the weakest concrete seems to be conservative. Recently, Santos and Júlio (2014) proposed

Strengthened Structural Members and Structures: Analytical Assessment, Fig. 5 Slip at a concrete interface crossed by reinforcement

design expressions where the effects of differential shrinkage and differential stiffness at the concrete-to-concrete interface are considered.

Shear Transfer Along Concrete-to-Concrete Interfaces

Shear transfer along interfaces has been a subject of continuous research since the 1970s. A variety of analytical models are available for modeling the main shear transfer mechanisms (friction and dowel resistance) by considering that they act separately or jointly. There are models where all forces are transferred through reinforcement (e.g., Birkeland and Birkeland 1966; Walraven 1981), whereas others that, apart from reinforcement contribution, include a cohesion term (e.g., Mattock and Hawkins 1972; Vecchio and Collins 1986; Tassios 1986). In the modified compression field theory (MCFT) (Vecchio and Collins 1986), the role of the cohesion term is played by the aggregate interlock mechanism, whereas in the model of Tassios (1986), by friction owing to the clamping action of reinforcement normal to the interface. In the rest of the models, the cohesion term corresponds to the friction resistance developed along the interface.

Shear transfer is affected by the roughness of the sliding planes, by the characteristics of the reinforcement, by the compliance of concrete, and by the state of stress in the interface zone.

Mechanisms that resist sliding (slip) are (i) aggregate interlock between contact surfaces, including any initial adhesion of the jacket concrete on the substrate; (ii) friction owing to the clamping action of reinforcement normal to the interface; and (iii) dowel action of any properly anchored reinforcement crossing the sliding plane. Dowel action develops by three alternative mechanisms, namely, by direct shear, by kinking, and by flexure of the bars crossing the contact plane. The relationship that describes the contribution of the individual shear transfer mechanisms is

$$\begin{aligned}\tau_{\text{tot}} &= \tau_{\text{agr}} + \tau_f + \tau_D = \tau_{\text{agr}} + \mu\sigma_N + \tau_D \Leftrightarrow \\ \tau_{\text{tot}} &= \tau_{\text{agr}} + \mu(\sigma_c + \rho\sigma_s) + \tau_D \\ &= \tau_{\text{agr}} + \mu(vf_c + \rho\sigma_s) + \tau_D\end{aligned}\quad (2)$$

where τ_{agr} represents the shear resistance of the aggregate interlock mechanism, μ is the interface shear friction coefficient, σ_N is the normal clamping stress acting on the interface, and τ_D is the shear stress resisted by dowel action, F_D , in cracked reinforced concrete. The clamping stress represents any normal pressure, p , externally applied on the interface, but also the clamping action of reinforcement crossing the contact plane, σ_s is the axial stress of the bars crossing the interface, ρ is the corresponding reinforcement area ratio, $v = N/(\sigma_c f_c) = \sigma_c / f_c$ is the normalized axial load at the interface of

area A_c , and f_c is the concrete compressive strength (Fig. 5). The first two terms in Eq. 2 collectively represent the *contribution of concrete* as they depend on the frictional resistance of the interface planes.

As it is mentioned in Model Code (2010) and the Greek Code for Interventions (KANEPE 2013), in real structures the various mechanisms interact, thereby affecting each other as a function of the shear slip. The aggregate interlock including any initial adhesive decreases at low slip values, whereas the maximum contribution of frictional and dowel resistance occurs at different slips. Therefore, Model Code (2010) as well as the Greek Code for Interventions (KANEPE 2013) introduce interaction factors which consider that the dowels crossing the interface are subject to bending and axial forced simultaneously and that the maximum values of the different shear resistance mechanisms occur at different slips. The interaction factors depend on various parameters such as the magnitude of the expected slip at the interface, the diameter of the reinforcing bars crossing the interface, the concrete compressive strength, cyclic loading, etc. Equation 2 is thus modified according to Model Code (2010) as follows:

$$\tau_{\text{tot}} = \tau_{\text{agr}} + \mu(\sigma_c + \kappa \cdot \rho \sigma_s) + \alpha \cdot \rho \cdot \sqrt{f_y \cdot f_c} \leq \beta \cdot v \cdot f_c \quad (3)$$

where the coefficients κ and α refer to the interaction factors for interface roughness and flexural resistance, respectively, whereas β is a coefficient related to the compressive struts. For the case where dowels are driven into the interface, $\kappa = 0.5$ for roughened interfaces and $\kappa = 0$ for smooth interfaces, whereas in the latter case $\alpha = 1.5$ denoting that the main resistance mechanism is provided by the dowel action. Model Code (2010, Chap. 7) provides detailed information regarding the design of the interface in shear and how the interaction coefficients are modified for different surface roughness.

The Greek Code for Interventions (KANEPE 2013) considers also the interaction between the

shear transfer mechanisms by estimating the shear resistance of the interface as

$$\tau_{\text{tot}} = \beta_F \tau_f + \beta_D \tau_D \quad (4)$$

where the β_F and β_D are the interaction factors of the friction and dowel resistance, which are equal to $\beta_F = 0.4$ and $\beta_D = 0.7$ for slip values $s \leq 1.00$ mm. These coefficients can be further decreased to 0.5 when either the expected slip value cannot be predicted or when the external compressive force at the interface is negligible.

The friction resistance, τ_f (Eq. 2), is calculated by considering the coefficient of friction, μ , which depends on the classification of the roughness of the interface. The majority of the experimental studies provide a qualitative description of the roughness of the interface after application of the selected type of treatment (e.g., sandblasting, use of pneumatic chipping device). It is obvious that the characterization by visual inspection only may lead to inaccuracies. Therefore, the roughness of the interface should be quantified by specific indicators. Although several methods have been developed that can successfully quantify the roughness of concrete interfaces (Santos and Júlio 2013), design codes in their majority still provide qualitative descriptions of the interface (e.g., smooth, rough, or very rough). An exception is Model Code (2010) which suggests two methods: the sand area method and the one where the average roughness is estimated (i.e., measuring the average deviation of the profile from a mean line).

From the above, it is seen that describing in detail the mechanisms mobilized along interfaces due to slip and their interaction is a complex mechanical issue which becomes even more complicated considering the response of the interface under cyclic loading conditions where degradation should also be accounted for. The research conducted on the derivation of constitutive models that describe the combined shear force resistance mobilized along interfaces due to sliding both under cyclic imposed deformations is limited. Palieraki et al. (2012) based on the previous studies of Tassios and Vintzileou (1987) and Vintzileou and Tassios (1986, 1987)

Strengthened Structural Members and Structures: Analytical Assessment,

Fig. 6 Response to symmetric cyclic loading: (a) friction and (b) dowel resistance

and after carrying out a new experimental program proposed the degradation rules for frictional and shear resistance, which were also adopted by the Greek Code for Interventions (KANEPE 2013). The frictional and dowel resistance is reduced at each cycle, n , according to (see Fig. 6)

$$\begin{aligned} \tau_{f,n} &= \tau_{f,1} \cdot \tau_{\text{deg}} \\ &= \tau_{f,1} \left\{ 1 - \left[0.05(n-1)^{1/2} \left(\frac{f_c}{\sigma_N} \right)^{1/2} \left(\frac{s}{s_u} \right)^{1/3} \right] \right\} \end{aligned} \quad (5)$$

$$F_{D,n} = F_{D,1} \cdot D_{\text{deg}} = F_{D,1} \left[1 - \frac{1}{7} \sqrt{n-1} \right] \quad (6)$$

where $\tau_{f,1}$ and $F_{D,1}$ are the peak frictional and dowel resistance value, respectively, attained in

the first cycle, n is the number of cycles, s is the slip value, s_u is the ultimate slip value, σ_N is the normal clamping stress acting on the interface, and f_c is the concrete compressive strength.

Analytical Assessment of Strengthened Members and Structures

Analytical Model: Slip at the Interface

The success of repair/strengthening, as quantified by the improvement of strength and stiffness of the retrofitted members, depends on its entirety on the degree of collaboration between the various monolithic phases of the composite member. The response of the retrofitted member is modified proportionally to the slip that takes place along the interface. The calculation of slip

and its effects on the mechanical characteristics of the retrofitted members presuppose the use of analytical models where the interface characteristics need to be explicitly modeled. This comprises a quite challenging subject of continuous research.

In case of R/C jacketing of columns, Thermou et al. (2007, 2012b) have developed an analytical model for predicting the response under monotonic and reversed cyclic loading of structural members with *old-type* detailing, strengthened with R/C jacketing. The analytical model introduces one additional degree of freedom between the existing member and its outer R/C shell, thus allowing slip to take place at the interface between the existing member and the jacket. Shear resistance mechanisms, such as aggregate interlock, friction, and dowel action, are mobilized to resist slip. The magnitude of shear flow sustained along the contact surface is calculated by considering the states of stress of the composite member at a cracked cross section and at a point between successive cracks, in order to introduce in the flexural behavior the effect of the moment gradient (shear force magnitude). A detailed description of the analytical model for R/C jacketed members is presented in the last section of this article. The same approach has also been implemented after the necessary modifications for predicting the response of thin reinforced self-compacting three-jacketed beams (Chalioris et al. 2014). Moreover, Tsioulou and Dritsos (2011) developed an analytical model for predicting the flexural capacity of beams strengthened by the addition of a concrete layer in the tension or compression zone. The algorithm developed aimed at the evaluation of slip and shear stress distribution along the interface.

The analytical models, as the ones previously presented, may provide information relative to the effectiveness of the selected intervention method applied at member level. Stiffness and strength of the retrofitted (composite) members are estimated and assessed. The interrelation between the effects that the changes at local level may have on global level is a key issue in the assessment of strengthened structures. These

may be evaluated rapidly through standard Rayleigh-type or Stodola-type iteration (Clough and Penzien 1993), using secant-to-yield stiffness values for the individual members (Thermou et al. 2012c). The estimated fundamental translational response shape and period may guide definition of retrofit objectives. Additional lateral strengthening of the building (owing to the implicit relationship between stiffness and strength) by means of controlled stiffness addition along the building height may be required. Proportioning the stiffness of the individual floors is determined so as to even out large discrepancies in relative drift between successive floors detected in the fundamental response shape pattern.

Simplified Design Approach: The Use of Monolithicity Factors

A pragmatic design approach commonly adopted by codes of practice considers the monolithic approach for the analysis of composite members making use of properly defined *monolithicity factors* for obtaining the mechanical properties of the strengthened member. The redesign procedure is thus simplified substantially and is used extensively in practice for various intervention methods for different types of structural members (slabs, beams, columns, walls, or footings). The values given so far to these modification factors are empirical or semiempirical. The use of reliable analytical models (e.g., Thermou et al. 2007, 2012b) can be utilized for the derivation of monolithicity factors after extensive study of their sensitivity to the characteristics of the intervention method (e.g., Kappos et al. 2012).

The use of monolithicity factors simplifies substantially design calculations and is applicable to various types of structural members (slabs, beams, columns, walls, foundation elements) and intervention methods (e.g., R/C jacketing, R/C infill walls). These reduction factors are used to obtain the strength and deformation indices of the jacketed members and are applied to the respective properties of monolithic members with identical geometry. The monolithicity factors are defined as follows:

$$K = \frac{\text{Response index of the composite member}}{\text{Response index of the monolithic member with identical geometry}} \quad (7)$$

The various monolithicity factors usually used in design are:

- The monolithicity factors that refer to the deformation capacity indices such as the chord rotations at yield and ultimate, which are defined as

$$\begin{aligned} \text{Chord rotation at yield : } K_{\theta_y} &= \frac{\theta_{y,J}}{\theta_{y,M}}; \\ \text{Chord rotation at ultimate : } K_{\theta_u} &= \frac{\theta_{u,J}}{\theta_{u,M}} \end{aligned} \quad (8)$$

- The strength related monolithicity factors

$$\begin{aligned} \text{Shear strength : } K_v &= \frac{V_{J,\max}}{V_{M,\max}}; \\ \text{Moment at yield : } K_{M_y} &= \frac{M_{y,J}}{M_{y,M}} \end{aligned} \quad (9)$$

- The stiffness monolithicity factor

$$\text{Stiffness at yield : } K_k = \frac{K_{y,J}}{K_{y,M}} \quad (10)$$

where the subscripts J and M correspond to the composite (jacketed) cross section and to the identical monolithic cross section, θ_y , θ_u are the chord rotations at yield and ultimate, $V_{\max}$ is the maximum strength of the cross section, M_y is the yield moment, and K_y is the secant flexural stiffness at yield, defined as the ratio of the yield moment (M_y) to the yield curvature (φ_y).

Eurocode 8, Part 3 (§A.4.2, 2005), and the Greek Code for Interventions (KANEPE 2013) suggest the monolithicity factors presented in Table 2 to be used in the design of R/C members (slabs, columns, beams, and foundation system) when strengthened with additional reinforced concrete layers. In the case of Eurocode 8, Part3 (§A.4.2, 2005), the values of the monolithicity factors for columns of Table 2 should be used under the assumptions of: (i) full composite

action between old and new concrete, (ii) application of full axial load to the jacketed member, and (iii) application of the concrete properties of the jacket over the full section of the element. It is noted that the monolithicity factors for the design approach as proposed by the Greek Code for Interventions (KANEPE 2013) are subject to certain limitations, i.e., that the target strength increase of the jacketed member should not exceed twice that of the original. On the other hand, considering the code minima regarding the percentage of longitudinal reinforcement of the jacket, but also of the entire composite cross section (equal to 1 %), and the pertinent detailing rules (minimum thickness of the jacket is 70 mm), it is seen that the strength of the strengthened member far exceeds twice its original strength. In the case of EC8-Part 3 (2005), there is no restriction related to the increase of resistance of the R/C member due to jacketing.

In case of R/C column jacketing, the sensitivity of the monolithicity factors to the construction materials of the existing cross section (core) and the jacket, as well as to the percentage of longitudinal reinforcement of the jacket for increasing axial load, has been highlighted by Thermou et al. (2007). The analytical model for R/C jacketed columns, which is presented in the last section of this article, was utilized by Thermou et al. (2007, 2014) for performing an extensive parametric study for the derivation of monolithicity factors. For the range of parameters considered in their study, the lower and upper limits for the monolithicity factors were found to be $K_{\theta_y} = 1.17 \sim 4.85$, $K_{\theta_u} = 0.45 \sim 4.13$, $K_{M_y} = 0.32 \sim 0.99$, $K_r = 0.35 \sim 1.02$ and $K_k = 0.19 \sim 0.95$. Lampropoulos et al. (2012) utilized a computational (finite element) model of experimental specimens, and for the specific range of parameters examined, the monolithicity factors received the following values: $K_{\theta_y} = 1.05 \sim 3.00$, $K_{\theta_u} = 0.95 \sim 2.85$, $K_r = 0.70 \sim 0.90$ and

Strengthened Structural Members and Structures: Analytical Assessment, Table 2 Suggested values of the monolithicity factors by EC8-Part 3 (2005) and KANEPE (2013)

Element type	K_i	K_v	K_{My}	K_k	$K_{\theta y}$	$K_{\theta u}$
Slab	KANEPE (2013)	0.95		0.85	1.15	0.85
Column	EC8-Part 3 (2005)	0.90	1.00	—	1.05 ^a	1.00
					1.20 ^b	
	KANEPE (2013)	0.90 ^c	—	0.80 ^c	1.25 ^c	0.75 ^c
Beam	KANEPE (2013)	0.85	—	0.80	1.25	0.75
Foundation	KANEPE (2013)	0.90		0.70	1.30	0.80

^aRoughening^bRest of measures or no measures^cRoughening and connection measures

$K_k = 0.25 \sim 0.75$. The comparison of the code suggested monolithicity factors to the experimental values for monolithicity factors revealed that there is large dispersion in the case of monolithicity factors $K_{\theta y}$, $K_{\theta u}$, and K_k (Thermou et al. 2014). This observation has to be further assessed by considering the limited range of parameters of the experimental database (Thermou et al. 2011) as well as the fact that deformation and stiffness values are difficult to measure experimentally and “ultimate” conditions are not defined in a uniform way in all tests (Thermou et al. 2014). The suggested values for the monolithicity factors to be used in EC8-Part 3 (2005) and KANEPE (2013) apply for the specific properties of the construction materials and level of applied axial load. These limits are defined by the experimental data as: (i) percentage of the longitudinal reinforcement of the existing cross section 0.81 ~ 2.01 %; (ii) percentage of the longitudinal reinforcement of the jacket 0.75–1.64 %; (iii) concrete compressive strength of the existing cross section 23–56 MPa; (iv) concrete compressive strength of the jacket 18–69 MPa; and (v) dimensionless axial load (with the assumption that it is applied to the jacketed cross section) 0–0.23.

Analytical Assessment of R/C Jacketed Columns

Reinforced concrete (R/C) jacketing is one of the most commonly applied methods for the rehabilitation of concrete members. Jacketing is

considered to be a global intervention method if longitudinal reinforcement placed in the jacket passes through holes drilled in the slab and new concrete is placed in the beam-column joint (Fig. 7). The main advantage of the R/C jacketing technique is the uniformly distributed lateral load capacity throughout the structure, thereby avoiding concentrations of lateral load resistance, which occur when only a few shear walls are added. A disadvantage of the method is the presence of beams which may require most of the new longitudinal bars in the jacket to be bundled into the corners of the jacket. Because of the presence of the existing column, it is difficult to provide cross-ties for the new longitudinal bars, which are not at the corners of the jacket.

The analytical model presented in section “Analytical Model for R/C Jacketed Columns” explicitly accounts for the slip at the interface between the existing member (core) and the jacket. The transfer of normal and shear stresses in the interface between the external layers of the jacket and the existing member determines the composite action developed by the strengthened members (Thermou et al. 2007). An alternative to this approach is presented in section “Simplified Analytical Expressions for R/C Jacketed Columns” where simplified analytical expressions in combination with the monolithicity factors may be used for designing the retrofit scheme.

Analytical Model for R/C Jacketed Columns

The proposed analytical model for predicting the flexural response of existing R/C members strengthened with concrete jacketing under

monotonic and cyclic loading conditions introduces a degree of freedom allowing the relative slip at the interface between the existing member and the jacket (Thermou et al. 2007). Slip along the member's length is attributed to the difference in normal strains at the contact interfaces (Fig. 8a). For flexural analysis, the cross section is divided into three layers which bend with the same curvature, φ (Fig. 8a). The two external layers represent the contribution of the jacket, whereas the internal one represents both the core (existing cross section) and the web of the jacket shell. Slip at the interface mobilizes the shear transfer mechanisms such as aggregate interlock, friction due to clamping action, and dowel action provided by the stirrup legs of the jacket and by the dowels placed at the interface between the core and the jacket in case that such a connection measure is taken (Fig. 8b).

According to the analytical model of Thermou et al. (2007) for R/C jacketed members, shear transfer at the interface between the existing member and the jacket takes place between half crack intervals along the length of the jacketed member, as commonly considered in bond analysis. At the initial stages of loading, cracks form only at the external layers (jacket) increasing in number with increasing load, up to crack stabilization. This occurs when the jacket steel stress at the crack, $\sigma_{s,cr}$, exceeds the limit (fib 2010)

$$\sigma_{s,cr} > f_{ctm,J} \frac{1 + \eta \rho_{s,eff}}{\rho_{s,eff}} \quad (11)$$

where $f_{ctm,J}$ is the tensile strength of concrete, $\eta(=E_s/E_c)$ is the modular ratio, and $\rho_{s,eff}$ is the effective reinforcement ratio defined as the total steel area divided by the area of mobilized

Strengthened Structural Members and Structures: Analytical Assessment, Fig. 9 (a) Free body equilibrium in the tension zone of the core of the composite section; (b) section equilibrium between adjacent cracks; (c) crack spacing

concrete in tension, usually taken as a circular domain with a radius of $2.5D_b$ around the bar (Model Code 2010). Using the same considerations in the combined section it may be shown that a number of the external cracks penetrate the second layer (core) of the jacketed member (Fig. 8a). The distance between those cracks, taken as c , is a key element of the proposed methodology (Fig. 9a).

After crack stabilization and assuming that the neutral axis depth is about constant in adjacent cross sections, from the free body equilibrium in the tension zone of the core of the composite section (Fig. 9a), the crack spacing is defined as follows (Thermou et al. 2007):

$$c = \frac{0.64 \cdot b_J l_c f_{ct,c}}{n_c D_{b,c} f_{b,c} + n_J D_{b,J} f_{b,J}} \quad (12)$$

where b_J is the width of the jacketed cross section, l_c is the height of the tension zone in the core of the composite cross section, $f_{ct,c}$ is the tensile strength of concrete core, n_c, n_J are the number of bars in the tension steel layer of the core and the jacket, respectively, $D_{b,c}, D_{b,J}$ are the bar diameter of the core and jacket longitudinal reinforcement, respectively, and $f_{b,c}$ and $f_{b,J}$ are the average bond stress of the core and the jacket reinforcement layer, respectively.

Shear stress demand at the interfaces, $\tau_{d,i}$, is determined by examining the cross section along the height and along a member length equal to the distance between successive cracks (Fig. 9b). The layer force resultant ΣF_i (sum of concrete and steel forces at each layer), for the externally

applied axial load, N_{ext} (considered to be applied to the jacketed section), is used to calculate the vertical shear stress demand in the member, $\tau_{d,i}$ (Fig. 9b). With the assumption that the shear flow, q , reversal takes place at length equal to $c/2$ (where c is the crack spacing), the average stress demand $\tau_{d,i}$ is equal to

$$\tau_{d,i} = \frac{\Sigma F_i}{0.5 c b_J} \quad (13)$$

where ΣF_i is the layer force resultant, b_J is the width of the jacketed cross section, and c is the crack spacing length.

Shear Transfer Mechanisms Under Monotonic and Cyclic Loading

The monotonic and cyclic behavior of interfaces is described by the constitutive model developed by Vassilopoulou and Tassios (2003) where the models of friction and dowel resistance of Tassios and Vintzileou (1987), Vintzileou and Tassios (1986, 1987) are adopted. The interface model accounts for the combined shear force resistance mobilized along interfaces due to sliding both under monotonic and cyclic imposed deformations. This model was further modified by Palieraki et al. (2012) and adopted by the current Greek Code for Interventions (2013) (see Fig. 6). In case of cyclic loading, additional modifications and extensions were applied (Thermou et al. 2012b).

Solution Algorithm

The objective of the calculation algorithm at each loading step was twofold: simultaneous

Strengthened Structural Members and Structures: Analytical Assessment,

Fig. 10 Comparison of moment–curvature response histories with the corresponding experimental ones (SS1 and SS3 specimens from Rodriguez and Park (1994), R and E from Vadoros and Dritsos (2008))

establishment of equilibrium between the shear stress capacity and demand at the interfaces for relative slip, s , and force equilibrium at the cross section. An iterative procedure was followed, and equilibrium is established until convergence is achieved. Due to the complexity of the proposed solution algorithm, a program was necessary to be developed where fiber analysis was considered. The analytical model was set up to predict moment–curvature response curves. More details can be found in Thermou et al. (2012b).

Comparison with Experimental Data

The validity of the proposed analytical model for predicting the flexural response of R/C jacketed members was examined by comparing: (i) for monotonic loading, the analytical lateral load versus lateral displacement curves along with the envelope experimental curves of the recorded lateral load versus lateral displacement hysteretic loops from various experimental studies (Thermou et al. 2007) (the monotonic moment–curvature response curves were derived according to the analytical model and then converted to force–displacement response curves). In Fig. 10, the experimental lateral load versus drift curves of a representative number of test specimens are compared to the corresponding analytical curves; (ii) For cyclic loading, the

moment–curvature histories derived by the analytical model with those for the specimens studied by Bousias et al. (2007). The decision to select this experimental study was based not only on its scope, but also on the fact that it provides detailed test results in terms of moment–curvature curves. The comparison between the experimental and the analytical moment–curvature histories for some of the specimens of Bousias et al. (2007) is presented in Fig. 11. It is observed that the analytical curves reasonably match the strength and stiffness level of the experimental curves at each loading step. When slip is taken into account, pinching is more pronounced in the analytical model, indicating less energy dissipation at each loading cycle, which is an indication of conservatism.

Simplified Analytical Expressions for R/C Jacketed Columns

The composite cross section is considered as monolithic, assuming that there is full connection in the interface between old and new concrete. The monolithic factors may be utilized to modify the response indices in order to indirectly account for the adverse effect of slip on the interface (see section “Simplified Design Approach: The Use of Monolithicity Factors”). A simplified model of a typical jacketed cross section of a

Strengthened Structural Members and Structures: Analytical Assessment, Fig. 11 Comparison of moment–curvature response histories with the

corresponding experimental ones for specimens QR/CR, QR/CD, QR/CRD, and QR/CW from Bousias et al. (2007)

column member is depicted in Fig. 12 (Thermou et al. 2012c). Dimensions of the initial section are b_c and h_c , whereas those of the section after jacketing are b_J , h_J . Compression zone depth c is expressed as a fraction of the depth of the jacketed section, $c = \xi_y^J \cdot d_J$. For calculations of yield moment and flexural stiffness, all reinforcement is considered to act at the location of the added (jacket) reinforcement. Note that according to Steiner's theorem, existing tension longitudinal reinforcement (equal to compression reinforcement, Fig. 12), given by the area ratio ρ_c , contributes to flexural stiffness of the jacketed section through the term $\rho_c b_c d_c (0.5h_c - d_c)^2$; thus, in order to maintain the same contribution in this calculation, the equivalent amount that is transferred to the location of jacket reinforcement

is $\rho_c b_c d_c (0.5h_c - d_c)^2 / (0.5h_J - d_J)^2$. Furthermore, any other existing web longitudinal reinforcement is neglected, as it is considered to have a small influence on post-jacketed flexural strength. Thus, the equivalent longitudinal tensile reinforcement ratio ρ_e , of the jacketed cross section (total reinforcement area divided by the total area of the jacketed member) is given by

$$\rho_e = \rho_J + \rho_c \frac{(0.5h_c - d_c)^2}{(0.5h_J - d_J)^2} \cdot \frac{b_c h_c}{b_J h_J} \quad (14)$$

where $\rho_c (=A_c/b_c h_c)$ and $\rho_J (=A_J/b_J h_J)$ are the tension longitudinal reinforcement ratios of the existing cross section (equal to compression reinforcement) and the jacket, respectively, h_c and h_J are the heights of the existing and jacketed cross

Strengthened Structural Members and Structures: Analytical Assessment, Fig. 12 Simplified model for R/C jacketed members (existing web longitudinal

reinforcement is neglected as it is considered to have a small influence on post-jacketed flexural strength)

sections, respectively, b_c and b_j are the widths of the existing and jacketed cross sections, respectively, and d_c and d_j are the depths of the existing and jacketed cross sections, respectively.

The j th member translational stiffness (secant to yield) is defined as

$$K_{y,j}^J = \frac{12E_c I_{y,j}^J}{h_{st}^3} = \frac{12M_{y,j}^J}{\varphi_{y,j}^J h_{st}^3} \quad (15)$$

The moment at yield, $M_{y,j}^J$, at the center of gravity of the simplified jacketed cross section is estimated equal to

$$M_{y,j}^J = \varphi_{y,j}^J b_j h_j^3 E_c [0.40 \rho_e (\xi_y (-1 - 0.25 \eta_c) + 1.15 \eta_c + 0.10) + 0.25 \xi_y^2 (1 - 0.66 \xi_y)] \quad (16)$$

Hence, the j th member translational stiffness is equal to

$$K_{y,j}^J = \frac{b_{j,j} h_{j,j}^3 E_c}{h_{st}^3} \left\{ 4.8 \rho_{e,j} [1.15 \cdot \eta_c - \xi_{y,j}^J] \cdot (1 + 0.25 \eta_c) + 0.1 \right\} + 3 \left(\xi_{y,j}^J \right)^2 (1 - 0.66 \xi_{y,j}^J) \quad (17)$$

where ρ_e is the equivalent longitudinal tensile reinforcement ratio, $\eta_c (= E_s/E_c)$ is the modular

ratio of steel and concrete, and $\xi_{y,j}^J$ is the normalized depth of compression zone of the R/C jacketed member.

Depending on the magnitude of the axial load ratio, $\nu_j = N_j/b_j h_j f_c'$, yielding may occur when either the tension steel reinforcement reaches yielding or the compressive concrete strain exceeds the limit of linear response in the compressive stress-strain envelope, estimated in the range of $\varepsilon_c = 1.8 \cdot f_c'/E_c$. From the basic cross-sectional equilibrium, the normalized depth of compression zone, $\xi_{y,j}^J$, associated with these two alternative definitions of phenomenological yielding is obtained from:

(a) Upon yielding of tension steel

$$\xi_{y,j}^J = - \left[(2\eta_c - 1) \rho_{e,j} + \frac{\nu_j f_c'}{E_c \varepsilon_{sy}} \right] + \left\{ \left[(2\eta_c - 1) \rho_{e,j} + \frac{\nu_j f_c'}{E_c \varepsilon_{sy}} \right]^2 + 2 \left[(1.10 \eta_c - 0.10) \rho_{e,j} + \frac{\nu_j f_c'}{E_c \varepsilon_{sy}} \right] \right\}^{0.5} \quad (18a)$$

where f_c' is the concrete compressive strength and ε_{sy} is the steel strain at yielding.

(b) At the onset of concrete strain nonlinearity, $\varepsilon_c = 1.8 \cdot f_c'/E_c$

$$\begin{aligned} \zeta_{y,j}^J = & - \left[(2\eta_c - 1)\rho_{e,j} + 0.55v_j \right] \\ & + \left\{ \left[(2\eta_c - 1)\rho_{e,j} + 0.55v_j \right]^2 + 2(1.10\eta_c)\rho_{e,j} \right\}^{0.5} \end{aligned} \quad (18b)$$

From the above, the secant to yield stiffness and the moment at yield may be calculated directly by utilizing Eqs. 15 and 16, respectively, after being multiplied by the adequate monolithicity factors according to Table 2.

Bridge; Damage; Design; Earthquakes; Rehabilitation; Repair; Retrofitting; Seismic; Strengthening

Introduction

The goal of seismic design is to prevent life-threatening damage and to allow moderate damage that can be repaired after an earthquake. From a life safety perspective, the most serious bridge damage occurs when the deck collapses, because of inadequate seat details, column failure, or cap beam-column joint failure. The collapse of the link span of the San Francisco-Oakland Bay Bridge during the 1989 Loma Prieta earthquake (Fig. 1a) was caused by failure of two bolted

connections under the span's supporting truss which led to its unseating (Buckle et al. 1990). The bridge failure of the Hanshin elevated expressway during the 1995 Great Hanshin Kobe earthquake (Fig. 1b) is attributed to column failure caused mainly by poor anchorage of the circular hoop ends which were lap spliced in the cover concrete (Park 1996) and inadequate amount and details of the longitudinal and transverse reinforcement (Anderson et al. 1996). This entry presents a summary of observed damage in past earthquakes and seismic strengthening techniques of existing bridges. The stages of evolution of bridge design in the USA from the 1970s including vulnerabilities and typical design details are outlined.

Seismic Bridge Design

The seismic design of bridges is separated into three periods, based on the State of California provisions (Caltrans 2006).

Pre-1971 Design

In this period, it was recognized that earthquakes generate forces proportional to the structure's dead weight. Until 1965, the maximum lateral seismic design force was 6 % of the structural dead weight. Vulnerabilities of bridges built during this period include: (a) column shear failure, (b) column longitudinal reinforcement pullout, and (c) unseating of expansion hinges. Typical design details of the period are 13 mm diameter column ties at 300 mm spacing (regardless of column or bar size), very short seat widths at expansion joints (150–200 mm), inadequate lap splices of column bars from the footing (20 bar diameters), inadequate development of column bars into the footing (20 bar diameters without standard hooks), and lap-spliced column ties in the cover concrete (absence of seismic hooks).

1971–1994 Design

After the 1971 San Fernando earthquake, the importance of ductility and detailing was recognized, and the concept of capacity design was

Strengthening Techniques: Bridges, Fig. 1 Bridge failure: (a) San Francisco-Oakland Bay Bridge (© California Department of Transportation (2003)

(CALTRANS)); (b) Hanshin elevated expressway (<https://www.fhwa.dot.gov/publications/publicroads/96fall/imgs/p96au18.jpg> (FHWA))

introduced in the design code. Vulnerabilities of bridges built during this period include: (a) column shear failure of plastic hinge regions, (b) shear failure of flared columns, and (c) unseating of expansion joint hinges. In retrofitted bridges, vulnerabilities were found at expansion joint hinge restrainers, particularly for skewed bridges. Typical details for this period include: closer spacing and improved column shear detailing (spacing 100–150 mm, but no confinement/anti-buckling requirement for plastic hinges), top reinforcement in footings and pile caps (but no shear reinforcement), column longitudinal splices were prohibited at maximum moment locations, short seat widths at expansion joints (300 mm), no cap beam-column joint reinforcement, and poor column flare details.

Post-1994 Design

After the 1994 Northridge earthquake, a capacity design philosophy was adopted that would ensure ductile flexural failure of the columns while all other bridge components remained elastic. Typical design details include: tight confinement reinforcement in plastic hinge regions (100 mm spacing), long seat widths at expansion joints (600 mm), improved flare column details (gap between top of flare and superstructure), no lap splices in plastic hinge zones, shear reinforcement in footings, and cap/column and footing/column joint reinforcement.

Damage to Bridges in Past Earthquakes

After an earthquake, lessons are learned which influence seismic strengthening of existing bridges as well as the development of new design codes. This section describes damage and its location as observed in bridges from past earthquakes (Caltrans 2006). Deck damage includes complete collapse of a span, as shown in Figs. 1a and 2a, b, or movement of the deck, as shown in Fig. 2c. Cap beam, cap beam-column joint, and girder shear damage are shown in Fig. 3. Damage to columns can be flexural as shown in Fig. 4 or shear damage as shown in Fig. 5; shear damage is brittle and frequently leads to collapse. Soil settlements can occur around columns, and gaps between columns and soil may become large as shown in Fig. 6. Abutment failures are also common, as shown in Fig. 7.

Bridge Seismic Strengthening

There is historic evidence which supports the assertion that seismic strengthening of bridges is effective. Damage in past earthquakes, such as the 1994 Northridge earthquake, has been reported from cable restrainers breaking through the hinge diaphragm; however, no bridge retrofitted after the 1989 Loma Prieta earthquake experienced any serious damage (Yashinsky 1998). Similarly, most of the observed structural

Strengthening Techniques: Bridges, Fig. 7 Abutment failures (© California Department of Transportation (2006))

damage in the 2011 Great East Japan earthquake has reportedly occurred in older bridges that had not yet been retrofitted after the 1995 Great Hanshin Kobe earthquake or only partially so (Marsh et al. 2011).

Several measures are used to strengthen bridges: restrainers, steel girder plate connections,

seat extenders, column strengthening, infill wall between columns, footing and abutment strengthening, and cap beam-column joint strengthening. In addition, retrofit measures such as seismic isolation reduce the demand imposed on a bridge system, and in this sense they improve its seismic performance significantly.

Strengthening Techniques: Bridges, Fig. 8 (a) Cable restrainer, (b) steel bar restrainer, (c) pipe seat extender, (d) bumper blocks

Restrainers/Expansion Joint Seat Width Extenders/Steel Plates/Bumper Blocks

Cable restrainers (Fig. 8a) and longitudinal steel bar restrainers (Fig. 8b) are used to prevent girders from falling off their supports (Yashinsky 1998). The typical cable restrainer is a galvanized 19 mm diameter steel cable with galvanized cold-swaged fittings and 25 mm diameter threaded studs at each end. Loss of support of the superstructure can be achieved using beam seat extenders, pipe seat extenders shown in Fig. 8c, steel plates used to connect two steel girders at expansion joints, and bumper blocks as shown in Fig. 8d (Pantelides et al. 2004).

Failure of restrainer cables has been observed in the 1989 Loma Prieta, 1994 Northridge, and 1995 Kobe earthquakes (FHWA 2006). Restrainers ruptured, anchorage plates pulled through concrete diaphragms, fittings pulled away from cables, and anchorage nuts worked loose from the ends of cable units. Restrainers alone may not be the best solution in many cases

because of the need to limit restrainer forces to protect other structural elements, while increasing restrainer forces to accomplish their intended purpose. Alternatives that should be considered when loss of support is a possibility include seat extensions, bearing strengthening, and replacement with conventional or isolation bearings.

Column Jacketing: RC/Steel/Fiber Reinforced Polymer (FRP)

Strengthening of concrete columns can be achieved by reinforced concrete (RC) jackets. This is an intrusive and time-consuming procedure, but in some cases it is necessary. However, the effect of strengthening a column using RC jackets should be examined carefully as this method will increase column flexural strength and stiffness more than a steel jacket, FRP composite jacket, or wire wrap, with potentially undesirable effects on bridge performance.

Steel jacketing of circular columns by circular steel jackets (Fig. 9a), and of rectangular columns by elliptical steel jackets, was found to be

Strengthening Techniques: Bridges, Fig. 9 Column jackets: (a) steel (Photo credit: Washington State Department of Transportation. [http://sdotblog.seattle.gov/2012/](http://sdotblog.seattle.gov/2012/06/21/fauntleroy-expressway-wearing-new-jackets/#sthash.nlxozUnm.dpbs)

[06/21/fauntleroy-expressway-wearing-new-jackets/#sthash.nlxozUnm.dpbs](http://sdotblog.seattle.gov/2012/06/21/fauntleroy-expressway-wearing-new-jackets/#sthash.nlxozUnm.dpbs)), (b) FRP square, (c) FRP circular

effective in enhancing shear strength and flexural ductility (Priestley et al. 1994). Encasing circular columns with a bonded steel jacket was found to inhibit bond failures in lap splices of longitudinal reinforcement in plastic hinge regions (Chai et al. 1991). Rectangular steel jackets are effective in enhancing the performance of shear critical columns. These jackets can improve column ductility by eliminating the brittle shear mode of failure, but it is important to recognize that the failure mode may then shift to a flexural one for which the rectangular jacket can provide only limited assistance.

Seible et al. (1997) used continuous FRP jackets for flexural hinge confinement of circular and rectangular columns, shear strengthening, and lap splice clamping. Full-scale tests (Fig. 9b) have shown that significant increases can be gained in the ductility of bridge column bents strengthened with FRP composites (Pantelides et al. 1999, 2007). FRP composites have been used widely for seismic strengthening of existing bridges (Priestley et al. 1996; Ogata and Osada 2000), as shown in Fig. 9c for the State

Street Bridge on I-80 in Salt Lake City, Utah (Pantelides et al. 2004).

The advantage of using FRP composites stems from their superior resistance to corrosion, high stiffness-to-weight ratio, high strength-to-weight ratio, and ability to control the material's behavior by selecting the proper fiber orientation. FRP composites must be protected against ultraviolet radiation; even though carbon fibers themselves are not affected by moisture, the quality of the epoxy matrix is critical in the performance of the composite. Carbon fiber systems have shown loss of tensile strength at high temperatures due to moisture absorption. Another consideration when using FRP systems is their high initial cost; however, they have a superior life-cycle cost as compared to steel because of their resistance to corrosion. In shear and flexural critical applications, bond of FRP composites to concrete is a critical parameter which must be considered in the design (ACI 440 2002); mechanical anchorage of FRP laminates to concrete has been used successfully to postpone debonding.

Another effective strengthening technique is to wrap prestressing wire under tension around a column (Hawkins et al. 1999). Rectangular steel columns have been strengthened with steel angles and circular steel columns with circular steel pipes (Nishikawa et al. 1998).

Infill Wall Strengthening

Infill shear walls are reinforced concrete walls cast in place between the columns of a multicolumn bent, as shown in Fig. 10. The reinforced concrete columns can have a circular or rectangular shape. They have been used successfully to increase transverse shear capacity. These walls prevent the formation of plastic hinges in the columns during transverse loading and help overcome deficiencies in the flexural or shear strength of the cap beam. To be effective, infill shear walls should be designed to act compositely with existing members. This is done by providing drilled and bonded dowels in the columns and the bottom of the cap beam, so that shear is transferred at the interfaces through a shear friction mechanism; this may require the existing concrete surfaces to be roughened. A footing should be provided under the infill wall which is tied into the existing column footings. There needs to be sufficient reinforcement to transfer all seismic forces, and the potential for differential settlement between the existing and new footings should be considered.

Foundation Strengthening

Footings that support columns may be structurally unable to resist the forces transmitted from those columns. This usually occurs when there is a lack of reinforcement in the top of the footing. A concrete overlay can be designed to provide increased negative moment capacity in the footing. Existing positive moment reinforcement is utilized along with the additional footing depth provided by the overlay to increase positive moment capacity. For isolated pile caps a grade or link beam is utilized to improve shear capacity, as shown in Fig. 11. In addition, longitudinal reinforcement in reinforced concrete piles may be terminated too close to the top of the pile, resulting in insufficient tensile capacity; in this

Strengthening Techniques: Bridges, Fig. 10 Pier strengthening using infill wall

case, it is desirable to add hold-down anchors or supplemental tension piles. An alternative is to drill holes into the piles from the top of the pile cap and epoxy high strength steel bars into the pile cap and piles (Pantelides et al. 2001); these vertical bars are shown in Fig. 11 (Pantelides et al. 2007).

Abutment Strengthening

Strengthening of seat-type abutments in the longitudinal and transverse directions can reduce forces on the piers. Anchor slabs are used to increase the ability of abutments to carry both longitudinal and transverse loads, and resist displacement in either direction, as shown in Fig. 12. Transverse abutment shear keys and anchors can reduce forces on the piers (FHWA 2006).

Cap Beam Joints: RC Bolsters/Posttensioning/Steel Jackets/FRP Jackets

Cap beam-column joints are subjected to large stresses and are vulnerable to damage in earthquakes transverse to the bridge. Existing cap beams and joints were not usually designed to behave in a ductile manner, so any strengthening measure must ensure that these elements are either capable of accommodating the ductility demands placed on them or are capable of elastically resisting the forces that will result from plastic hinging in the columns.

RC bolsters are used to improve flexural capacity, with or without prestressing. Another

a

Strengthening Techniques: Bridges, Fig. 11 Footing strengthening using grade beam and pile cap to pile steel bars

Strengthening Techniques: Bridges, Fig. 12 Abutment strengthening using anchor slab

strengthening method is to use external posttensioning as shown in Fig. 13a. Steel jackets bonded to the sides of the joint and anchored to the bent cap are also effective (Thewalt and Stojadinovic 1995). Finally, FRP jackets in the form of an ankle wrap have been tested (Gergely et al. 2000) and used to strengthen column to cap beam-column joints as shown in Fig. 13b (Pantelides et al. 2004). The nominal principal tensile stress developed in the beam-column joint is used to design the carbon FRP composite layers. When strengthening of these joints is required to improve the longitudinal response, transversely prestressed bolsters may be used.

Seismic Isolation: Elastomeric Bearings/ Friction Pendulum Bearings

Seismic isolation bearings can shift the natural frequency of the bridge away from the region of dominant earthquake energy; in addition, they increase damping and reduce and redistribute the earthquake-induced lateral forces to levels within the elastic capacities of the substructure and foundation (Mayes et al. 1994). An elastomeric bearing (Fig. 14a) consists of alternating layers of rubber and steel plates and often has a lead core to dissipate seismic energy. A friction pendulum bearing (Fig. 14b) consists of a stainless steel concave dish and articulated slider surfaced with a composite liner. During an earthquake, the slider moves back and forth on the concave dish; the spherical surfaces of the slider and the dish define a motion similar to that of a pendulum. A friction pendulum bearing isolates a bridge from an earthquake through pendulum motion and absorbs energy through friction.

Summary

The entry presents a number of methods for seismic strengthening of existing bridges. A brief review of seismic bridge design evolution and

Strengthening Techniques: Bridges, Fig. 13 Cap beam-column joint strengthening: (a) posttensioning (Photo Credit: VSL International Ltd. <http://vsl-sg.com/sps-images/4-004.jpg>), (b) FRP jacket

Strengthening Techniques: Bridges, Fig. 14 Bridge bearings: (a) elastomeric (Photo Credit Federal Highway Administration. <https://www.fhwa.dot.gov/publications/publicroads/99marapr/images/seismic3.gif>), (b) friction pendulum (Photo credit: Federal Highway Administration)

an overview of damage to structural elements of bridges have been presented. Strengthening techniques covered include restrainers, expansion joint seat width extenders, column jackets, footings, abutments, and cap beam-column joints. Retrofit measures such as seismic isolation reduce the demand imposed on a bridge system thus improving the seismic performance. Hinges and abutments are the two areas where retrofitted bridges continue to experience damage. The 1994 Northridge and 2011 Great East Japan earthquakes have shown that retrofitted bridges did not experience any serious damage. This clearly demonstrates that seismic strengthening of bridges is valuable and should be continued. A unique feature of earthquakes is that they often expose the weaknesses of a structural system. Despite the

progress made in designing new and strengthening existing bridges, it is likely that future earthquakes will expose additional vulnerabilities of existing and retrofitted bridges.

Epoxy grouting; Interfaces; Monolithicity coefficients; RC jacketing; Repair; Shrinkage; Strengthening

Introduction

Nowadays, many buildings need to be upgraded, especially in earthquake-prone areas, because of increased strength demands introduced by modern design codes or damage due to strong earthquakes. As a result, many techniques have been developed to improve the performance of the existing buildings. There is a wide range of applications of fiber-reinforced polymers (FRPs) in the form of rebars, plates, and sheets for the

strengthening of the existing buildings. These materials can be used for flexural and/or shear strengthening of existing structures, and a comprehensive description of this technique can be found in Essay 382,109 “Retrofitting and Strengthening of Contemporary Structures: Materials Used.”

In this entry, special emphasis is given on the technique of reinforced concrete (RC) jacketing. RC jacketing is a widespread technique used for the strengthening of existing columns, beams, and walls. The use of epoxy resins for the crack repair of damaged structural elements is also presented.

In earthquake-prone areas, the majority of the old buildings could be characterized as “code deficient,” and these buildings need to be upgraded.

“Code-deficient” buildings are the buildings that do not satisfy the requirements proposed by the new codes (Eurocode 8 2005; Code of Structural Interventions 2012; fib 2010). There are different factors responsible for structural deficiencies in existing buildings. The structural system of many old buildings was designed with configuration problems. Lack of regularity in geometry, in strength or stiffness, in plan, or in elevation are common characteristics of several existing buildings. Also, in the past, approximations and simplifications were adopted in carrying out structural analysis. Computers were not available, 3D analysis was not feasible, even 2D analysis was rarely used, and (continuous) beams and columns were considered as independent elements. Some critical requirements concerning the behavior of structures under earthquakes, such as ductility, capacity design, and detailing provisions (minimum amount of stirrups, lower limits for compressive strength, upper limit for tensile reinforcement), were also ignored. Also, in the past, the seismic actions used for the design of structures were much lower than the actions currently used for the design of new structures (Dritsos 2012).

As a consequence, the majority of existing buildings are deficient and in need of strengthening. Also, some of the old buildings are already damaged after previous strong earthquakes. The type of intervention that will be used for

strengthening deficient buildings depends on the level of damage and the requirements. In case of lightly damaged concrete elements, where there are no requirements for further upgrading of the structure, the technique of epoxy grouting is widely used. Epoxy grouting can be used to improve the performance and the durability of cracked reinforced concrete elements.

In case of heavily damaged structural elements or structures that need to be upgraded to conform with modern codes, seismic strengthening is required. There are a number of available techniques for the earthquake strengthening of existing buildings, such as jacketing of load-bearing elements, addition of infill walls or bracing systems, and installation of energy dissipation systems. For the jacketing of structural elements, steel, fiber-reinforced polymers (FRPs), and reinforced concrete can be used. The decision for the selection of the most suitable technique is not always easy and depends on a number of parameters such as cost, required time, and disruption of the occupants. Detailed descriptions of a number of different repair and strengthening techniques have been published by Tassios (2009) and Dritsos (2005).

In this entry, the technique of repair of damaged buildings with epoxy grouting and the strengthening with RC jackets are described in detail, and practical recommendations are presented. Special focus is given on the modeling and design of the jacketed elements. Critical parameters for the effectiveness of this technique are the bond between the old and new concrete elements and shrinkage of the new concrete. To take into account these two parameters, finite element method can be used. However, for the practical design of strengthened elements the use of monolithicity coefficients is proposed, which is a simplified procedure. Monolithicity coefficients are used to correlate the strength, stiffness, and deformation at yield and failure of strengthened columns to those of respective monolithic columns, the behavior of which can be determined by following conventional concrete design procedures. Monolithicity coefficients for jackets with different characteristics are presented at the end of this entry.

Strengthening Techniques:

Code-Deficient R/C Buildings, Fig. 1

(a) Preparation of cracks before the use of epoxy resin and (b) repaired columns. <http://www.episkeves.civil.upatras.gr>

Repairing Existing RC Structures Using Epoxy Resins and Bonded Mortar

Epoxy grouting is one of the most commonly used techniques for the repair of cracked structural elements. For the successful application of this technique, the surface of the damaged or cracked section needs to be properly prepared (Fig. 1a). Depending on the type of damage, different epoxy resin types and installation procedures can be used (Fig. 1b).

In this section, the technique of epoxy resin injection for crack sealing and the use of epoxy-bonded concrete replacement for the repair of damaged concrete are described.

Epoxy Resin Injection for Crack Sealing

The resin characteristics and the application methods used for the epoxy resin injection depend on the environmental and concrete temperature, the crack width, the thickness of the concrete member, and the extent of cracking.

Substrate Preparation

The first critical step for the successful application of this method is the preparation of the substrate. Any existing contaminants should be removed to

improve substrate conditions. All the existing coatings along the crack, at intervals of not less than the thickness of the concrete member or 10 cm (ETEP 2012), should be removed.

Port Installation

Entry ports (tube-like devices that provide for the successful transfer of the epoxy resin under pressure into the crack) together with “cap” crack sealing should be installed on the face of the crack to ensure containment of the epoxy as it will be injected under pressure into the crack (ACI 2003; Fig. 2). In case of crack penetration throughout a section, the use of cap seals on both sides of the crack elements is suggested (ACI 2003).

The distance of the ports depends on the opening at the face of the crack. The recommended port distance values proposed by ETEP (2012) are presented in Table 1.

Before the cap seal installation, the location of the widest portion of the crack should be marked. The material used for the seal cap should be carefully prepared with accurate batching of components and with a consistent application of the material over the crack. The use of 25 mm wide and 5 mm thick cap seals is proposed by ACI (2003).

Strengthening Techniques: Code-Deficient R/C Buildings,

Fig. 2 Installation of ports for crack sealing with epoxy resins

Strengthening Techniques: Code-Deficient R/C Buildings, Table 1 Recommended port spacing for different crack widths (ETEP 2012)

Crack width (mm)	Port spacing (mm)
0.3–0.5	100
0.5–1	100–135
1–2	135–170
2–3	170–200
3–10	200

Epoxy Resin Injection

Epoxy resins cure to form solids with high strength and relatively high modulus of elasticity. Epoxy resin used for crack injection should be a 100 % solid resin that meets the requirements of specification ASTM C-881 (2010) for type I or IV, grade 1 (low viscosity), class B or C (depending on the ambient temperature). If the purpose of injection is to restore concrete to its original load-bearing capacity, a type IV epoxy should be used. If full restoration of load-bearing capacity is not envisaged, a type I epoxy is sufficient. No solvents or nonreactive diluents are permitted in the resin (USBR 1997). Class B epoxy is used between 4 °C and 16 °C, while class C is used above 16 °C (ASTM C-881 2010).

The injection should start from the bottom in the case of vertical cracks, while for horizontal cracks the starting point should be the widest crack section. The injection should continue until refusal or bleeding of the adjacent port (ACI 2003; ETEP 2012).

Strengthening Techniques: Code-Deficient R/C Buildings, Table 2 Recommended resin viscosity and injection pressure values for different crack widths (ETEP 2012)

Crack width (mm)	Dynamic viscosity of the resin (cps)	Required injection pressure (MPa)
0.3–0.5	1,000	—
	500	0.8
	250	0.4
	130	0.2
0.5–1	1,000	0.8
	500	0.4
	250	0.2
1–2	1,000	0.4
	500	0.2
	250	0.1
2–3	1,000	0.3
	500	0.1
	250	0.005

The injection pressure and the dynamic viscosity of the resin depend on the crack width. In Table 2, the recommended values proposed by ETEP (2012) are presented.

Upon completion of the resin injection, the ports and the cap seals will be removed by heat chipping or grinding (ACI 2003).

Quality Control

The first check should be done by hand 48 h after the injection, to check if the coagulation

(polymerization) of the epoxy resin has been completed.

Then, an additional check is required to ensure that the crack is filled with the resin. Cores should be taken with a diameter of 25–50 mm and depth equal to the thickness of the cracked element and at least equal to 15 cm (ETEP 2012). At least one core is required for 30 m crack length, and the core will be visually inspected to check if the crack is filled to the appropriate level with resin. The cores can also be tested for compressive and tensile loading following ASTM C42 (1999) and (ACI 2003). The removed core should be patched with a non-shrink or expansive cementitious or epoxy grout (ETEP 2012; ACI 2003).

The use of an endoscope is also recommended for quality control. In this method, holes with a diameter 2 mm larger than the diameter of the tube of the endoscope should be drilled, to a depth equal to the thickness of the cracked element and at least 15 cm. At least two points (in two different crack segments) for every 30 m of crack injected (total length of the injected crack segments) should be inspected. There are also non-destructive methods suggested for the inspection of the repaired elements. Use of the ultrasonic pulse velocity method is also an option (ETEP 2012; ACI 2003). At least three measurements should be taken (in three different crack segments) for every 30 m of crack injected (total length of the injected crack segments) (ETEP 2012).

Epoxy-Bonded Mortar or Concrete for Concrete Repair

Epoxy-bonded mortar or concrete is used for repairs involving shallow replacement of concrete. Epoxy-bonded mortar is used for depth of replacement less than 40 mm, while epoxy-bonded concrete is used in depths between 40 and 140 mm (USBR 1997). Shallow concrete replacements are subject to poor curing conditions as a result of moisture loss to evaporation and to capillary absorption by the existing concrete element with subsequent poor bond to the existing structure. The use of epoxy-bonded mortar or concrete can be used to ensure adequate bond between the old and the new material

(USBR 1997). The surface preparation of the old concrete and the materials used for the repair are critical parameters for the effectiveness of the technique.

Old Concrete Preparation

The first step for the old concrete preparation is to saw cut the perimeter of the damaged area to a depth of 25–40 mm in order to provide a retaining boundary for the compaction and consolidation of the repair material. Then, the deteriorated concrete needs to be removed to create a sound substrate for the bonding of the new repair material (USBR 1997). There are several techniques for the damaged concrete removal such as the use of high-pressure hydroblasting, jackhammer, shotblasting, and dry or wet sandblasting (USBR 1997).

Materials Used for Epoxy-Bonded Repair

The epoxy resin used for epoxy-bonded mortar repairs (less than 40 mm depth) should be two component, 100 % solid type, meeting the requirements of specification ASTM C-881 (2010) for type III, grade 2 (medium viscosity), class B or C (depending on the ambient temperature).

The material used in this technique is conventional concrete and epoxy resin bonding agent. The concrete should be the same as the old concrete but with consistency (slump value) within 40 mm. The resin should be of two components, 100 % solid type, meeting the requirements of specification ASTM C-881 (2010) for type II or type V, class B or C (depending on the ambient temperature). Type II can be used for use in non-load-bearing applications to bond fresh to hardened concrete, while for load-bearing applications, type V should be used (ASTM C-881 2010).

Strengthening Using Additional Layers/Jackets

This technique involves casting of an additional reinforced concrete element in connection to the existing load-bearing elements and is extensively used to upgrade existing buildings (Fig. 3).

Strengthening Techniques: Code-Deficient R/C Buildings,

Fig. 3 Jacketing of existing column and wall. <http://www.episkeves.civil.upatras.gr>

Two crucial issues for the effectiveness of this technique are the interface between the old and the new concrete and shrinkage of the new concrete layer or jacket (Lampropoulos and Dritsos 2011). Concrete shrinkage induces an initial slip at the interface which in some cases can be high enough and even lead to debonding (Beushausen and Alexander 2006, 2007). Also, tensile stresses are developed at the new concrete, which may lead to a reduced concrete compressive strength due to biaxial stress state (Lampropoulos and Dritsos 2010, 2011; Lampropoulos et al. 2012a). Practical recommendations for the strengthening of the additional elements using additional layers or jackets are presented in section “[Interface Preparation](#)”, while in section “[Analysis and Design of Strengthened Elements](#)”, analysis and design methods for strengthened/composite specimens are presented.

Practical Recommendations for Jacketing Procedure

Interface Preparation

In order to guarantee a sufficient connection between contact surfaces, the shear force acting at the interface should be lower than, or equal to, the shear resistance.

Four mechanisms contribute to the shear resistance at the interface: concrete-to-concrete adhesion, concrete-to-concrete friction (Fig. 4a), the connecting action from either steel bars placed across the interface between the old and the new concrete (Fig. 4b), and bent-down bars welded between the bars of the old and the new concrete (Fig. 4c; Dritsos 2007). These four mechanisms can be subdivided into the two groups of unreinforced and reinforced interfaces, depending on whether or not additional steel is placed across the interface or welded between the bars of the old and the new concrete (Dritsos 2007).

The roughening of the interfaces is crucial for the performance of the strengthened specimens especially in case of unreinforced interfaces. The roughening of the surface of the existing elements can be achieved using jet with water and sand mixture or light air equipment or electric needle (Code of Structural Interventions 2012). In Fig. 5, the use of air chipping hammer for roughening the surface of a beam is presented.

There are two main techniques currently used to characterize the interface roughness. The one of the two is a qualitative approach, wherein the surface of the existing elements is compared to standard surface samples with different roughness

**Strengthening
Techniques:
Code-Deficient R/C
Buildings,**

Fig. 4 Friction, steel bars across the interface, and bent-down bars used in concrete-to-concrete interfaces

Strengthening Techniques: Code-Deficient R/C Buildings, Fig. 5 (a) Roughening procedure and (b) roughened surface

grades. The second one, which is a quantitative approach, is the sand patch test. This method consists in uniformly spreading a standard volume of sand (V) and then measuring the diameter (D) of the covered area from which the roughness is calculated ($=4 V/\pi D^2$). This method presents the advantage of being inexpensive and easy to

perform, both in place and in laboratory, and as all interfaces are horizontal top surfaces, it is easy to be applied (ASTM E965 2003; Santos and Júlio 2010, 2013).

Based on the roughness value, the surface can be classified as very smooth when the roughness is not measurable, smooth when the roughness is

**Strengthening
Techniques:
Code-Deficient R/C
Buildings,**

Fig. 6 Construction detail of a typical jacketed column (Tassios 2009)

lower than 1.5 mm, rough when the roughness is higher than 1.5 mm, and very rough when the roughness is higher than 3 mm (Santos and Júlio 2013; fib 2010).

Apart from the two techniques presented above, there are other “relatively new” techniques used to determine the roughness of the interface (i.e., outflow meter, mechanical stylus, circular texture meter, digital surface roughness meter, microscopy, ultrasonic, slit-island method, roughness gradient method, photogrammetric method, shadow profilometry, air leakage method, processing of the digital image (PDI) method, two-dimensional laser roughness analyzer (2D-LRA) method, and three-dimensional laser scanning method). Most of these methods are based on optical techniques, and their main benefits are the improved accuracy and the fact that they are not destructive methods and can be applied both in the laboratory and in situ (Santos and Júlio 2010).

**Casting of New Concrete and Reinforcement
Details**

For the casting of new concrete, small aggregate size of about 2 mm is normally used because of the lack of space in the jacket or the additional

layer, while use of non-shrinkage concrete is also recommended (Júlio et al. 2003).

The anchorage of the added longitudinal reinforcement to the existing element is essential to prevent debonding. In case of jacketed columns, continuity between floors is recommended (Júlio et al. 2003). However, it is not always feasible to continue a jacket to the other floors. In such cases, or in order to minimize occupant disturbance, the following construction details are required (Fig. 6) (Tassios 2009):

- (i) Filling of the gap between the jacket and the slab with epoxy resin injection to ensure effective compressive load transfer. The epoxy resin should be injected at least one month after the casting of the jacket.
- (ii) The longitudinal bars of the jacket should be anchored to the slab with double bolts to ensure tensile load transfer.
- (iii) Welding of at least one bent-down bar with each reinforcing bar of the initial column.

In case of “open” jackets, where the jacket cannot be cast on all four sides of the column, special provisions are required to prevent debonding. In three-sided jackets, epoxy grout

Strengthening Techniques:**Code-Deficient R/C**

Buildings, Fig. 7 Typical shear stress-slip model for roughened interface and for interface with dowels

should be used to integrate the stirrups of the jacket into the initial column. In case of strengthening with additional layers only on one or two sides, the connection of the new with the old reinforcement using bent-down bars is essential (Dritsos 2005).

Analysis and Design of Strengthened Elements

To take into account the effect of the interface and concrete shrinkage, finite element analyses can be conducted (Lampropoulos and Dritsos 2011). However, in practice, it is not feasible to perform sophisticated finite element analyses and take into account all these parameters, so the use of monolithicity coefficients is proposed by the codes (Eurocode 8 2005; Code of Structural Interventions 2012). Monolithicity coefficients correlate the characteristics of the strengthened members to those of the respective monolithic ones. This procedure is quite old; however, most of the proposed monolithicity coefficients are empirical, and single values are proposed without accounting for the different values of the normalized axial load, the thickness of the jacket, and the shrinkage of the new concrete parameters that considerably affect the response of the strengthened specimens (Lampropoulos et al. 2012b). In the literature, there are studies (Dritsos 2007; Thermou et al. 2007; Thermou et al. 2014) where monolithicity coefficients values are proposed, and the effect of jacket concrete shrinkage has been ignored. It must be stated that the restrained shrinkage of the jacket concrete significantly influences the response of strengthened columns and cannot be overlooked (Lampropoulos and Dritsos 2010; Lampropoulos

et al. 2012a). Detailed investigations have recently been published where monolithicity coefficient values have been calculated for different values of the normalized axial load and jacket thicknesses (Lampropoulos et al. 2012b; Thermou et al. 2014). The effect of jacket's restraint shrinkage has also been studied (Lampropoulos et al. 2012b), and it has been shown that in some of the examined cases, the "code"-proposed values are not conservative. In the following section (section "Concrete-to-Concrete Interface"), different models for the shear stress calculation at the interface are presented. The proposed method for modeling concrete shrinkage effects is presented in section "Concrete Shrinkage Effect".

Concrete-to-Concrete Interface

There are a number of available models for the calculation of the interface strength between old and new concrete. In most of these models, the shear stress at the interface between the old and new concrete is related to the slip at the interface (Tassios 1986; Tassios and Vintzileou 1987; CEB-FIP 1993; Code of Structural Interventions 2012). In these studies, concrete-to-concrete interfaces with different roughening grades were examined. A typical shear stress-slip model for roughened interfaces with and without steel dowels is presented in Fig. 7.

For the shear resistance due to cohesion, the following model is proposed by CEB-FIP (1993) and Code of Structural Interventions (2012). The distribution of the shear stress with the slip at the interface is considered linear until the limit value for the shear resistance (τ_{fud}) which is the shear stress value for slip equal to 0.01-0.02 mm.

After that point, shear resistance is considered to be constant and equal to the limit value (τ_{fud}). The τ_{fud} value depends on the interface type Eq. 1.

$$\tau_{fud} = \begin{cases} 0.25 \cdot f_{ct}, & \text{smooth interface} \\ 0.75 \cdot f_{ct}, & \text{rough interface} \\ f_{ct}, & \text{shotcreting} \end{cases} \quad (1)$$

where:

τ_{fud} is the shear resistance at the interface,
 f_{ct} is the concrete tensile strength.

The shear stress-slip distribution is presented in Fig. 8.

In case of smooth interfaces, there are also similar models for the shear stress distribution due to friction (Tassios and Vintzileou 1987; CEB-FIP 1993; Code of Structural Interventions 2012; Fig. 9).

According to this model, the shear stress distribution is linearly increasing up to the point of its limit value, while after that point the stress remains constant. The maximum shear stress point is calculated using Eq. 2.

$$\tau_{fud} = 0.4 \cdot \sigma_c, \quad s_{fu} = 0.15 \cdot \sqrt{\sigma_c} \quad (2)$$

where

s_{fu} is the slip at maximum shear strength (τ_{fud}) and σ_c is the design compressive strength at the interface.

Various models have also been proposed for roughened interfaces. The first model for roughened interfaces is presented in Fig. 10 (Tassios 1986; CEB-FIP 1993).

According to this model, the shear strength of roughened interfaces is linearly increasing up to a slip equal to 0.1 mm. At this point, the shear stress is equal to half of its maximum value. For slip values higher than 0.1 mm and lower than 2.0 mm, the shear resistance can be derived using Eq. 3.

$$\left(\frac{\tau_f}{\tau_{fud}} \right)^4 - 0.5 \cdot \left(\frac{\tau_f}{\tau_{fud}} \right)^3 = 0.3 \cdot s - 0.03$$

where $\tau_{fud} = 0.4 \cdot (f_c^2 \cdot \sigma_c)^{1/3}$

(3)

Strengthening Techniques: Code-Deficient R/C Buildings, Fig. 8 Shear stress-slip model for concrete-to-concrete interfaces due to cohesion (CEB-FIP 1993; Code of Structural Interventions 2012)

A similar model is presented in the Code of Structural Interventions (2012), where the shear stress distribution with the slip is defined using two different equations, before and after half of the maximum slip value Eq. 4 (Fig. 11):

$$\begin{aligned} \frac{s}{s_{fu}} \leq 0.5 &\rightarrow \frac{\tau_f}{\tau_{fud}} \\ &= 1.14 \cdot \sqrt[3]{\frac{s}{s_{fu}}}, \quad \frac{s}{s_{fu}} > 0.5 \rightarrow \frac{\tau_f}{\tau_{fud}} \\ &= 0.81 + 0.19 \frac{s}{s_{fu}} \quad \text{where} \quad \tau_{fud} = 0.4 \cdot (f_c^2 \cdot \sigma_c)^{1/3} \end{aligned} \quad (4)$$

The recommended maximum shear stress at the interface (τ_{fud}) proposed by Model Code 2010 (fib 2010) is in the range of 1.5–2.5 MPa for strengthened interfaces with sandblasting, while for a well-roughened interface with high-pressure hydroblasting, the maximum shear stress is in the range of 2.5–3.5 MPa. These values are valid for concrete with strength lower than C50/60.

Values for the coefficients of friction and cohesion at the interface of strengthened elements have also been proposed. The suggested values according to CEB (1983), together with the coefficient of friction values proposed by Eurocode 2 (1996) and Model Code 2010 (fib 2010) are presented in Table 3.

From the values of Table 3, it can be observed that the design values for the coefficient of friction proposed by Eurocode 2 (1996) are lower for

Strengthening Techniques:

Code-Deficient R/C Buildings, Fig. 9 Shear stress-slip models due to friction for smooth interfaces (Tassios and Vintzileou 1987; CEB-FIP 1993; Code of Structural Interventions 2012)

Strengthening Techniques:

Code-Deficient R/C Buildings, Fig. 10 Shear stress-slip distribution due to friction for roughened interfaces (Tassios 1986; CEB-FIP 1993)

Strengthening Techniques:

Code-Deficient R/C Buildings, Fig. 11 Shear stress-slip distribution due to friction in roughened interfaces (Code of Structural Interventions 2012)

well-roughened interfaces compared to the values proposed by CEB Bulletin No. 162 (CEB 1983) and Model Code 2010 (fib 2010). The coefficient of friction values proposed by Model Code 2010 (fib 2010) are close to the values proposed by CEB (1983).

In the study of Tassios and Vintzileou (1987) and in the Code of Structural Interventions (2012), an analytical relationship for the calculation of coefficients of friction for different

values of the normal to the interface stresses is proposed (Eq. 5).

$$\mu = 0.44 * \left(\frac{\sigma_c}{f_c} \right)^{-2/3} \quad (5)$$

Another investigation has been conducted for dowel-reinforced interfaces, and models for the distribution of the shear stress with the friction

Strengthening Techniques: Code-Deficient R/C Buildings, Table 3 Coefficient of friction and cohesion values for strengthened elements with various roughening levels (CEB 1983; Eurocode 2 1996; fib 2010)

	CEB Bulletin No. 162 (1983)		Eurocode 2 (1996)	Model code 2010 (fib 2010)
	Coefficient of friction	Cohesion (MPa)	Coefficient of friction	Coefficient of friction
Well-roughened interface	1.5	1.9	0.9	1–1.4

Very smooth interface	–	–	0.5	–

Strengthening Techniques: Code-Deficient R/C Buildings, Fig. 12 Shear stress-slip relationship for dowel action (Vintzileou and Tassios 1986)

have been proposed (Vintzileou and Tassios 1986; CEB-FIP 1993; Code of Structural Interventions 2012). In the model proposed by Vintzileou and Tassios (1986), the variation of

the shear stress with the slip is defined by two relationships, depending on the slip values (Eq. 6):

$$\frac{V}{V_u} = \left(200 * \sqrt{\frac{f_c}{f_{sy}}} \right) * \frac{s}{d_b} \quad \text{for } s \leq 0.14 \text{ mm, and } \frac{V}{V_u} = \frac{4}{3} * \sqrt{\frac{s}{d_b}} \quad \text{for } s > 0.14 \text{ mm} \quad (6)$$

where $V_u = 1.3 * d_b^2 * \sqrt{f_c * f_{sy}}$

where:

V	is the shear stress (N),
V _u	is the shear strength (N),
f _{sy}	is the yield stress of steel (MPa), and
d _b	is the diameter of the dowels (mm).

This model is presented in Fig. 12.

A similar bilinear model has been proposed by CEB (1983). The equation for the initial branch

($s \leq 0.14$ mm) is similar to Eq. 6 with the only difference that a coefficient equal to 250 is proposed instead of 200. After the initial elastic branch, there is a second linear one up to the maximum shear resistance.

A different model has been presented in CEB-FIP (1993). According to this model, the shear resistance due to dowel action linear increases up to half of the maximum shear stress.

At this point, the slip equals to 0.05 of the maximum slip and after this point Eq. 7 is used. The

shear stress-slip distribution is presented in Fig. 13.

$$\frac{s}{s_u} = 1.7 \cdot \left(\left[\frac{V}{V_u} \right]^4 - 0.5 \times \left[\frac{V}{V_u} \right]^3 \right) + 0.05 \quad \text{for} \quad 0.05 \leq \frac{s}{s_u} \leq 1 \quad \text{where} \quad s_u = 2.0 \text{ mm} \quad (7)$$

$$V_u = \frac{1.30}{\gamma_{Rd}} \cdot d_b^2 \cdot \left[\sqrt{1 + (1.3 \cdot \varepsilon)^2} - 1.3 \cdot \varepsilon \right] \cdot \sqrt{f_{cd} \cdot f_{yd} \cdot (1 - \zeta^2)} < A_s \cdot f_{yd} / \sqrt{3}$$

where

γ_{Rd}	is considered equal to 1.30,
A_s	is the dowel cross section, and
e	is the load eccentricity.

In the model proposed by the Code of Structural Interventions (2012), the maximum shear strength value is calculated using the same equation proposed by CEB-FIP (1993). The variation of the shear stress with the slip is considered linear for slip equal or lower than 0.005 dB. For any value between 0.005 and 0.05 dB, the shear stress value is calculated using Eq. 8. This model is presented in Fig. 14.

$$s = 0.1 \cdot d_u + 1.80 \cdot d_u \cdot \left(\left[\frac{V}{V_u} \right]^4 - 0.5 \cdot \left[\frac{V}{V_u} \right]^3 \right)$$

$$d_u = 0.05 \cdot d_b \quad (8)$$

The model for the dowel action proposed by Model Code 2010 (fib 2010) is given by Eq. 9

$$V_u = k \cdot A_s \cdot \sqrt{f_{cd} \cdot f_{yd}} \left(\frac{s}{s_u} \right)^{0.5}, \quad (9)$$

$$s_u = 0.1 - 0.2 \cdot d_b$$

where $k \sim 1.6$ for circular reinforcement cross section and concrete strength equal to or lower than C50/60.

There are also models for the reduction of shear stress due to cyclic loading in roughened interfaces and for dowel action (Vintzileou and Tassios 1986, 1987; Tassios and Vintzileou 1987; Code of Structural Interventions 2012). According to these models, there is a shear stress

reduction after each loading cycle. Characteristic diagrams of the shear stress distribution with the slip under cyclic loading are presented in Fig. 15 (Vintzileou and Tassios 1986, 1987; Tassios and Vintzileou 1987).

The first model for the calculation of the reduced shear stress due to cyclic loading is the one proposed by Tassios and Vintzileou (1987) (Eq. 10)

$$\tau_{f,n} = \tau_{f,1} \cdot \left(1 - [0.002 \cdot (n-1) \cdot (s/s_{fu}) / (\sigma_{cn}/f_c)]^{1/3} \right) \quad (10)$$

where

$\tau_{f,n}$	is the shear stress at the interface in the n^{th} loading cycle,
$\tau_{f,1}$	is the shear stress at the interface in the first loading cycle,
N	is the number of cycles, and
σ_{cn}	is the normal to the interface stress in the n^{th} loading cycle.

In the Code of Structural Interventions (2012), two models have been presented for the shear stress reduction in smooth (Eq. 11) and roughened interfaces (Eq. 12).

Smooth interfaces:

$$\tau_{f,n} = \tau_{f,1} \cdot \left(1 - 0.15 \cdot \sqrt{(n-1)} \right) \quad (11)$$

Roughened interfaces:

$$\frac{\Delta \tau_{f,n}}{\tau_{f,1}} = 0.05 \cdot \left(\frac{f_c}{\sigma_{cn}} \right)^{1/2} \cdot (n-1)^{1/2} \cdot \left(\frac{s}{s_{fu}} \right)^{1/3} \quad (12)$$

Strengthening Techniques: Code-Deficient R/C Buildings, Fig. 13 Shear stress-slip relationship for dowel action (CEB-FIP 1993)

Strengthening Techniques: Code-Deficient R/C Buildings, Fig. 14 Shear stress-slip relationship for dowel action (Code of Structural Interventions 2012)

The following model has been proposed by Vintzileou and Tassios (1986) and Vintzileou and Tassios (1987) for dowel action under cyclic loading (Eq. 13)

$$D_n = D_1 * \left(1 - \frac{1}{7} * \sqrt{(n - 1)}\right) \tag{13}$$

where

D_n	is the maximum shear stress due to dowel action in the n^{th} loading cycle,
D_1	is the maximum shear stress due to dowel action in the 1 st loading cycle.

Concrete Shrinkage Effect

Concrete shrinkage can considerably affect the performance of strengthened elements with additional layers or jackets. Tensile stresses are induced to the new concrete of the layer or jacket while there is also an induced slip at the interface between the old and the new concrete. Denarie and Silfwerbrand (2004) presented a model where the tensile stresses of the new concrete due to restrained concrete shrinkage are proportional to coefficient “R.” Coefficient “R” is characteristic of the connection between the old and the new concrete and the degree of restraint (Eq. 14).

$$\sigma = E * \epsilon_{fsh} * R \tag{14}$$

where

E:	modulus of elasticity of concrete,
ϵ_{fsh} :	free shrinkage strain, and
R:	degree of restraint.

Values for the coefficient R have been proposed by Abbasnia et al. (2005) based on experimental investigations. The risk of debonding and cracking of the new layer of strengthened beams was investigated by Beushausen and Alexander (2006, 2007) where the tensile stress relaxation due to concrete creep was also taken into consideration.

The biaxial stress state in strengthened elements due to the development of restrained shrinkage tensile stresses was numerically investigated, and the importance of the restrained concrete shrinkage in case of jacketed columns was highlighted (Lampropoulos and Dritsos 2010, 2011). An extensive experimental study was also conducted to validate the reliability of the numerical results (Lampropoulos et al. 2012a). In this study, specimens with and without steel plates (with expanded polystyrene) were cast, to simulate the concrete of the jacket under restrained and free shrinkage, respectively. Specimens were stored until testing in a room with a constant temperature and relative humidity, and shrinkage strain at the end of the specimens was measured using micrometer dial

Strengthening Techniques: Code-Deficient R/C Buildings, Fig. 15 Characteristic shear stress-slip diagrams for friction and dowel shear stress due to cyclic loading

Strengthening Techniques: Code-Deficient R/C Buildings,

Fig. 16 Specimens with and without steel plates and strain measuring setup

gauges. The specimens together with the setup for the shrinkage strain measurements are presented in Fig. 16.

Each pair of specimens (with steel plates or expanded polystyrene cast from the same batch of concrete) was tested in compression at a different age, to obtain results for different values of the shrinkage strain. The specimens with restrained and free concrete shrinkage were tested under compression (Fig. 17a). The ratio of the tensile stress to the tensile strength together with the respective reduction of the concrete strength was calculated. It was found that there is a significant reduction of concrete strength due to restrained concrete shrinkage and the subsequent biaxial stress state, and this is in agreement with the model proposed by Kupfer et al. (1969) (Fig. 17b).

In the tested square prism specimens, the reduction of the concrete strength was found to range from 20 % to 30 %. This reduction was more significant for larger values of tensile stresses caused by the restrained concrete shrinkage (Lampropoulos et al. 2012a).

Modeling of Strengthened Elements and Monolithicity Coefficients for the Design of Strengthened Elements

Finite Element Modeling

For modeling the strengthened elements, the finite element method has been used. Different assumptions have been examined, and the accuracy of the numerical models was validated using experimental data (Lampropoulos and Dritsos 2011).

Strengthening Techniques: Code-Deficient R/C Buildings, Fig. 17 (a) Compressive test setup and (b) Biaxial stress state due to restrained concrete shrinkage (Lampropoulos et al. 2012a)

Interface Between the Old and the New Concrete The interface between the old and the new concrete can be simulated using spring elements or using special contact elements. To determine the characteristics of the interface, the models presented in section “Concrete-to-Concrete Interface” can be used. Strength deterioration due to cyclic loading should also be taken into account (Lampropoulos and Dritsos 2011).

Concrete Shrinkage Concrete shrinkage effect can be simulated by applying volumetric strain to the elements of the jacket. The effect of concrete creep should also be included to take into account the tensile stress relaxation. In a previous study (Lampropoulos and Dritsos 2010), in order to include creep effects, application of a volumetric strain equal to half of the free concrete shrinkage strain was proposed.

Monolithicity Coefficients

The accuracy of the numerical models was validated using a number of different experimental data. The same assumptions were used in a parametric study where columns with different characteristics were examined (Lampropoulos et al. 2012b). Analyses were performed for the strengthened and the respective monolithic specimens (Fig. 18), and monolithicity coefficients were calculated using Eq. 15. Monolithic specimens are specimens with exactly the same characteristics as the examined strengthened

columns, with the only difference that there is full connection (no slip) between the original column and the jacket, and concrete shrinkage is neglected.

The load and the deflection at the points of yield, maximum load, and failure of the specimens were estimated, and Eq. 15 was used to calculate monolithicity coefficient values.

$$K_F = \frac{[F_{\max}]_{STR}}{[F_{\max}]_{MON}}, \quad K_k = \frac{\left[\frac{F_y}{\delta_y}\right]_{STR}}{\left[\frac{F_y}{\delta_y}\right]_{MON}}, \quad (15)$$

$$K_{\delta, \theta_y} = \frac{[\delta_y]_{STR}}{[\delta_y]_{MO}}, \quad K_{\delta, \theta_u} = \frac{[\delta_u]_{STR}}{[\delta_u]_{MO}}$$

where K_F , K_k , and $K_{\delta, \theta_y, u}$ are monolithicity coefficients for the strength, stiffness, and deflection or rotation angle at yield and failure, respectively, F_y and $F_{\max}$ are the yield and maximum load, and δ_y , δ_u are the deflections at yield and failure. Subscripts *STR* and *MON* indicate strengthened and monolithic specimens, respectively.

The proposed design values are based on the assumption of concrete with free shrinkage strain of 800 microstrains. A roughened interface was assumed without any other connection technique (bent-down bars or dowels) which is a conservative assumption. Different values have been proposed depending on the normalized axial load (v) and the ratio of the concrete cross-sectional area of the jacket (A_{cj}) to the cross-sectional area of

Strengthening Techniques: Code-Deficient R/C Buildings,

Fig. 18 Typical load deflection relationship for the strengthened and the respective monolithic specimens (Lampropoulos and Dritsos 2011, 2012b)

the original column (A_{co}) (A_{cj}/A_{co}). The normalized axial load (v) can be calculated using Eq. 16.

$$v = \frac{N}{A_{co} \cdot f_{co} + A_{cj} \cdot f_{cj}} \tag{16}$$

where N is the axial load, A_{co} is the cross-sectional area of the original column, f_{co} is the concrete strength of the original column, A_{cj} is the cross-sectional area of the concrete jacket, and f_{cj} is the strength of the jacket concrete.

Four- and three-sided jackets have been examined. In case of three-sided jacket, the stirrups of the jacket were merged into the initial column in order to simulate anchorage, which is essential and in practice is ensured by using epoxy grout (Lampropoulos et al. 2012b).

The proposed values for a four-sided jacket with A_{cj}/A_{co} ratio of 1.5 and normalized axial load values of 0.1, 0.2, and 0.4 are presented in Table 4 (Lampropoulos et al. 2012b) together with the values proposed by existing codes (Eurocode 8 2005; Code of Structural Interventions 2012).

Table 5 presents monolithicity coefficient values for a normalized axial load of 0.2 and different A_{cj}/A_{co} ratio values for a four-sided jacket (Lampropoulos et al. 2012b).

Strengthening Techniques: Code-Deficient R/C Buildings, Table 4 Monolithicity coefficient values for a four-sided jacket with different normalized axial load values and an A_{cj}/A_{co} ratio of 1.5 (Lampropoulos and Dritsos 2012b)

	v	Monolithicity coefficients			
		K_F	K_k	K_{δ_y, θ_y}	K_{δ_u, θ_u}
Proposed design values	0.1, 0.2	0.85	0.55	1.50	1.00
	0.4	0.70	0.50	1.30	1.10

Code of Structural Interventions (2012)		0.90	0.80	1.25	0.80

The proposed values for the monolithicity coefficients for a three-sided jacket with an A_{cj}/A_{co} ratio of 1.0, and normalized axial load values of 0.1, 0.2, and 0.4 are presented in Table 6 (Lampropoulos et al. 2012b).

Table 7 presents proposed monolithicity coefficients values for a three-sided jacket and a normalized axial load value of 0.2 with different A_{cj}/A_{co} ratio values (Lampropoulos et al. 2012b).

Monolithicity coefficients for any case with a different A_{cj}/A_{co} ratio or normalized axial load

Strengthening Techniques: Code-Deficient R/C Buildings, Table 5 Monolithicity coefficient values for a four-sided jacket with different A_{cj}/A_{co} ratio values and a normalized axial load of 0.2 (Lampropoulos and Dritsos 2012b)

	A_{cj}/A_{co}	Monolithicity coefficients			
		K_F	K_k	K_{δ, θ_y}	K_{δ, θ_u}
Proposed design values	0.5	0.90	0.70	1.30	0.95
	1.5	0.85	0.55	1.50	1.00
	4.0	0.75	0.75	1.05	2.85
Eurocode 8, Part 3 (2005)		0.90	0.95	1.20	1.00
Code of Structural Interventions (2012)		0.90	0.80	1.25	0.80

Strengthening Techniques: Code-Deficient R/C Buildings, Table 6 Monolithicity coefficient values for a three-sided jacket with different of normalized axial load values and an A_{cj}/A_{co} ratio of 1.0 (Lampropoulos and Dritsos 2012b)

	v	Monolithicity coefficients			
		K_F	K_k	K_{δ, θ_y}	K_{δ, θ_u}
Proposed design values	0.1, 0.2	0.80	0.55	1.40	1.10
	0.4	0.70	0.35	1.90	1.70
Eurocode 8, Part 3 (2005)		0.90	0.95	1.20	1.00
Code of Structural Interventions (2012)		0.90	0.80	1.25	0.80

value from those presented in Tables 4, 5, 6, and 7 can be estimated by linear interpolation (Lampropoulos et al. 2012b).

The monolithicity coefficient values for the design of strengthened RC columns presented herein depend on the type of the jacket (four or three sided), the normalized axial load value, and the thickness of the jacket. The proposed values are more realistic than using one value to cover all situations, as is the case with present code recommendations (Eurocode 8 2005; Code of Structural Interventions 2012). It was also found that in many cases, monolithicity coefficient

Strengthening Techniques: Code-Deficient R/C Buildings, Table 7 Monolithicity coefficient values for a three-sided jacket with different A_{cj}/A_{co} ratio values and a normalized axial load of 0.2 (Lampropoulos and Dritsos 2012b)

	A_{cj}/A_{co}	Monolithicity coefficients			
		K_F	K_k	K_{δ, θ_y}	K_{δ, θ_u}
Proposed design values	0.5	0.85	0.55	1.70	1.15
	1.5	0.80	0.55	1.40	1.10
	4.0	0.75	0.25	3.00	1.00
Eurocode 8, Part 3 (Eurocode 8 2005)		0.90	0.95	1.20	1.00
Code of Structural Interventions (2012)		0.90	0.80	1.25	0.80

values proposed by codes are not conservative. The proposed values of the present work can also be used when considering other techniques to connect between the original column and the new jacket (such as dowels crossing the interface or bent-down bars welded between the two sets of longitudinal bars), as these values are conservative (only roughening at the interface was considered) and are suitable for design purposes (Lampropoulos et al. 2012b).

Summary

In this entry, the technique of concrete repair with epoxy grouting and the strengthening of existing structures with additional reinforced concrete layers and jackets were described in detail. Practical recommendations were presented for both techniques. For the strengthening of the existing structures using additional layers and jackets, recommendations for the analysis and monolithicity coefficients for the design of the strengthened elements were also presented.

The following general recommendations can be drawn:

- Epoxy resins can be used for the crack sealing and for the replacement of damaged concrete. Due consideration should be given to

successfully apply this method. In this chapter, a step-by-step procedure was presented, with detailed instructions about the epoxy resin injection technique, including details about the substrate preparation, the nozzle placement, and the quality control. The use of epoxy resins for shallow concrete replacements was also described, and information about the suitable material for these applications was presented.

- The technique of strengthening using additional layers and jackets is one of the most commonly used techniques. Two crucial parameters for the effectiveness of this technique are the connection between the old and the new elements and shrinkage of the new concrete.
- Models for the shear stress at the interface for reinforced and unreinforced interfaces and models for the strength deterioration of the interfaces due to cyclic loading were presented.
- For the modeling of the strengthened specimens, it is essential to simulate the interface between the old and the new concrete and the shrinkage effect of the new concrete. The interface can be simulated using contact elements, while concrete shrinkage effect can be simulated by applying a volumetric strain to the elements of the jacket.
- For the design of strengthened elements, monolithic coefficient values can be used. Various values have been proposed for the design of strengthened RC columns, based on the type of the jacket (four or three sided), the normalized axial load value, and the thickness of the jacket.

Strengthening Techniques: Code-Deficient Steel Buildings

Konstantinos Daniel Tsavdaridis

School of Civil Engineering, University of Leeds, Leeds, UK

Introduction

The design of steel buildings is often governed by lateral wind loads and not seismic loads. Also, statistics indicate that the number of fatalities during earthquakes due to failure of all types of steel buildings is significantly less compared to other types of buildings. Consequently, much effort has been invested to seismically retrofit buildings having unreinforced masonry walls and reinforced concrete frames. However, recently steel buildings have received significant attention, while this interest mainly stems from the realization, following the 1994 Northridge earthquake, that the welded beam-to-column connections in moment-resisting frames were likely to fail in a brittle manner, prior the development of significant inelastic response, therefore negating the design intent and possibility causing safety hazards.

Recent research has expanded the variety and versatility of the tools available in the structural

engineer's toolbox to meet the seismic performance objectives. This entry provides an overview of how this research is expanding the available options for the seismic strengthening of steel buildings, by reporting on some selected research projects.

Structural strengthening and proving seismic resistance for steel building, but also masonry and reinforced concrete, may be done by first considering the direction of the weak links in the structures. For instance, for a heavy building with large dead load, this would be the major factor that contributes to the increase of lateral seismic load. Therefore, it is reasonable to first consider reducing the overall existing dead load and then provide the necessary strengthening technique for the lateral load-resisting system of the structure.

The use of structural steel in buildings' retrofitting can be often considered economical and efficient because:

- Steel buildings are particularly effective under performance-based design.
- Steel members exhibit ductile behavior beyond elastic limit, hence dissipate considerable amount of energy before damages occur.
- Steel members have higher strength-to-weight and stiffness-to-weight ratios; hence, the buildings attract less base shear under an earthquake.
- A better quality control is practiced in the production of the material as well as the fabrication and erection of them, while ensuring results close to the theoretical predictions.
- Steel can be generally used to retrofit all types of structures without increasing the dead weight dramatically, making the works less intrusive and time consuming.

Code-Deficient Buildings

All buildings can carry their own weight. They can usually carry a bit of snow and a few other floor loads vertically, so even badly built buildings and structures can resist some up-and-down loads. However, buildings and structures are not necessarily resistant to lateral loads, unless this has been taken into account carefully during the

structural engineering design and construction phase with some earthquake-proof measures taken into consideration. It is the side-to-side load which causes the worst damage. Poorly designed buildings often collapse on the first shake. The side-to-side load can be even worse if the shocks come in waves, as taller buildings can vibrate like a huge tuning fork, while each new sway is bigger than the last one, until failure. Usually, significant weight is added in time to such code-deficient steel buildings (i.e., walls, partitions to make more and smaller rooms, etc.) or even due to extreme reinforcing techniques. The more weight there is, and the higher this weight is located in the building, the stronger the building and its foundations must be to withstand the earthquake actions. Many buildings have not been strengthened when such extra weight was added. These buildings are then more vulnerable to even a weak aftershock, perhaps from a different direction or at a different frequency, and can cause collapse. Moreover, in a lot of multistory steel buildings, the ground floor has increased headroom with taller slender columns as well as with more large openings and fewer walls. So, these columns, which carry the largest loads from both the self-weight and the cumulative sideways actions from the seismic event, are vulnerable and they are often the first to fail. It only takes one to fail for the worst disaster; therefore, it is deemed necessary to cautiously strengthen steel buildings with the most appropriate method.

The potential deficiencies are different for different types of steel buildings (i.e., steel moment frames, steel braced frames, steel frames with concrete shear walls, steel frames with infill masonry shear walls). The indicators such as the global strength and stiffness, the configuration, the load path, the component detailing, the diaphragm, and the foundation design demonstrate the performance under seismic actions and the margins for improvement in specific ways; hence, they should be studied carefully before any decision is taken.

Retrofitting of existing code-deficient steel buildings accounts for a major portion of the total cost of hazard mitigation. Therefore, it is

important to identify correctly the structures that need and can accept strengthening or weakening, while the overall cost should be also monitored. If appropriate, seismic retrofitting should be performed through several methods such as increasing the load, deformation, and energy dissipation capacity of the structure (FEMA 356 2000).

Code-Efficient Buildings Resistant to Earthquake

To be earthquake proof, the buildings and their foundations need to be built to be resistant to sideways loads. The lighter the building is, the less the loads are. In steel, especially in high-rise buildings, the sideways resistance mainly comes from the diagonal bracing which must be placed equally in both directions. Where possible, the diagonal bracing should be strong enough to accept tension as well as compression loads; the bolted or welded connections should resist more tension than the ultimate tension value of the brace or much more than the design load. If the sideways load is to be resisted with moment-resisting framing, then great care has to be taken to ensure that the joints are stronger than the beams and that the beams will fail before the columns. Also in such a case, special care should be provided to the foundation-to-first-floor level, avoiding soft-story effects, while the columns should be much stronger than at higher levels. The foundations could be enhanced by having a grillage of steel beams at the foundation level able to resist the high column moments and keep the foundations in place. The main beams should be fixed to the outer columns with full capacity joints, which almost mean hunched connections, and care should be taken to consider the shear within the column at these connections.

When the steel beams are able to yield and bend at their highest stressed points, without losing resistance, while the connections and the columns remain full strength, then the resonant frequency of the whole frame changes, while the energy is absorbed and evenly dissipated across the framing.

The vibration occurred from the shock waves is tend to be damped out. This phenomenon is called “plastic hinging” and is easily demonstrated in steel beams. In extreme earthquake sway, the beams should always be able to form hinges somewhere, while the columns should behave elastically. In this way, the frame can deflect and the plastic hinges can absorb energy, while the resonant frequency of the structure is altered without major loss of strength and inevitable collapse. All floors should be connected to the framing in a robust and resilient way and should be as light as possible. They should possibly span around each column and be fixed to every supporting beam using enough shear connectors (e.g., studs). An effective way of reducing the vulnerability of large buildings is to isolate them from the floors using bearings or dampers; however, this is an expensive process, and it is not applied to low to medium rise buildings which have not been classified as important, due to the content they carry and the occupancy usage.

Nothing can be though guaranteed to behave as such, even in code-based designs; hence, most of the steel buildings and especially those under-designed with older seismic codes can be considered as code-deficient buildings in certain circumstances.

Design Concept for EC8

Eurocode 8 (EC8) follows three general design concepts based on the ductility requirements and capacity design considerations of steel buildings: the concept of the low-dissipative structural behavior of DCL structures, the concept of dissipative structural behavior of DCM and DCH structures satisfying the ductility and capacity design requirement, and the concept of dissipative structural behavior with steel dissipative-controlled zones. In the latter case, when composite action may be considered from Eurocode 4 (EC4) in the presence of the steel and concrete (slab) interaction, specific measures have been stipulated to prevent the contribution of concrete under seismic conditions, hence apply general rules for steel frames.

Introduction to Strengthening Techniques

Preliminary Investigation

It is becoming preferable, both environmentally and economically, to upgrade building structures rather than to demolish them and rebuild them. Engineers assessing structures for increased or special loadings are finding that new methods of analysis using, for instance, computer models are revealing shortcomings under service and ultimate conditions. Under such circumstances, a method has to be found to bring the structure up to the required standard. There is a range of techniques which can be used on structures, but, one must take into consideration that disruption to normal stage must be minimal while work is in progress.

Evaluation and subsequent strengthening of existing structures require a realistic and pragmatic design approach. However, some of the solutions proposed by researchers do not lie within this category and they will be eliminated in the current study. Also, effective communication between the owner, structural engineer, architect, risk analyst, insurance provider, and other stakeholders is paramount to a successful finished solution. In general, in the case where additional load-carrying capacity is required of an existing building, engineers have the option of either **reinforcing** the existing framing or **adding** new framing to replace or supplement the existing.

Where a decision is made to strengthen some parts of an existing facility or a specific structural system or element, the design approach is influenced by a series of factors such as:

- Information about relevant existing conditions which is often limited
- Part of the structure to be strengthened is commonly hidden or obstructed by existing architectural or building services systems that are difficult or costly to remove
- Structural renovation work is typically constrained by the need for continuity of building operations
- Level of ductility of the existing construction may limit its strength

- The susceptibility to local buckling of outstanding flanges as well as the lack of connection ductility

Often, the nonstructural costs will likely exceed the structural costs; therefore, the true costs of a retrofit project are primarily dependent on the number of locations of work than the amount of work done in each location, and thus, this influences the structural design and analysis decisions.

The general approach to strengthen existing structures includes the following aspects:

- Risk assessment and structural vulnerability assessment
- Preliminary analysis
- Consideration of alternatives (structural and nonstructural)
- Detailed design and impact of connections

The common goal is to:

- Protect specific structural elements.
- Provide redundancy to structural systems.
- Strengthen a specific part of the structure.

Assessing Existing Conditions and Strengthening Methods

Introduction

A site visit should also be performed to inspect the building, especially for structures more than 30 years old. Some key things to look for when assessing the existing condition of a steel building are: damage to framing, noticeable corrosion, signs that modifications to the structure that may have been performed without engineering review, unusual deflections in floor framing, cracks in supported slabs, signs of foundation settlement, signs for new rooftop equipment, heavy hung piping loads, folding partitions, rigging, or other suspended loads that may have been added without proper structural engineering review (Schwinger 2014). A valuable resource available to structural engineers working with existing building structures is the *AISC Steel Design Guide 15 – AISC Rehabilitation and*

Retrofit Guide (Brockenbrough 2002). Other publications for further reference are ASCE 41-06 2006, FEMA 274 1997, and FEMA 547 2006.

The strengthening methods can be categorized as follows:

1. Passive against active methods.
2. Strengthening techniques:
 - (a) Reinforcing beams by welding (enlarge section with plates).
 - (b) Reinforcing (or weakening) connections:
 - Framing.
 - Seated angles.
 - Partial-depth end plate.
 - Replace with high-strength fasteners.
 - Add welds at the perimeter of the connection and/or properly clean existing welds.
 - Converting single- to double-shear connections by adding angles or plates.
 - Add web stiffener plate.
 - Add steel cover plates.
 - Enhance column splices.
 - Enhance braced frame connection.
 - (c) Shortening span (provided that there are no fitting issues):
 - Add beams.
 - Add columns and girders.
 - Add diagonal braces.
 - Add walls with openings.
 - Add steel braced frame.
 - Add concrete, masonry, or steel plate walls.
 - Enhance strength and ductility of braced frames.
 - (d) Introducing composite action:
 - Steel (partially or fully) encased with concrete
 - Shear connectors
 - (e) Post-tensioning (or external pre-stressing) of beams and connections (considering eccentricities of brackets on member capacity – some need protection from corrosion, fire, and vandalism).
 - (f) Openings in existing beams (using thermal cutting – plasma arc cutting is faster than

oxy-fuel – while avoiding cuts at areas subjected to high shear):

- Place reinforcement (e.g., stiffeners) before cutting holes.
- (g) Replacement of members (may be economical).
 - (h) Strengthening columns.
 - (i) Convert gravity frame to moment-resisting frame.

Determining Load Capacity of Existing Buildings

Knowing the yielding strength of the steel used in the framing is essential for computing the load capacity; therefore, testing should be performed to ascertain and verify the actual yield strength. One technique is to test the steel to determine its actual yield strength, in hope of finding it to be a higher value than the one that was used in the original design. Another technique applied in existing structures is to analyze the framing using the load and resistance factor design (LRFD) method (AISC 1999); in LRFD usable strength is approximately 1.5 times greater than the older allowable stress design (ASD) service level strength.

Increasing Capacity of Connections

The technique by which existing shear and moment connections can be strengthened is limited only by the imagination of the engineer. Various techniques are going to be presented thereafter, based on well-established but also recent research outcomes obtained from numerous computational analyses and experimental campaigns. It is worth to be aforementioned that the capacities of existing connections must be determined when existing framing is modified or additional capacity is sought.

Increasing Flexural Strength Floor Framing Members

There are two options for reinforcing existing flooring systems to support additional loads: (a) **add** new framing to supplement the existing framing and (b) **reinforce** the existing beams, girders, and connections. The easiest solution is usually that of reinforcing the existing structural

**Strengthening Techniques:
Code-Deficient Steel Buildings,**

Fig. 1 Examples of strengthened beams

**Strengthening Techniques:
Code-Deficient Steel Buildings,**

Fig. 2 Examples of strengthened columns

elements, provided that the floor slab has sufficient capacity to carry the loads. The most efficient way is to weld rectangular high-strength steels (HSS) to the flanges as shown in Fig. 1.

Increasing Axial Load Capacity of Columns

The buckling limit state and its variable slenderness should be determined in order to evaluate the axial load capacity of columns. Column strengthening serves both to reduce slenderness by increasing the radius of gyration of the section and to reduce stress. Column buckling is a mid-height phenomenon; therefore, increasing column stiffness between the supports, not at the supports, is required to increase column capacity. Both methods shown in Fig. 2 are effective; however, the one on the left better increases the weak axis stiffness of an H-shaped section.

Dealing with Weldability Issues

Weldability is verified by mechanical and chemical testing. The former measures ductility and the latter determines the “carbon equivalent” value.

Connecting New Frame to Existing Frame

Similarly to the connections, there are numerous ways that new framing can be connected to existing framing. Welding the new steel members to the existing members is a straightforward approach which requires less precision as compared to the bolting process, while drilling new holes through existing steel and bolting in the field. Various details for connecting new framing to an existing one can be found by Schwinger (2014).

Detailed Description of Retrofitting and Strengthening Techniques

Introduction

The performance of steel frames can be synthesized in three very different behaviors:

1. Formation of plastic hinges
2. Local and global instabilities
3. Fracture and structural discontinuity

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 3 (a) Reduced beam section (RBS) connection (Crawford 2002), (b) welded haunch connection (Uang et al 2000), (c) bolted brackets

These three behaviors and/or combinations of them are likely to occur and govern the capacity of a connection or member with result on the structural continuity and integrity of the system. Overall, it is known from seismic studies that frame capacity is related to two different aspects of frame behavior:

1. The **member** response, as controlled by plastic rotational strength and deformation characteristics (including local and global buckling)
2. The **connection** response, as controlled by bolt fracture, premature brittle weld failure, and panel zone failure

Determining the capacity of columns is difficult as in many situations code-deficient buildings are not designed for large lateral loading.

Steel Connections: Fuses

Beam-to-Column Connections: Developing Ductile Behavior (Fuse Concept)

In parallel with the FEMA/SAC steel research program, the National Institute of Standards and Technology (NIST) and the AISC initiated a research project to upgrade existing special moment frames (SMFs) and investigate the effectiveness of two rehabilitation schemes. Modifications to pre-Northridge moment connections to achieve improved seismic performance focused on reducing or eliminating some of the

contribution factors to the brittle fractures. Brittle fractures originated in the beam flange groove welds and often propagated to rupture beam flanges or columns. A cooperative effort by NISC, AISC, the University of California at San Diego, the University of Texas at Austin, and Lehigh University examined three techniques for the retrofit of existing code-deficient steel moment connections trying to force plastic hinging of the beam away from the column face, namely, (a) the reduced beam section (RBS) concept to weaken a portion of the beam near the column so that plastic hinging would occur at the designated location, (b) the addition of a welded haunch to strengthen the steel beam near the welded connection, and (c) the use of bolted brackets to reinforce the connection (Fig. 3). More RBS patterns have been developed by Plumier in 1997 and appeared in different configurations, as it is shown in Fig. 4.

Further analytical research on the same connection complement this work, as design model and guidelines have been recommended. A target plastic rotation capacity of 0.02 rad was selected. In 2004, Engelhardt recommended (Bruneau 2004) the following as potential positive solutions:

- The use of a bottom flange RBS combined with the replacement of top and bottom beam flange groove welds with high toughness weld metal provided plastic rotations on the order of 0.02 to 0.025 radian. The presence of a

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 4 Various RBS patterns

composite slab had little effect on the performance of this retrofit technique.

- The addition of a welded bottom haunch, with the existing low toughness beam flange groove welds left in-place, resulted in significantly improved connection performance, which was dramatically influenced by the absence or presence of a composite concrete floor slab. In the former case, the specimens developed plastic rotations of 0.015 to 0.025 radian, whereas in the latter case developed plastic hinges in excess of 0.03 radian.
- The use of bolted brackets at the top and bottom flanges provided plastic rotations in excess of 0.03 radian.

Design recommendations have been provided for fully restrained, radius cut RBS connections. A step-by-step procedure is presented, with commentary for various design considerations. A similar procedure is included in FEMA 351 (2000) and AISC 358 (2005), which also provides design guidelines for other prequalified post-Northridge connections such as the bolted flange plate (BFP) moment connections, the bolted unstiffened (BUEEP) and stiffened extended end plate (BSEEP) moment connections, and the so-called ConXtech ConXL and Kaiser bolted bracket (KBB) moment connections.

It is worth to note that conventional beam theory cannot provide a reliable prediction for neither of the above structural systems. Uang et al. (2000) and Yu et al. (2000) proposed a simplified model that considers the interaction of forces and deformation compatibility between the beam and the haunches.

Exhaustive research works have been conducted on RBS connections varying the geometric characteristics of both the beam and the connection assembly itself. More recently, RBS moment-resisting connections have been also investigated by researchers in Europe using European HEA-profile sections (Pachoumis et al. 2008), since so far they have been only investigated by the US design construction practices. The result is the readjustment of the geometric characteristics of the RBS in order to apply to the European profiles. Limitation in using RBS is the shear connection between the top steel flange and the metal decking of the steel-concrete composite (SCC) slab due to the significant width reduction.

More recently, the same concept has been applied to steel frames as a strengthening-weakening technique, while introducing a circular opening (Fig. 5) in the beam's web instead, at a certain distance from the beam-to-column connection, as an effective method to improve the

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 5 Failure mode of connection with circular web opening (Qingshan et al. 2009)

aseismic behavior of MRFs (Qingshan et al. 2009). The accurate position and size of the circular opening has been investigated through numerical modeling as well as experimental works, while the plastic hinge positions is effectively controlled. Similar studies have demonstrated the effect of various nonstandard web opening shapes (Fig. 6), in enhancing the ductility but also the strength of the connections (Tsavdaridis et al. 2014). Step-by-step procedures have been proposed to determine the most suitable geometries to achieve adequate connection strength, ductility, stiffness, and rotational capacities. Such techniques prove suitable in cases where large plastic rotations are required (i.e., larger than 0.03 rad). Tsavdaridis et al. (2014) have further proposed the use of previously patented novel elliptically based web opening shapes, which can also be used for perforated beams (e.g., cellular and castellated beams) adding numerous advantages from the manufacturing process to their life-span, while they can develop rotational capacities up to 0.05 rad with insignificant strength degradation (Fig. 7).

The so-called reduced web section (RWS) connections have been studied, yet not extensively, assessing local connection models mainly computationally with cyclic (quasi-static), and pseudo-dynamic (PSD) analyses. The results

show that the ultimate displacement of the modified buildings increases a lot due to the web openings, and thus, the building ductility is improved greatly. Moreover, brittle weld fractures can be avoided and the maximum plastic zone moved to the weakened areas. RWS connections can easily be applied to the beams of new as well as existing code-deficient buildings as the web cutting does is away from the composite slab that sits on top of the compression steel flange. It is worth to mention that different geometric characteristics and limitations of beams and columns should be used for different RWS connection types. There is a need to bring the attention and propose more experiment physical testings to validate and establish RWS connections in the current European and American practices.

Similarly, welded haunches and bolted brackets are used to move the plastic hinges away from the column, but also strengthen the existing connection and seek to maintain the original flexural capacity of the beam.

Ductile Behavior: Fuses in Bracing Members

The concept of adding ductile fuses in bracing members of steel concentrically braced frames (CBFs) resisting seismic loads is well linked to the RBS technique. Current code provisions require that steel CBFs are designed to exhibit ductile energy dissipation. Limits on brace overall slenderness ratio must be satisfied to achieve ductile inelastic behavior. It is apparent that implementation of this design approach may result in significant increases in design loads for brace connections, beams, and columns (Egloff et al. 2012).

In order to reduce seismic design loads, ductile fuses in bracing members have been recently proposed, as they control their axial resistances. Such behavior can be achieved by locally reducing the brace cross-sectional area or by introducing ductile components that yield in both tension and compression. In the former case, the reduced section might need to be confined to prevent local buckling, or it can be resized (reshaped - restructured) to yield in tension while remaining elastic in compression, which means that the

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 6 Types of perforated beam webs (Hedayat and Celikag 2009)

effect of fatigue loading will be minimized. In the latter case, the overall buckling is eliminated, and hence, the strength degradation is limited due to symmetrical hysteretic behavior. This type of fuse technique can be applied in open and closed profile sections of the bracing members, while it has been noticed that the former ones perform better exhibiting higher ductility. A special fuse (Fig. 8) for controlling the tension resistance of

open bracing members has been proposed by Vincent in 2008. A part of the flange to web intersection is removed to limit the impact on the brace flexural stiffness and buckling resistance. In 2012, Egloff et al. introduced a new local buckling restraining system (LBRS) which includes two cold-formed channels that support the web and the flanges. Moreover, external cover plates can be bolted to the channels in order to

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 7 Geometric parameters of various novel perforated beam-to-column moment connections and von Mises plastic stresses (Tsavdaridis et al. 2014)

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 8 Ductile fuse for H-shaped bracing members (Vincent 2008)

prevent local buckling of the brace flanges. Splice plates can also be used to provide lateral support to the flanges in the fuse (Fig. 9). This LBRS can slip longitudinally with respect to the brace so that it does not attract any axial forces. Further

improvements and the design procedure for the fuse and the fuse LBRS are available in the literature.

Cast Connex, a high-strength steel connector for round hollow structural section brace

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 9 Proposed fuse local buckling restraining mechanism (Egloff et al. 2012)

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 10 Structural details of pin-fuse connection (Coedova and Hamburger 2011)

members in CBF, has also developed a yielding fuse connector for CBF, called the Scorpion Yielding Brace System (SCBF), that relies on the flexural yielding of fingerlike plates that are specially designed to dissipate energy locally and can be used in both architecturally exposed and nonexposed braced bays.

Pin-Fuse Joints

A new type of connection, which begun its prequalification process in 2011, is the pin-fuse connection (Fig. 10) which incorporates a curved plated end connection using slip-critical bolts and a steel pin adjacent to the beam-to-

column joint. The bolts are designed to slip within slotted holes allowing the pin joint to rotate, dissipating the energy through frictional resistance. This joint acts as the fuse for the system, while the rest of the steel frame can be designed to remain elastic. Following an earthquake, and avoiding damages, the frame can be adjusted to its initial position, reducing the potential for permanent residual displacements while both the connection and the frame maintain their structural integrity and reduce the need for costly structural repairs. The simplicity of the pin-fuse connection offers the ability to accommodate braces and dampers.

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 11 Proposed connections with replaceable link (Shen 2009)

Replaceable Links

Using RBS- and RWS-type connections has been proved very efficient for certain applications; however, there are some drawbacks. As the yielding fuse is a part of the beam, strength design and drift design of the structure are interlinked. For instance, due to increased drift requirements, the capacity of the yielding fuse may be also increased, which then leads to higher demands on the other parts of the structure including columns, floor slabs, connections, and foundations and often resulting in oversized buildings with increased overall cost. Further, significant damage can result in the beam from repeated inelastic deformation and localized buckling (hence crack propagation) during a design-level earthquake. As this cumulative inelastic action of the building cannot be precisely anticipated, it is not trivial to assess the extent of damage on site and the residual capability of the structure to adequately provide the required level of safety for any subsequent loading. In such a case, repair of the beam is not a straightforward procedure and it can be disruptive and costly.

The replaceable link concept (Fig. 11) effectively eliminates the aforementioned concerns instead of reducing the beam section size; dismantlable dissipative elements (Fig. 12)

which can be removed and replaced with smaller flexural capacities are used at the locations of the expected inelastic actions. Consequently, the other structural elements in the frame will remain elastic during an earthquake. This efficient method of repair for MRFs allows for quick inspection and replacement of damaged links while it minimizes the disruption time. Further, the welding of critical elements of beam-to-column connections can be done in the shop while improving construction quality and significantly reducing the initial erection time (Shen 2009).

In particular, two types of replaceable links have been proposed by Shen (2009): (i) H-section with end plates and (ii) back-to-back channels eccentrically bolted to the beam web. The former one is prepared in the shop using complete joint penetration welds. The end plate (flush or extended) is then bolted to the column flange using prestressed high-strength bolts. The latter type of these double channel-built sections intended to act as truss girders in special truss moment frames, and they have been connected using welded reinforcing gusset plates. In certain circumstances, lateral bracing is deemed necessary in the region adjacent to the plastic hinge to achieve large (i.e., 0.06 rad) plastic rotation of the hinge. However, sometimes

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 12 End plate model boundary conditions (Shen 2009)

large overstrength has been observed in these buildup channel sections.

The end plate links can exhibit 0.04 rad contributing to 90 % of the total story drift and demonstrate higher energy-dissipating capacity than the double channel links, while some strength degradation occurs due to ductile local flange and web buckling. On the other hand, higher story drift can be reached by the double channel links before experiencing strength degradation at 0.06 rad. The degradation has been also caused due to ductile tearing of the flanges and the webs. Overall, double channel links type has been considered to be preferable as it provides a more gradual transmission of forces at the connections via friction. For more stability, further modifications can take place enhancing the connection of the channel webs and the connection of the beam segments.

Steel Connections: Stiffeners

Introduction

Forcing the plastic deformation to the beam end away from the connection is a common practice in seismic moment-resisting frames, but in contrast to the fuse concept, this can be also achieved by increasing the relative stiffness of the column and the connection with respect to the beam. Eventually, this is an alternative in effectively controlling the position and intensity of the plastic hinge in the connection zone when such modifications are allowed.

SidePlate™ Connections

A well-promising retrofitting method for upgrading an existing traditional moment-resisting connection is shown in Fig. 13. This concept uses the so-called SidePlate™ retrofit system where the

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 13 SidePlate™ retrofit connection (Crawford 2002)

physical separation between the face of the column flange and the end of the beam, for mitigating the stress concentration, is achieved using parallel full-depth side plates which act as discrete continuity elements to sandwich the connecting beam(s) and column (Crawford 2002). Similar design concept can be used for steel and concrete-filled hollow section columns (Fig. 14).

Whole steel frame is eventually stiffened, and the zone panel deformation is eliminated using this type of connections due to the increased stiffness of the side plates that ultimately provide the three panel zones. This connection system uses all fillet-welded fabrication which predominately carries all shear actions as well as moments through the combination of vertical shear plates and fillet welds. The side plates should be designed with sufficient strength and stiffness to force all significant plastic behavior of the connection system into the beam.

The same system can be used to upgrade construction of deficient buildings. The difference is that an initial hole is required in each side of the plates to permit welding access, while the holes are closed with the same cutoff plate following the completion of the welding process. All new welds are again fillet welds loaded in shear along their length, whereas if there are any existing Complete Joint Penetration (CJP) welds, they are removed by air arcing to eliminate the reliance on through thickness properties and triaxial stress concentrations. More information can be found from FEMA 351 (2000).

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 14 Strengthening retrofit concept: concrete-filled hollow section of column (Crawford 2002)

Stiffeners at Connections

In addition to the prequalified connections for SMFs and intermediate moment frames (IMF) presented in AISC (1999) and the SidePlate™ system, research has been focused on the effect of stiffeners on the strain patterns of the welded connection zone.

For example, the effect of both internal and external stiffeners on the behavior of I-beam to hollow-column section connections (Fig. 15) has been initially thoroughly investigated by Chen and Lin (1990). It has been observed that the connections with triangular stiffeners have the lowest rigidity, in contrast to those with side stiffeners which present significantly higher moment rotation capacities, stiffness, and ductility. Moreover, the performance of the retrofitted connections with side stiffeners has been investigated (Ghobadi et al. 2009) and design guidelines proposed. The benefits of using side stiffeners have been also introduced on concrete-filled tubular (CFT) columns connected to I-beams, while stable hysteresis and adequate ductility are provided. Overall, it has been concluded that connections with both column stiffeners and top-flange stiffeners have the highest value of energy dissipation, while the beam top-flange

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 15 Typical I-beam to box-column connection (Kiamanesh et al. 2010)

stiffener is the most effective one, especially when it is incorporated with the column stiffeners of a hollow section.

Steel Frames: Modifications

Frame Modification at Beam's Mid-Span (Fuse Concept)

A retrofitting method which can be used for new construction as well as a strengthening technique for existing moment-resisting frames has been developed by Leelataviwat et al. (1998). This technique replaces certain beams and is introducing a ductile fuse element in shear at their mid-span instead of modifying the beam-to-column connections (Fig. 16). A braced rectangular opening is created in the web of each girder at the mid-span, to move the plastic deformation away from the critical connection regions, while ensuring the development of a ductile mechanism.

Cabling: Self-Centering Systems

The use of the cables is another promising technique, which can be applied to both slabs and connections. Placement of cables with connections

to girders or cables with connections to beams is very important especially for high-rise buildings. Self-centering braces have been designed and built using prestressed aramid fiber strands in conjunction with friction pads or memory alloys. Energy dissipation is implemented using yielding seat angles, friction dampers, or energy-dissipating bars confined in tubes. Researchers have investigated self-centering column bases that use post-tensioned (PT) bars or spring-loaded wedges. Tendons can span over multiple floors, while elastomeric spring dampers and fuse bars can be used to provide energy dissipation.

Furthermore, self-centering structural systems (Fig. 17) have been proposed, for the seismic retrofit of special moment-resisting frames, by Christopoulos et al. (2002). This is a post-tensioned energy-dissipating (PTED) steel frame design, where high-strength bars or tendons provide the post-tension at each floor. Confining steel sleeves have been often used to prevent the energy-dissipating bars from buckling during cyclic inelastic loading. It has been concluded that these economical innovative systems:

- Incorporate the nonlinear characteristics of yielding structures and, thereby, limit the induced seismic forces and provide additional damping characteristics.
- Encompass self-centering properties allowing the structural system to return to its original position after an earthquake.
- Reduce or eliminate cumulative damage to the main structural elements.

Later, Garlock et al. (2004) has proposed a similar structural system with high-strength steel PT strands, after bolted replaceable top-and-seat angles have been installed (Fig. 18). Here, the vertical shear is supported by both the angles and the friction between the beam and the column, and it is expected to continue to perform if failure of one or more strands occurs. It is proved that this system can achieve greater strength and ductility.

Recently, researchers have designed and experimentally evaluated a new self-centering PT connection using yielding web hourglass shape pins (WHPs) as seismic energy dissipaters. WHPs do

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 16 Frame modified with mid-span truss opening (Leelataviwat et al. 1998)

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 17 PTED system (Christopoulos et al. 2002)

not interfere with the composite slab and can be very easily replaced without the need for welding and bolting and, therefore, can significantly decrease downtime in the aftermath of a strong earthquake. Repeated experiments are described in detail and proved the reparability of the PT connection with WHPs (Vasdravellis et al. 2013).

Structural System: Adding Structural Elements (Walls, Blocks, Bracings)

Introduction

Conventional retrofitting methods include the addition of new structural elements to the system,

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 18 Post-tensioned moment connection with top and bottom seat angles (Garlock et al. 2004)

enlarging the existing members. Bracings, masonry (Fig. 19), and reinforced concrete (pre- and post-cast infill) shear walls are the most popular and efficient strengthening techniques as they provide lower overall cost and they are easy to use. Braces are more effective due to their much higher ductility, but the shear walls are indeed the most commonly applied method, as they also reduce the demand on the other

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 19 Ordinary hybrid wall (Adopted by <http://masonryedge.com/site/mim-archives-the-storypole-vol-38-no-4/143-filling-in-the-frame->)

structural members resisting large lateral loads, hence increasing their safety in a simple manner. The actual capacity of bearing walls has been often underestimated or even ignored. However, it can be a major contributor, and it can provide the required capacity, without the need of more complex strengthening techniques (Sarhosis et al. 2014).

Bearing Walls

Walls must go equally in both directions, and they must be strong enough to add stiffness to the steel framing system while they are tied in to any framing in order to take load in their weakest direction. Also, they must not fall apart and must remain in place after the worst shock waves, so as to retain strength for the aftershocks.

In particular, three approaches have been identified (Crawford 2002) for enhancing the resilience of a building's bearing walls under the progressive collapse and seismic scenarios. These are the following: (i) backup wall, build a second wall or gravity-carrying frame to support the existing wall; (ii) strong wall, employ fabric retrofit to control the breach area; and (iii) ductile

wall, polyurethane spray to prevent punching shear failure. Moreover, openings can be accommodated in such walls, especially with multistory buildings, while further enhancements are needed.

Steel Plate Shear Walls

In addition to concrete and reinforced concrete walls with SCC beams, research has been initially conducted by Thorburn et al. (1983) later on steel plate shear wall (SPSW) design (Fig. 20a) and retrofitting methods. SPSWs can be used as the primary lateral force resisting system in steel buildings allowing the occurrence of shear buckling. Following buckling, diagonal tension field is developed to transfer the lateral load in the panel, while the forces in beams and columns are reduced. Furthermore, the use of low-yield-strength steel panels and RBS connections as well as light-gauge cold-formed steel plates has been examined as potential applications by Berman and Bruneau (2004). The former one demonstrates an earlier onset of energy dissipation by the panel, while perforated panel specimens (Fig. 20b) can be used to control the

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 20 (a) SPSW specimen with cutout corners (*right*), (b) buckled panel and RBS yielding of SRW specimen (Vian and Bruneau 2004)

stiffness and overstrength issues using hot-rolled plates. This option is also useful in a retrofit situation, providing access for utilities to penetrate the predesigned system.

Braced Frames

Braced frames can be constructed of single diagonal, x and k braces, chevron and split braces, and lattice or knee braces, and they can be used in interior cores – so connections could be easily made with wall panels, as well as in the exterior. Composite braced frames are also becoming popular where concrete bracings are supporting steel frames.

A simplified design procedure for suspended zipper frames, initially proposed by Khatib et al. (1988), has been introduced by Leon and Yang (2003) and consists of inverted V-braces

adding zipper columns which connect the intersection point of the braces above the first floor. The zipper columns tie all brace-to-beam intersection points together and force compression braces in a braced bay to buckle simultaneously, hence better distribute the dissipated energy over the height of the building (Bruneau 2004). A suspension system has been proposed later, ensuring that the top story braces are designed to remain elastic, whereas all other compression braces are designed to buckle, while the suspended zipper struts are designed to yield in tension. Therefore, adequate ductility is provided, with superior seismic performance.

Engaging the fuse, the replaceable links, the self-centering, and the braced frame retrofitting concept, Eatherton et al. (2008) proposed a controlled rocking system which virtually eliminates

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 21 A non-buckling brace

residual drifts and concentrates the majority of structural damage in replaceable fuse elements. The system is consisted of three components: (a) a stiff steel braced frame which remains elastic, but it is not tied to the foundation and hence allowed to rock, (b) a vertical post-tensioning that strands the top of the frame down to the foundation and brings the frame back to the center, and (c) the replaceable fuses that absorb the energy as the frame rocks.

Non-Buckling Braces

Conventional braces tend to buckle under the compression cycle of the seismic load, hence dissipating little energy under compression. This causes pinching of the hysteresis loop and failure of the braces within a few cycles, due to the formation of plastic hinge close to mid-length of the member. The use of non-buckling braces (also known as buckling restrained braces or un-bonded braces) bypasses this problem. In this type of bracing system, the requirements of adequate strength to resist compression, as well as rigidity to avoid buckling, have been addressed separately to a core and a sleeve (Fig. 21).

In the last decade, buckling restrained braced (BRB) frames have received much attention in the United States, as they demonstrate stable hysteretic behavior and excellent low-cycle fatigue life characteristics. However, buckling and cracking of gusset plates are expected in certain cases, similarly to all types of braced frames.

Strengthening Members

Strengthening members by adding plates or encasing/filling them with concrete provides an

effective technique to add strength, and it can be applied for a particular group of members, such as on the ground floor. Thus, concrete encasement of columns (Figs. 14), and floor beams (Fig. 22) as proposed (Tsavdaridis et al. 2013), constitute forms of strengthening techniques for new and existing steel buildings.

Materials

Innovative ways have been explored for the strengthening and rehabilitation of deficient steel buildings, due to the demand to access the specified load capacity and the deterioration as a result of corrosion. In particular, externally bonded fiber-reinforced polymer (FRP) composites can be applied to various structural members such as columns, beams, slabs, and walls in order to improve their structural performance in terms of stiffness, load-carrying and deformation capacity, and ductility, while simultaneously providing environmental durability. Generally, FRPs have been widely used mostly in applications that allow complete wrapping of the member, while attention deemed necessary to avoid brittle shear and de-bonding failures, especially prone when used on steel. In such cases, the actual member can entirely waste the strengthening application, or the composite material might harm the member itself by decreasing its ductility (Buyukozturk et al. 2003). It has been proposed that for buildings with large seismic deficiencies, a combination of conventional and FRP strengthening techniques may prove to be an effective retrofitting solution.

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 22 Schematic representation of the USFB system and the internal actions (Tsavdaridis et al. 2013)

The preformed high-strength carbon fiber plates currently being used for concrete structures are typically 4 mm thick. To strengthen steel beams, they would need to be at least 20 mm thick, in order to achieve a significant increase in bending moment for the steel or SCC beam. Consequently, new high-modulus carbon fiber-reinforced polymer (CFRP) materials are likely to provide solutions for steel structures' deterioration issue (Schnierch et al. 2005). Time should be allowed for the surface preparation, application of the adhesive, and curing time (usually between 4 and 8 h). Specific surface preparation and detailing are critical to ensure adequate bond interaction between steel and FRP materials, both in the short and long term, and capable of sustaining the high interfacial

stresses necessary to appreciate the full strength of these materials (Lenwari et al. 2006).

Energy Dissipation and Active/Passive Structural Control Systems

A quite different retrofitting method, which can be quite cost-efficient, is the installation of complementary energy dissipation devices in structures as a means of passive, semi-active, or active structural control systems. These are not described thoroughly here, as it is beyond the scope of the present entry. The main objective of structural control is to minimize structural vibrations improving safety and serviceability limits mainly under wind and earthquake actions. Up to date, the majority of passive energy dissipation devices have been found very effective in

Strengthening Techniques: Code-Deficient Steel Buildings, Fig. 23 Supplemental energy dissipation devices (Adopted from MIT.edu website)

controlling the seismic response of steel frames. Further advanced techniques seem very promising such as the introduction of an “inertor” (Smith 2002; Marian and Giaralis 2014), and its combined use with the already well-operated tuned mass dampers, with scope to reduce the size of the mass required to control and dissipate the energy of high-rise buildings. Figure 23 shows the basic principles of various control systems commonly used on building structures.

There is a vast research conducted on energy dissipation devices during the past 20 years, while their use becomes more direct and apparent with the upsurge of technology. However, a diverse background of researchers is required, integrating a number of disciplines, some of

which are not within the domain of traditional civil engineering. In particular, the control theory is elaborated with computer science, data processing, sensing technology and materials science using the knowledge and principles of earthquake (and wind) engineering, structural dynamics, as well as stochastic processes. It is essential to mention though, that the effectiveness of such dissipation devices is predominantly dependent of the deformation capacity of the structure. Consequently, the application of such devices to code-deficient buildings with inadequate seismic detailing or post-earthquake damages should be carefully considered, and perhaps it should be combined with an appropriate strengthening technique with deformation enhancement measures as proposed above.

Ongoing research on special strengthening techniques involving the use of simple and robust active control systems, while emphasizing on the performance of various controllers (Demetriou et al. 2014) as well as new conceptual methods introducing the ability of structures to adapt under dynamic loads (Slotboom et al. 2014), are posing great expectations.

Summary

It is worth to mention that there are factors which inhibit retrofit design when it comes to strengthening existing buildings. Many times important issues are misaddressed due to the complexity of strengthening design concepts, lack of technology understanding or even ignoring it, while uncertainties about the design of the building involved. Therefore, existing buildings should be best approached with a risk-based retrofit scheme in order to concentrate the works where they are actually needed most. In this way, more safe, effective, and cost-efficient steel buildings will stay operated in the future. This inherently requires more skilled designers and engineers, better design tools, and more truly innovative “smart” retrofit techniques to be developed for the seismic strengthening of code-deficient steel buildings.

Introduction

Masonry structures constitute a large part of the existing structures throughout the world. A significant part of the existing masonry structures belong to the built cultural heritage. Furthermore, many countries with rich cultural heritage are situated in earthquake-prone areas (in Europe, in Asia, in South America). The built cultural heritage includes unique monuments (temples, churches, castles, palaces, bridges, etc.) and (inhabited and leaving) historic centers. Therefore, there is a continuous need for the preservation of this wealth, whose cultural, historical, social, and economic values cannot be overestimated.

On the other hand, the international scientific community is working quite intensively in the field of preservation of the existing stock of structures, and, thus, the knowledge acquired in the last decades allows for interventions to be more rationally selected and better applied.

It is obvious that the vast variety of existing masonry structures, in terms of typology, of materials used for their construction, of their cultural significance, etc., does not allow this text to be of general applicability and to cover all possible cases. Thus, to make this text to be of some use, one has to limit its scope to a part of the existing masonry structures. Unique monuments are usually the subject of specific studies

(exhaustive surveys, in situ and laboratory tests, monitoring, sophisticated analyses, etc.) leading to the selection of adequate intervention techniques by multidisciplinary national or international teams. Thus, they are left out of the scope of this text. Furthermore, structures other than buildings (e.g., towers, bridges, etc.) present peculiarities that need to be treated separately. Therefore, those structures as well are not covered by this text. However, the repair and strengthening techniques, concisely presented and treated herein, are applicable also to the categories of structures that are not explicitly covered.

Prerequisites for the Selection of Adequate Intervention Techniques: Intervention Strategies

Interventions to individual structural members or to parts of an existing masonry structure should be part of a global intervention strategy. The selection of a strategy and, hence, of appropriate intervention techniques (for the repair or strengthening of a structure) is based on a series of investigations and studies that should precede the redesign of the structure, as briefly described herein:

- (a) **Documentation of the history of the structure:** It comprises the date of construction, information on construction phases, events that may have affected the structural system (earthquakes, floods, fires, wars, etc.), previous damages and interventions, etc. This phase is of paramount significance especially for cultural heritage structures.
- (b) **Documentation of the structural system:** It comprises the documentation of both the structural system and its current state. The documentation of the structural system includes the survey of the bearing system (bearing elements, their interconnections, path of forces from the region of their application to the Earth), as well as type and properties of materials, construction type of masonry, etc. The documentation of the

current state of the structure includes the survey of its pathology (survey of damage and decay), as well as qualitative interpretation of damage and decay. This step may require in situ and laboratory investigations (destructive and/or nondestructive, depending on the significance of the structure, its state, its future use, the characteristic to be detected, etc.).

- (c) **Diagnosis and assessment:** The input from steps (a) and (b) serves the needs of diagnosis (i.e., the identification of the causes of the observed pathological image) and assessment (i.e., the margins of safety of the structure in its current state). At this step, the structure is adequately modeled and subjected to normal (self weight, live loads, etc.) and to accidental actions (e.g., seismic action) with the purpose to reproduce the main damages of the structure. This is a step of major significance, as it allows for identification of the causes of damage and of the regions of the structure that are vulnerable, for checking the adequacy of modeling, and for assessing the margins of safety of the existing structure.

The output of steps (a) to (c) allows the engineer to select the strategy of interventions, to choose among the available intervention techniques those techniques that serve better the purpose of repair or strengthening of the structure, and to proceed with dimensioning of the interventions.

Depending on the results of the assessment of the existing structure and taking into account the actions that are expected to act on the structure in the future (e.g., change of use, required seismic upgrading of the structure, etc.), one of the following strategies of interventions may be applied:

- (i) **Local interventions to bearing elements:** This strategy is applicable when the bearing system is in principle adequate, whereas local inadequacies are detected in a limited number of bearing elements. The interventions consist in enhancing the bearing capacity or the deformation capacity or the

stiffness or the interconnection of limited number of elements, without major alteration of the bearing system.

- (ii) **Alleviation of irregularities:** This strategy is applicable, when the irregular distribution of masses, stiffnesses, and/or strengths leads to respective excessive requirements in some regions of the structure. In such a case, the alleviation of irregularities (by adding shear walls, by modifying the arrangement of existing bearing walls, etc.) may constitute the best strategy. It should be noted, however, that this strategy may be of limited applicability in the case of cultural heritage structures.
- (iii) **Global enhancement of bearing capacity:** This strategy is adequate when (a) a large number of bearing elements are severely damaged or (b) large inelastic deformations are expected to be imposed to the structure. In such a case, a global enhancement of the bearing capacity of the structure is advisable (strengthening of existing elements and/or addition of new bearing elements). Needless to say, the resulting enhancement of the global stiffness of the structure has to be taken into account.
- (iv) **Global enhancement of stiffness:** This strategy may be selected when the calculations show that the expected deformations are larger than those the (brittle) masonry elements can sustain. If this is the case, global enhancement of stiffness may be achieved by strengthening of the bearing elements and/or by improving the box action of the structure, e.g., by enhancing the diaphragm action of floors. Thus, the deformations to be imposed to the structure are reduced to a level the masonry elements can sustain.
- (v) **Reduction of masses:** This is a strategy that is desirable for structures to be subjected to seismic actions. In case of masonry structures, it may consist in using lighter materials for roof and floor pavements, as well as by reducing live loads (selection of appropriate use of the structure). It should be noted, however, that this strategy does not

lead to spectacular results, as – in the case of masonry structures – their self weight constitutes the most significant part of the vertical loads.

- (vi) **New bearing system:** When the existing bearing system is inadequate for seismic actions, a new bearing system may be constructed inside the existing structure. The new bearing system (e.g., made of reinforced concrete (RC) or steel) is connected to the existing structure, thus contributing to the resistance to seismic actions. This is a strategy applied in some cases to cultural heritage structures, where extensive interventions to the existing bearing system are invasive and, thus, undesirable. It should be noted that, the dimensioning of the new bearing system will be governed by the compatibility of deformations with those of the existing one, rather than by the required additional bearing capacity.

Repair and Strengthening Techniques

The information included in this chapter regards the most commonly applied techniques for the repair and strengthening of existing masonry structures. It should be noted that some of the techniques presented here, although of frequent use, are not sufficiently documented through experimental work or through monitoring of structures after intervention. The research on intervention techniques, as well as on the production, testing, and use of new materials, is ongoing.

The material included in this chapter is organized as follows: (a) Repair and strengthening techniques for masonry as well as for the connection between masonry elements are first presented. The aim of those techniques is to reinstate the pre-damage bearing capacity of individual elements or to enhance their bearing capacity, so that they may sustain seismic actions in the future. Finally, the repair of damage in the connection between masonry elements as well as its strengthening is examined, since the so-called box action of masonry structures strongly

depends on those connections. Subsequently, (b) techniques for the enhancement of the diaphragm action of floors and roofs as well as for their connection with the vertical elements are presented. The purpose of those techniques is, in most cases, not to enhance the bearing capacity of floors and roofs, but to ensure almost equal displacements of all vertical elements and to prevent diaphragms from moving independently of the vertical elements during an earthquake, thus, causing severe damage to the walls. Finally, (c) some indicative solutions frequently applied to cope with problems such as sliding soil or insufficient dimensions of the foundation are briefly presented.

Repair and Strengthening Techniques for Masonry Walls

Deep Rejointing

Deep rejointing consists in the removal of the mortar from the joints to a depth at least equal to the thickness of the joints and filling with a mortar of improved properties. The technique should preferably be applied on both faces of masonry. In order to reach a significant enhancement of the mechanical properties of masonry, and taking into account that the contribution of the mortar to the strength of masonry is rather limited, a large part of the existing mortar has to be replaced. Therefore, this technique may be efficient only when applied to masonry of limited thickness (say 300 mm max.). This limits the applicability of deep rejointing to brick or block masonry, excluding stone masonry walls (of minimum thickness around 400 mm). It has to be noted that rejointing may be needed for reasons other than strengthening (e.g., to avoid water permeability of masonry or to prepare masonry for the application of grouts). In those cases, usually, there is no need for deep rejointing.

The application of the new mortar has to be made very carefully, so that the voids created due to the removal of the existing mortar are fully filled. Furthermore, the new mortar should not be excessively strong compared to the existing one. Otherwise, the compressive stresses on the

Strengthening Techniques: Masonry and Heritage Structures,

Fig. 1 (a) Qualitative interpretation of spalling of masonry units due to defective application of deep rejoining, (b) A brick wall tested in compression after a defective application of deep rejoining (Vintzileou 2001)

exterior (limited in thickness) part of masonry may be excessive (Fig. 1a) and lead to spalling of the masonry units (Fig. 1b). As a result, the compressive strength of masonry may be reduced, instead of being increased.

In conclusion, (a) deep rejoining may be efficient in case of brick masonries, 300 mm thick at maximum, and (b) provided that the technique is applied with due care and using adequate materials, (c) in case of stone masonries, it is not advisable to apply deep rejoining both because it is not expected to contribute to the improvement of the mechanical properties of masonry and because it is a quite expensive technique (mainly in workmanship). Even if applied to stone masonries, deep rejoining is considered as a repair technique, reinstating the initial mechanical properties of masonry.

Grouting of Cracks

This repair technique is applicable to cracks having a width that does not exceed 10 mm approximately:

(a) Preparation of masonry: When masonry is plastered, plaster is removed in the vicinity of the crack. In cases where plaster cannot be removed (e.g., when masonry is covered with paintings or frescoes or mosaics or other decorative elements), special care has to be taken for the protection of the decoration of masonry. For example, it should be

checked whether the frescoes are fixed on masonry. If not, their adequate fixing should precede the application of grout. Furthermore, during the application of grout, special care should be taken for immediate cleaning of the face of masonry, in case of leaking of the grout.

- (b) Holes are drilled to masonry at distances along the crack. The distance of consecutive holes should not exceed the thickness of masonry. Transparent plastic tubes are installed into the holes. Part of the length of the tubes is protruding.
- (c) The crack is sealed along its entire length, using an adequate mortar.
- (d) The materials for the grout (see also section “Generalities”) are mixed and the grout is introduced to the crack from the lower tube until it leaks from the immediately higher up placed tube and so on, until the crack is filled over its entire length. The grout is applied with a pressure not exceeding 1 bar. Depending on the state of the masonry, in order to avoid excessive hydrostatic pressure that might cause further damage to masonry, the crack length to be grouted should be limited within 1 day. For damaged, low strength masonries, this length should be limited to 1 m per day.
- (e) After hardening of the grout, the protruding parts of the tubes are cut and masonry is plastered, if this is the case.

Strengthening Techniques: Masonry and Heritage Structures, Fig. 2 Stitching of wide cracks

Strengthening Techniques: Masonry and Heritage Structures, Fig. 3 Repair of wide cracks by means of reinforced zones (indicative reinforcement)

Stitching of Cracks

In case of almost vertical wide cracks (width exceeding 10 mm), grouting alone cannot lead to reinstatement of the initial strength of masonry. In such a case, stitching of the cracks, prior to grouting, is needed.

Stitching consists in the removal of cracked masonry units along the crack and replacement with new sound masonry units laid in mortar of adequate composition (Fig. 2). If necessary, some of the bed joints along the crack may be locally reinforced. To this purpose, steel plates are inserted in the mortar joints (Fig. 2). The plates are smooth and, hence, of limited bond with the mortar. It is therefore advisable to artificially roughen them.

This technique cannot be applied to masonry walls that are cracked due to shear (diagonal or bi-diagonal cracks), as the removal of cracked masonry units along the cracks is not feasible. In those cases, the wall should be either demolished (and reconstructed) or it should be carefully grouted, provided that its construction type and its state allow grouting (see section “Grouting”).

An alternative, applicable exclusively to buildings without any heritage value, would be that of vertical and horizontal reinforced zones (Fig. 3). Grooves are created in the wall, both horizontally and vertically on both sides of masonry. Steel reinforcement is placed and a mortar of adequate composition or concrete is poured.

Stitching of Vertical Cracks Between Perpendicular Walls

The same technique is applicable to large cracks in the connection of walls. In that case, stones or bricks are removed and replaced by intact ones positioned diagonally (Fig. 4), to connect the two walls.

Alternatively, steel plates can be introduced to mortar joints (Fig. 5), provided that the thickness thereof is large enough for accommodating the plates.

Strengthening Techniques: Masonry and Heritage Structures, Fig. 4 Stitching of vertical cracks between perpendicular walls. Stones 1 and 2 are substituted by stone 3

It should be noted that (a) the separation between the walls is not reversible and (b) the steel plates inserted into mortar joints are passive (i.e., they are mobilized in case further relative displacement of the walls takes place). Therefore, the cracks – after stitching – have to be grouted.

Grouting

Generalities Grouting of masonry (termed also as “homogenization” of masonry) consists in filling all voids and cracks within the mass of masonry using a hydraulic mixture. Organic binders (mainly epoxy resin) are not in use for masonry; the exothermal reaction of their hardening, combined with the (quite often) large voids within the mass of masonry may lead to disintegration of the epoxy resin-based grout before the application of any actions to the building. Furthermore, due to the dust present in the mass of masonry, the bond between the grout and the in situ materials may be defective. Finally, due to durability considerations, organic binders are excluded. It should also be noted that hydraulic grouts, even of low to medium mechanical properties can ensure significant enhancement of the mechanical properties of masonry (e.g., Binda et al. 1994; Valluzzi 2004; Vintzileou and Miltiadou-Fezans 2008), thanks to their high bond with the in situ materials.

A special mention needs to be made here of cement-based grouts (with a cement content exceeding 50 % per weight). Although they

Strengthening Techniques: Masonry and Heritage Structures, Fig. 5 Steel plates accommodated in horizontal mortar joints for stitching cracks

Strengthening Techniques: Masonry and Heritage Structures, Fig. 6 Grid of holes in a masonry wall to be grouted

constitute the first application of grouts to masonry, the experimental work carried out in several countries (Vintzileou and Tassios 1995; Toubakari 2002) has proven that cement-based grouts are not more efficient than ternary grout (cement content of approximately 30 % per weight, lime (and additives)) or hydraulic lime-based grouts. Furthermore, several cases of durability problems due to the use of cement are reported (e.g., efflorescence). Thus, in the recent years, the use of cement-based grouts is very limited, if not fully abandoned.

The Design of the Grout Hydraulic grouts injected into masonry have to comply with a set of requirements, namely, rheological (injectability, i.e., penetrability into fine cracks and voids, according to the design, and sufficient fluidity for the grout to be diffused into masonry, as well as stability), physical (low hydration heat, limited shrinkage, adequate hardening time, and hygroscopic properties), chemical (e.g., resistance to expansion and chemical stability of the products of chemical reactions), and mechanical requirements that are related to the desirable

mechanical properties of the grouted masonry (i.e., strength and deformability characteristics), depending on the actual state of masonry, the actions to be imposed, the overall scheme of interventions, etc.

Therefore, the design of a grout requires sufficient knowledge on the construction type of masonry, on its state, on the in situ materials, and on the aim of the intervention, all these combined with knowledge on material science.

Preparation of Masonry, Mixing of Grout, and Application The preparation of masonry for grouting is similar to that described in section “[Grouting of Cracks](#).” Holes are drilled to masonry at distances, forming a grid. In the general case of application of grouts from both faces of masonry elements, holes are drilled on both faces of masonry. As shown in Fig. 6, the holes on the interior face of masonry are drilled halfway between consecutive holes drilled on the exterior face of masonry. Thus, the resulting grid of holes is dense and it ensures better filling of the internal voids and cracks. The holes should be drilled deep enough (Fig. 7) to reach the core of

Strengthening Techniques: Masonry and Heritage Structures, Fig. 7 Drilling holes in masonry

masonry, thus ensuring that the grout will fill all the internal voids and cracks. Transparent plastic tubes are installed into the holes (Fig. 8) with an inclination toward the bottom of the element (to facilitate the flow of the grout). The (horizontal and vertical) distance between consecutive tubes may vary between 0.5 m and 1.0 m. However, it should in no case exceed the thickness of the elements to be injected.

The plastic tubes are numbered and reported on a drawing (Fig. 8). This is of major importance, because it allows for full control of the application procedure (tubes from which the grout is introduced and those from which the grout overflows are marked during the injection). All cracks are sealed (Fig. 9).

The materials to be used for the production of the grout should be available at the vicinity of the region to be injected, together with the mixer (Fig. 10). The use of high turbulence mixer is recommended, to provide adequate mix of the materials. After mixing of the constituent materials, the grout is transferred to a transparent

tube (Fig. 11), equipped with a device that provides a mechanical stirring of the grout during application (to avoid segregation).

When the preparation of masonry is completed (Fig. 12) and the grout mix is ready, the grout is applied with low pressure from the bottom to the top of masonry. The consumed quantity of grout is recorded. This is a very significant piece of information; it is taken into account when the enhanced mechanical properties of masonry are estimated.

Masonry is cured (kept wet) during the entire procedure that may last for several days, depending on the size and state of the injected element.

Reinforced Plaster

This is a technique applicable to masonry of limited thickness (not exceeding 0.40 m). It is applied after repair of masonry (by grouting or by stitching of cracks, by rejoining masonry, etc.). Reinforced plaster should preferably be applied on both sides of masonry. Actually, it is beneficial especially against out-of-plane bending, and, therefore, either the interior plaster or the exterior one is mobilized (in tension) depending on the direction of the seismic action.

The plaster is removed and masonry is cleaned from any loose material. The (metallic or nonmetallic) grid of reinforcement is placed on the faces of masonry and fixed on it (using anchors). In order to achieve better bond of the reinforced plaster, it is advisable to remove the mortar from the joints as deep as possible and fill them during the application of the plaster. In case of metallic reinforcement (steel grid), the plaster is usually a cement-based one. In case of nonmetallic reinforcement (e.g., fiber-reinforced wires or bars), the plaster can be a hydraulic lime + pozzolan mortar.

Recently, fiber-reinforced mortars are also applied to masonry.

It should be noted that the use of reinforced plasters may not be advisable in the case of cultural heritage assets, where masonry is quite thick, and the application of the reinforced plaster may be possible only on the interior face of masonry (therefore, in its least efficient position).

Strengthening Techniques: Masonry and Heritage Structures, Fig. 8 Plastic tubes installed into drilled holes. Tubes are numbered and reported to drawings

Local Demolition and Reconstruction

In case of local collapse of walls or in case of partial collapse of the exterior leaf of a double- or three-leaf masonry or in case of significant out-of-plane displacement of a wall (Fig. 13), the only solution is the reconstruction of the part that has collapsed or undergone significant deformations.

Needless to say, reconstruction is usually combined with repair or strengthening techniques described in the previous paragraphs (e.g., grouting of three-leaf masonry, stitching of

large cracks in other than the collapsed regions of the building, etc.).

Strengthening of Walls Using FRP Rods, Laminates, or Sheets

The use of FRPs in strengthening (bearing and infill) masonry is quite extensive in the recent years. FRPs with various types of fibers and in various forms (rods, laminates, or sheets) are used for strengthening masonry walls (Fig. 14) either against out-of-plane (bending) or in-plane (shear) actions.

The use of FRP materials is supported by extensive experimental research (collected, e.g., in Morbin 2001; Rashadul 2008), whereas models for the dimensioning of the intervention are also proposed (e.g., Faella et al. 2004;

ElGawady 2005). The available experimental data prove that the technique is quite efficient in enhancing the bearing capacity of masonry, as well as its ductility, provided that a good bond with the substrate (masonry) is ensured.

The technology of FRP applications is not presented in detail in this text for several reasons, namely, (a) most of the tests available in the Literature refer to monotonic loading of masonry specimens; in a limited number of cases, also repeated loading (without change of sign) or cyclic loading (e.g., Grillo 2003, on concrete masonry) was applied to the specimens. On the other hand, (b) in laboratory tests, masonry walls are subjected either to out-of-plane bending or to in-plane shear. However, during an earthquake, masonry walls are subjected to cyclic actions, as well as to simultaneous in-plane and out-of-plane actions. This is a very adverse condition which is not sufficiently covered by the international Literature. The problem that may arise is

Strengthening Techniques: Masonry and Heritage Structures, Fig. 9 Sealing of cracks

Strengthening Techniques: Masonry and Heritage Structures, Fig. 10 Materials for preparation of the grout mix. High turbulence mixer

a premature de-bonding of the FRPs from the substrate with subsequent loss of the strengthening of the walls. Furthermore, (c) fire protection of the intervention is an issue. Another issue that

Strengthening Techniques: Masonry and Heritage Structures, Fig. 11 Device for mechanical mixing of the grout before application

needs to be very carefully examined is (d) whether, after the occurrence of damage in FRP strengthened masonry, its repair or strengthening is still possible. Actually, as proven by tests, the failure of FRP strengthened walls – even under monotonic actions – may be associated with extensive cracking and disintegration of masonry. Especially in the case of historic masonry, for which the possibility to re-intervene after a seismic event is a prerequisite, this aspect may be governing. Last but not least, (e) there are limited data regarding strengthening of historic masonry using FRP materials. It is questionable whether poor-quality (double-leaf or three-leaf) stone masonry, having very low elastic properties, can be strengthened using high-strength and low-deformability materials. In such a case, prior strengthening of masonry using “traditional” techniques would be required, whereas the issue of compatibility of the in situ and added materials should be carefully examined. For example, the application of FRP sheets, covering large portions of masonry elements, may create problems of building physics (e.g., entrapment of humidity in the mass of masonry walls), thus leading to decay of the covered masonry. Another example would be that of inserting FRP rods in (horizontal and vertical) mortar joints. Even if the practical difficulties in finding

Strengthening Techniques: Masonry and Heritage Structures, Fig. 12 Masonry walls ready for the application of grouts

Strengthening Techniques: Masonry and Heritage Structures, Fig. 13 (a) collapse of the corner of a building, (b) partial collapse of the exterior leaf of

a three-leaf masonry wall, (c) significant out-of-plane displacement of a masonry wall

Strengthening Techniques: Masonry and Heritage Structures, Fig. 14 Alternative configurations of FRPs for masonry strengthening (schematic)

continuous bed joints in rubble stone masonries, the fact that grooves should be created to insert vertical FRP rods, and the difficulties in anchoring the rods at the top and at the base of a wall, as well as into transverse walls, are neglected, the problem remains of the behavior of rather soft original mortar joints that are partially filled with a (by orders of magnitude) stronger material. In real buildings, where the wall will be subjected to simultaneous cyclic shear and cyclic out-of-plane

bending, there is a danger of stress concentration in the reinforced portions of the masonry section. The stress concentration may lead to spalling of the masonry units and to subsequent adverse effects on the bearing capacity of the masonry element (comp. with Fig. 1). Moreover, (f) in case of historic buildings, the application of FRPs may be not be acceptable, as it alters the appearance of (unplastered) masonry. Thus, although the application of FRPs seems to be a technically

Strengthening Techniques: Masonry and Heritage Structures, Fig. 15 Typical damages due to out-of-plane bending of walls

promising intervention, it is believed that this technique should be applied with caution for strengthening masonry buildings that are to be subjected to seismic actions. It is believed that the (under investigation) use of inorganic bonding material (mortar) instead of an organic one (resins) may be a sensible alternative.

Enhancement of the Box Action of Masonry Buildings

Introductory Remarks

It is well known that masonry is a brittle material; it reaches its maximum resistance at small deformation value, whereas an abrupt decrease of its resistance takes place for imposed deformations exceeding the deformation corresponding to the maximum resistance. The vulnerability of existing masonry buildings to large deformations imposed by an earthquake is due to various typical construction features, namely, the defective connection of walls among them, the flexibility of floors and roofs, the large openings (especially when located close to the corners of the building), the large distance between transverse walls, etc. All measures taken with the purpose of alleviating those sources of vulnerability contribute to an improved seismic behavior of masonry. Last but not least, all the techniques that improve the box action of masonry buildings lead to an

increase of their stiffness and to subsequent reduction of their natural period. In this way, the building “moves” to the left region of the response spectrum and, hence, to lower seismic actions.

Enhancement of the Diaphragm Action of Floors and Roofs

In existing masonry buildings, typically, timber floors and roofs are simply resting on vertical elements (walls or piers). Furthermore, due to the flexibility of floors and roofs in their plane, masonry walls are quite vulnerable to out-of-plane bending (Fig. 15). Under such actions, vertical cracks close to the connections between longitudinal and transverse walls, as well as out-of-plane collapse of portions of walls, constitute typical damages of masonry buildings.

The enhancement of the diaphragm action of floors and roofs leads to almost equal deformations of all vertical elements, thus limiting the out-of-plane vulnerability. Thanks to the overall increase of the stiffness of the building, the imposed deformations are also significantly reduced.

There are several techniques for the enhancement of the diaphragm action of floors and roofs. The Engineer has to select those most appropriate for each specific case and document (through analysis) the efficiency of the selected techniques.

Strengthening Techniques: Masonry and Heritage Structures, Fig. 16 Enhancement of the diaphragm action of a floor, arrangement of transverse beams connected to the existing ones (schematic)

Strengthening Techniques: Masonry and Heritage Structures, Fig. 17 Arrangement of steel ties for the enhancement of the in-plane stiffness of a floor (schematic)

Some of the possible alternatives are briefly presented herein:

- (a) Providing transverse beams to the existing floor: Typically, in existing structures, floors consist of beams spanning in one direction (normally, the smaller of the two). The in-plane flexibility of the floor can be reduced by arranging (timber or steel) beams perpendicular to the existing ones (Fig. 16), thus forming a grid. It should be noted that the cross-sectional dimensions of the transverse beams, their spacing, and the dimensioning of their connections to the existing members are to be determined for each specific case. Similarly, in case of a trussed roof, beams perpendicular to the existing trusses can be arranged.
- (b) Providing a system of bi-diagonal steel ties: Significant enhancement of the in-plane stiffness of a floor (or roof) can be achieved by arranging steel ties along the two diagonals of the floor (Fig. 17). A system of multiple ties may be needed in the case of rectangular floors, in which one in-plan dimension is significantly larger than the other. As in the previous case, the ties (adequately connected to the existing floor beams or to the existing trusses of the roof) are to be adequately dimensioned. It should be noted that, typically, ties should be dimensioned to develop a tensile stress not exceeding 50 % of their yield strength, in order to avoid excessive strains of the steel elements and, hence, avoid significant in-plane deformations of the floor.
- (c) Providing a second pavement: In the frequent case of a timber pavement of floors and roof, significant enhancement of the in-plane stiffness can be reached through a second pavement. This second pavement can be located either on top of the existing one or at the bottom of the beams (to avoid changes in the height of the story). The second pavement should be either perpendicular to the existing one or, preferably, arranged at an angle of 45° (Fig. 18). In this case too, the Designer should check the efficiency of the solution through modeling and analysis of the structure.
- (d) Alternatively, instead of providing a second pavement, the in-plane stiffness of the floor may be enhanced by arranging bi-diagonal FRP laminates (Fig. 19). This alternative solution should be applied with caution: The efficiency of the FRP plates depends on their bond with the existing pavement. The simultaneous flexural (due to vertical loads) and in-plane (due to seismic actions) deformations of the floor may lead to detachment of FRP laminates from the substrate. In such a case, the efficiency of the intervention may be significantly reduced.
- (e) Replacement of the existing floors and roof by reinforced concrete slabs: This alternative, quite popular in previous decades, is

Strengthening Techniques: Masonry and Heritage Structures, Fig. 18 Existing timber pavement and additional timber pavement at an angle of 45°

Strengthening Techniques: Masonry and Heritage Structures, Fig. 19 FRP laminates glued on the existing pavement (schematic)

nowadays of rather limited application. Actually, it is rather invasive in case of cultural heritage buildings and, thus, not accepted by the competent authorities. Furthermore, recent research (Zaopo 2011; Mazzon et al. 2009; Magenes et al. 2012; Mouzakis et al. 2012) on floors stiffened using several alternative techniques, as well as shaking table tests on model buildings, has proven that solutions (a) to (d) provide sufficient in-plane stiffness to the floor, and, hence, the replacement of the existing floors and roofs with RC slabs is not inevitable.

When this alternative is selected, adequate connection of the RC slab with the walls should

be ensured. To this purpose, one of the following two techniques may be applied: (i) Grooves are made in masonry walls at distances (Fig. 20), steel reinforcement is positioned, and the grooves are filled with concrete, during the construction of the slab. The spacing, the dimensions, and the reinforcement of the grooves are determined so that they are able to transfer the shear (due to the design seismic action) from the slab to the walls. The respective resistance of masonry should also be checked, (ii) steel beams are positioned along the masonry walls (Fig. 20), and they are fixed onto masonry. The RC slab is supported by the steel beams. In this case too, the connection of the steel beams to masonry walls should be adequately dimensioned.

Independently of the alternative selected for the enhancement of the in-plane stiffness of floors and roofs, there are two prerequisites for the efficiency of the solution, namely, (i) adequate connection of the diaphragm to masonry walls should be ensured and (ii) the supporting masonry walls should be adequately repaired or strengthened. Actually, a very stiff diaphragm not connected to masonry walls may be displaced as a rigid body during the earthquake, causing damage to the masonry walls. If the stiff diaphragm is connected to masonry walls made of unstrengthened poor-quality masonry, catastrophic damage may occur (Fig. 21).

Figure 22 shows the connection between floor and walls provided to a building model tested on

Strengthening Techniques: Masonry and Heritage Structures, Fig. 20 Alternative connections of RC slabs to masonry walls (schematic)

Strengthening Techniques: Masonry and Heritage Structures, Fig. 21 Catastrophic effects of RC slabs supported by poor-quality masonry (Courtesy of Prof. C. Modena)

the earthquake simulator (Mouzakis et al. 2012). The diaphragm action of the floor was enhanced as shown in Fig. 18, and the walls (made of three-leaf masonry) were grouted. The connection was proven to be efficient, and no damage was caused to masonry walls even for an input acceleration exceeding 1g.

Improving the Connection Between Floors/Roofs and Vertical Elements

Frequently, in existing masonry buildings, roof and floors are simply resting on masonry walls. Thus, the vertical loads (the self weight of floors

and roof, the weight of pavements, as well as the live loads of the building) are concentrated at intervals. In case of poor-quality masonry, this may lead to local damage. Furthermore, during an earthquake, the floors are moving rather independently from the vertical masonry elements, thus, causing damage to the walls at their top (Fig. 23). Finally, the out-of-plane deformation of the walls is not prevented, due to loose connection with the horizontal elements. For all those reasons, it is desirable to provide better connection between horizontal and vertical elements.

Strengthening Techniques: Masonry and Heritage Structures,
Fig. 22 Detail of the connection between diaphragm and masonry walls. The building model after strengthening

Strengthening Techniques: Masonry and Heritage Structures,
Fig. 23 Damaged masonry walls due to the movement of simply supported roof

The improvement of the connection between horizontal and vertical elements can be achieved as follows:

- (1) Arrangement of a timber or a steel beam in the perimeter of floors and roof (Fig. 24) and

connection of the (timber or steel) beams of the floor with the collector beam. Although the beam shown in Fig. 24 was positioned during construction, it is feasible to provide a collector beam during interventions as well, by creating a recess in masonry walls. Floor

Strengthening Techniques: Masonry and Heritage Structures,
Fig. 24 The timber beams of the floor are connected to a perimeter collector beam

beams or roof trusses have to be connected to the collector beam, which should be connected to the walls (Fig. 22).

- (2) When the roof is replaced or temporarily removed during interventions, a reinforced concrete tie beam can be constructed at the top of the upper floor walls. Usually, the width of the RC tie beam is equal to the thickness of the walls. However, in case there are decorative elements on the facade (to be restored after interventions) or the accommodation of insulation is needed, the width of the RC tie beam can be adequately reduced. The construction of the RC tie beam is also possible after temporary shoring of the roof, if the roof is not to be replaced. The construction of the tie beam with the roof in its place is not encouraged, although it is technically feasible.

The tie beam may be connected to masonry using anchors. The diameter, the length, and the spacing of the anchors should be adequately designed. It should be noted that the construction of RC tie beams in intermediate floors is not recommended because (a) it is a quite invasive intervention and (b) the RC tie beam will inevitably be of limited width. Thus, its connection to the beams of the floor and to the walls should be ensured in a way similar to that described in the

previous paragraph (1), where all the application is dry and (c) durability problems may arise due to the continuous contact of timber elements and concrete.

Improving the Connection Between Walls

The significance of the adequate connection between walls was known to the constructors of masonry buildings. This is proven by the use of better quality, large-size cut stones in the corners of the buildings, even in the case of rather poor general construction quality (Fig. 25).

Nevertheless, the insufficiently stiff in their plane floors and roofs that are simply supported on the walls do not prevent damage due mainly to out-of-plane bending of walls and piers (Fig. 16).

It should be noted that, if enhancement of the diaphragm action of floors and roofs and adequate connection thereof with the walls is provided, further improvement of the connection between walls may not be needed. Actually, in such a case, the walls do behave as vertical slabs fixed along their perimeter, and their vulnerability to out-of-plane actions is significantly reduced. Nevertheless, if further improvement of the connection between walls is needed, steel ties can be used. The use of ties for the connection between walls was quite common during the construction of the existing masonry buildings.

Strengthening Techniques: Masonry and Heritage Structures, Fig. 25 Elaborate connection between walls at the corners of masonry buildings

Strengthening Techniques: Masonry and Heritage Structures, Fig. 26 The metallic tie (of limited length) was not able to prevent the out-of-plane collapse of the wall

In that case, the ties (of limited length) were arranged within the thickness of one wall and anchored on its transverse wall (Fig. 26).

Steel ties provided as an intervention to improve the connection between walls are not embedded in masonry. They are (preferably) arranged at both sides of a wall or only along the interior face of a wall. They may be arranged in one single level or in more levels, provided that the height of the story allows for more ties to be positioned. Ties may be provided along one or both main axes of the building.

The ties are usually passive (i.e., non-prestressed). Therefore, they are expected to be mobilized only in case differential movement of the two connected walls takes place. In case wall A (Fig. 27) tends to separate from walls C and D, the ties should be able to develop a tensile force sufficient to sustain wall A in its

position. The ties are dimensioned so that their tensile stress does not exceed 50 % of their yield strength, in order to avoid excessive deformations when they are mobilized. Special care should be taken for their anchorage on masonry. The dimensions of the anchoring plates should allow (a) for almost uniform distribution of the compressive stresses on masonry and (b) for sufficiently small compressive stresses on masonry, to avoid local crushing.

The use of FRP ties as an alternative to steel ties is not encouraged. Although FRPs have a very high tensile strength (compared to normal steel) and they may have very high modulus of elasticity (which could prevent the occurrence of large deformations), they are characterized by complete lack of ductility. Therefore, if deformations larger than their deformation at failure occur, their fracture will be imminent.

Strengthening Techniques: Masonry and Heritage Structures, Fig. 27 Arrangement of steel ties to improve the connection between walls (schematic)

Arches, Vaults, and Domes

In old masonry structures, arches (Fig. 28) were constructed to bridge openings in buildings (Fig. 28 a, b, f) and river bridges (Fig. 28g), to transfer loads from domes to masonry piers, and so on, whereas vaults and domes (Fig. 28c, d, e, f) are frequently used to bridge large spans. In most of cases, stone or brick curved elements can safely bear the vertical loads for which they were conceived and constructed. Damage may be due to excessive vertical loading resulting, for example, from inadequate use (Fig. 29) or due to the lack of maintenance and repair (Fig. 28e).

In cases of damage due to excessive loads or to decay, simple repair is sufficient. Repair may include local reconstruction, grouting, or stitching of cracks, as described in section “[Repair and Strengthening Techniques for Masonry Walls](#).”

It should be noted, however, that most of the damages of curved elements are due to the effects of the thrust. It is well known that the loads are transferred from the curved elements to their supports following a thrust line; the thrust line is oblique when it reaches the supports. Therefore, there is a horizontal component of the thrust that causes horizontal displacements to the supporting elements. In the (quite frequent) case of flexible supports, outwards moving vertical elements may be damaged and induce damage to the curved

elements as well. This phenomenon is accentuated in the case of seismic events.

A typical example of the aforementioned damage is presented in Fig. 30: The cupola itself remained undamaged. However, all piers of the drum failed (some of them in shear, others in out-of-plane bending). Due to the out-of-plane deformations of the piers, the supporting arches have failed. The horizontal component of the thrust of the arches has pushed the vertical elements apart, resulting to out-of-plane displacements of the walls exceeding 0.10 m (observe the deformed shape of the monument in Fig. 30).

It is, therefore, of major importance to take measures for the reduction of the effects of thrust, by applying the techniques described in the following.

Ties and Struts

This is a typical efficient measure to reduce the effect of thrust. The technique was applied in masonry structures either during construction or as a remedial measure during previous interventions (Fig. 31). The technique consists in providing at the base of the curved element horizontal ties that can sustain the horizontal component of the thrust. The ties (made of steel or stainless steel or titanium, depending on the case) are anchored to transverse elements. For the maximum acceptable stress in the ties, as well as for their anchorage to masonry, the rules presented in section “[Improving the Connection Between Walls](#)” are valid.

When the structure is subjected to seismic action, there is a cyclic (inwards/outwards) movement of the vertical supporting elements. Therefore, in addition to the ties, elements functioning in compression (struts) should also be provided. In old structures, quite frequently, timber elements were used, able to play the double role of strut and tie (due to their sufficient resistance in buckling). This solution can be applied in modern interventions as well. Alternatively, the solution shown in Fig. 32 (adopted for interventions to Dafni Monastery, Miltiadou et al. 2012) can be chosen: A timber compression element is provided. A hole is drilled at the core of the

Strengthening Techniques: Masonry and Heritage Structures, Fig. 28 Arches, vaults, and domes

timber element and a steel tie is accommodated. The tie is anchored on masonry.

Steel or FRP Ties in the Perimeter of the Curved Elements

This is a technique frequently applied at the base of cupolas, as well as at the base of their

drum (Fig. 33). The ties (made either of steel or FRP) are designed to sustain the horizontal component of the thrust. It has to be noted, however, that they do not lead to any reduction in the flexibility of the system. Therefore, their application is useful but, quite often, not sufficient for the protection of the curved elements.

Strengthening Techniques: Masonry and Heritage Structures, Fig. 29 Partial collapse of the bridge after the passage of a heavy track

Strengthening Techniques: Masonry and Heritage Structures, Fig. 30 The main church of Dafni Monastery (Greece) damaged due to the 1999 earthquake

Buttresses

This is a technique applied also in the past (Fig. 34): The flexible vertical elements

supporting a vault or a dome are stiffened by an external buttress. Thus, the out-of-plane deformations of the supporting elements are

Strengthening Techniques: Masonry and Heritage Structures, Fig. 31 Arches with timber ties

Strengthening Techniques: Masonry and Heritage Structures, Fig. 32 The timber strut/steel tie solution was tested in-laboratory and adopted for application to the monument (Dafni Monastery)

Strengthening Techniques: Masonry and Heritage Structures, Fig. 33 Dafni Monastery: existing steel tie at the base of the cupola, to be replaced by a stainless steel tie

Strengthening Techniques: Masonry and Heritage Structures, Fig. 34 (a) Ossios Lucas Monastery: external stone masonry buttresses were added against the southern facade. Due to architectural constraints, the buttresses do not reach the critical region of the system of arches that support the cupola. (b) Dafni Monastery:

during the extensive interventions of the early twentieth century, a pair of stone masonry buttresses was constructed against the northern wall of the church. This technique was not repeated against the southern wall (where the courtyard is located)

Strengthening Techniques: Masonry and Heritage Structures, Fig. 35 Dafni Monastery: steel diaphragms to be constructed on top of the system of vaults; they will be covered by a timber pavement

significantly reduced, and damage is avoided or significantly reduced.

It is obvious that in many cases, the construction of external buttresses, although a mechanically efficient solution, cannot be adopted either because there is no space for them to be accommodated or because the appearance of the structure is significantly altered.

Enhancing the Diaphragm Action of Vaults and Domes

This is an alternative solution applicable when diaphragms (metallic or wooden ones) can be

arranged either under the curved elements or on top of them, when the curved elements are visible from the interior of the building. In this way, the effects of the thrust are minimized and both the curved elements and their supporting vertical elements are protected. This solution was adopted also in the case of Dafni Monastery (Fig. 35).

Modification of the Structural System

If the existing bearing system proves to be inadequate to resist seismic actions or if the new use of the structure requires higher performance (e.g., a residential building is given the use of a cultural

Strengthening Techniques: Masonry and Heritage Structures, Fig. 36 Interventions to foundation

Strengthening Techniques: Masonry and Heritage Structures, Fig. 37 Micro-piles

center), there may be a need for drastic interventions, such as construction of additional bearing elements, closing of openings with masonry, etc. In such cases, the construction of a new bearing system in the interior of the existing structure may be envisaged. When this alternative is selected, usually the new bearing system is made of steel. It should be noted, however, that for the new added system to assist the existing one in sustaining seismic actions, the former has to be connected with the original structural members. Moreover, the two systems have to be compatible from the deformation point of view; otherwise, the new added system may cause damage to the

original one (due to pounding). Therefore, in the design of the new system, deformations (rather than forces) may be the governing parameter.

Strengthening of the Foundation

Interventions to the foundation are needed when the mass of the structure is significantly increased due to the interventions or due to the change of use (higher live loads or heavier pavements, etc.). There are also cases of interventions needed when there are damages in the building due to sliding or differential settlements. The interventions to the foundation consist usually in increasing the dimensions of foundation walls using

masonry or reinforced concrete (Fig. 36), depending on the case.

When the properties of the foundation soil are such that a deep foundation is needed, micro-piles (Fig. 37) constitute a good solution. In the case of buildings in regions of archaeological interest, it should be made sure – before the application of micro-piles – that there are no ruins of older structures under the foundation of the building under examination.

Summary

Techniques that are commonly applied either to reinstate or to enhance the bearing capacity of masonry, and masonry components and masonry buildings are briefly presented and commented upon. This text comprises techniques aiming at (a) reinstating the mechanical properties of masonry (such as rejoining, grouting and stitching of cracks, etc.), (b) enhancing the mechanical properties of masonry (such as grouting of masonry, reinforced plaster), (c) improving the overall behavior of a masonry building (such as enhancement of the diaphragm action of floors and roof, improved connection between horizontal and vertical elements, etc.), and (d) improving the foundation conditions of the building. The techniques presented herein are, in principle, applicable to existing masonry buildings independently of their architectural, historical, and cultural values. There are, however, some cases – indicated in the text – where intervention techniques have to be applied with caution, when a heritage building is to be repaired or strengthened.

Seismic actions; Structural

Introduction

The design of structures to resist earthquake effects in Australia and New Zealand follows the pertinent Australian Standard AS 1170.4:2007 and New Zealand Standard NZS 1170.5:2004 provisions. Both Standards are based on the common Australian/New Zealand Standard AS/NZS 1170:2002 on structural design actions; and although they share elements such as the site subsoil classification system, they incorporate certain provisions such as the near-fault factor in NZS 1170.5:2004 to account for the different seismotectonic regime of the two countries. Indeed, Australia is an area of generally low seismicity, with the most catastrophic recent event being the 1989 Newcastle earthquake of magnitude $M = 5.6$, which resulted in 13 casualties and significant damages in the wider Newcastle area. On the other hand, New Zealand is

located on the boundary between the Indo-Australian and Pacific Plate and suffers from frequent strong earthquakes. In fact, New Zealand is one of the first countries to account for seismic actions in a building standard; as early as 1935, and following the 1931 Hawke's Bay earthquake that claimed 256 lives, the NZS 95 provided seismic loads to be considered in design (McRae et al. 2011). Despite constant advances and amendments in the seismic standards over the years, the recent 22 February 2011 Christchurch earthquake of magnitude $M = 6.3$ resulted in 185 casualties, numerous injuries, and extensive damages in the central business district of Christchurch and its eastern suburbs.

The purpose of this entry is to provide an outline of the seismic design actions currently considered in the abovementioned Standards and a short discussion on the rationale behind their adaptation, in the light of other widely used modern seismic codes provisions, such as the Eurocode 8 EN-1998-1 and the American ASCE/SEI 7-10. It covers the determination of elastic and inelastic design response spectra to be used together with static and dynamic analysis methods, as well as scaling of strong motion recordings according to NZS 1170.5:2004 to perform time history analyses. Emphasis is put on the determination of the input rather than on the provisions about the performance of equivalent static, modal, and time-domain analyses, which can be found elsewhere, including the Standards themselves.

Elastic Response Spectra

The elastic response spectra for horizontal loading, $C(T)$, can be described by the following generic equation, compatible with both Standards:

$$C(T) = C_h(T) \cdot (Z \cdot R) \cdot N(T, D) \quad (1)$$

where $C_h(T)$ is the spectral shape factor, $Z \cdot R$ is the product of the hazard factor Z times the factor R that depends on the annual probability of exceedance of the design earthquake and the

Structural Design Codes of Australia and New Zealand: Seismic Actions, Fig. 1 Spectral shape factor (5 % damping) plots for (a) AS 1170.4:2007/equivalent

static analyses, (b) AS 1170.4:2007/dynamic analyses, (c) NZS 1170.5:2004/equivalent static analyses, (d) NZS 1170.5:2004/dynamic analyses

design limit state (ultimate or serviceability) under consideration, and $N(T, D)$ is the near-fault factor, applicable only to the NZS 1170.5:2004. The parameters comprising the elastic response spectra equation are presented in the following paragraphs.

Spectral Shape Factor for Different Subsoil Classes

The spectral shape factors $C_h(T)$ to be used for equivalent static analyses and for dynamic (modal and time history) analyses are plotted separately in Fig. 1, while the relevant functions are provided in Table 1 for the different site subsoil classes. These spectral shape factors correspond to 5 % structural damping, and a correction factor to convert them to other damping values is not provided as, e.g., in EN-1998-1. However, such

a provision would be of value only for special structures such as tanks containing liquids, which are not within the scope of the specific Australian and New Zealand Standards.

As mentioned in the Introduction, Australian and New Zealand Standards share a common site classification scheme, which is preferably based on the predominant site period (or low amplitude natural period) of the site T_s , estimated as:

$$T_s = 4H_s/V_s \tag{2}$$

where H_s is the depth to the seismic bedrock of the site and V_s is the shear wave velocity of the overlying soil layer. In the absence of sufficient data to estimate the predominant site period, the site can be classified to one of the five subsoil classes (A to E) using (in the order of most preferred to least

Structural Design Codes of Australia and New Zealand: Seismic Actions, Table 1 Spectral shape factor (5 % damping) for different site subsoil classes

Site subsoil class	Equivalent static method			Dynamic analyses methods		
	Structure period, T (sec)	AS 1170.4:2007	NZS 1170.5:2004	Structure period, T (sec)	AS 1170.4:2007	NZS 1170.5:2004
A	$0 < T \leq 0.1$	2.35	1.89	$0 < T \leq 0.1$	$0.8 + 15.5 T$	$1.0 + 1.35(T/0.1)$

	$3 < T$		$9.96/T^2$	$3 < T$		$9.96/T^2$

preferred): borehole log data together with in situ and laboratory tests, seismological methods including strong motion recordings (Nakamura 1989; Bouckovalas et al. 2002), qualitative borehole log descriptions, and geological information for the site. For layered sites, the site period can be estimated via an averaging method described in AS 1170.4:2007 and NZS 1170.5:2004.

The five different subsoil classes are defined in the Standards as follows (AS 1170.4:2007, NZS 1170.5:2004):

Class A: Strong rock. Strong to extremely strong rock, with:

- Unconfined compressive strength greater than 50 MPa, and

Structural Design Codes of Australia and New Zealand: Seismic Actions, Table 2 Maximum depth limits for site subsoil class C (After AS 1170.4:2007, NZS 1170.5:2004)

Soil type and description		Representative undrained shear strength, S_u (KPa)	Representative SPT N -values	Maximum depth of soil (m)
Cohesive soils	Very soft	<12.5	–	0
	Soft	12.5–25	–	20
	Firm	25–50	–	25
	Stiff	50–100	–	40
	Very stiff to hard	100–200	–	60
Cohesionless soils	Very loose	–	<6	0
	Loose dry	–	6–10	40
	Medium dense	–	10–30	45
	Dense	–	30–50	55
	Very dense	–	>50	60
	Gravels	–	>50	100

- (b) An average shear wave velocity over the top 30 m $V_{s,30} > 1500$ m/s, and
- (c) Not underlain by materials having a compressive strength less than 18 MPa or a shear wave velocity less than 600 m/s

Class B: Rock. Rock, with:

- (a) Unconfined compressive strength between 1 MPa and 50 MPa, and
- (b) An average shear wave velocity over the top 30 m $V_{s,30} > 360$ m/s, and
- (c) Not underlain by materials having a compressive strength less than 0.8 MPa or a shear wave velocity less than 300 m/s

A surface layer of no more than 3 m depth of highly weathered or completely weathered rock or soil material may be present in a class B site. It should be mentioned here that, based on the average shear wave velocity over the top 30 m criterion, other seismic codes such as EN-1998-1 or ASCE/SEI 7-10 would classify a site with $V_{s,30} > 360$ m/s to dense/stiff soil deposits, rather than rock (class B according to EN-1998-1, which corresponds to $360 < V_{s,30} < 800$ m/s, and class C according to ASCE/SEI 7-10, which corresponds to $366 < V_{s,30} < 762$ m/s). This suggests that class B in AS 1170.4:2007 and NZS 1170.5:2004 is rather broad, covering a range of subsoil conditions that may not exhibit similar behavior during an earthquake rich in high- to medium-frequency content (Bouckovalas and Kouretzis 2001).

Class C: Shallow soil sites. Sites that are not classified as class A, class B, or class E:

- (a) The predominant site period estimated as above is $T_s \leq 0.6$ s, or
- (b) Soil depth does not exceed the maximum values listed in Table 2.

Class D: Deep or soft soil sites. Sites that are not classified as class A, class B, or class E; and:

- (a) The predominant site period estimated as above is $T_s > 0.6$ s, or
- (b) Soil depth exceeds the maximum values listed in Table 2, or
- (c) Sites that are underlain by less than 10 m of cohesive soil with undrained shear strength $S_u < 12.5$ KPa or cohesionless soil soils with SPT values $N < 6$.

Class E: Very soft soil sites:

- (a) More than 10 m of very soft cohesive soil with undrained shear strength $S_u < 12.5$ KPa, or
- (b) More than 10 m of very loose cohesionless soils with SPT values $N < 6$, or
- (c) More than 10 m depth of soft-loose soils with shear wave velocity values $V_s < 150$ m/s, or
- (d) More than 10 m combined depth of soils with properties described in (a), (b), and (c) above.

A comparison between the spectral shape factors of AS 1170.4:2007 and NZS 1170.5:2004 is

Structural Design Codes of Australia and New Zealand: Seismic Actions,

Fig. 2 Comparison of AS 1170.4:2007 and NZS 1170.5:2004 dynamic spectral shape factor plots for rock (A, A and B) and soft soil (E) types (5 % damping)

attempted in Fig. 2, for the two extreme cases of rock (A and B) and soft soil (E) sites. The New Zealand Standard, which generally applies to earthquakes with higher magnitudes ($M \geq 6.5$), features lower spectral factor values in the low structural period range ($T < 1$ s) and higher spectral factor values in the high period range ($T > 1$ s). This is compatible with the fact that soil nonlinearity effects alter the spectral content of stronger earthquakes with magnitude $M > 5.5$, which in addition have a richer low-frequency content attributed also to near-fault effects.

Hazard Factor and Annual Probability of Exceedance

The hazard factor Z of a particular location corresponds to the peak ground acceleration (in g 's) for site class B (AS 1170.4:2007) or classes A and B (NZS 1170.5:2004), considering a design earthquake with return period of 500 years, i.e., a 10 % probability of exceedance during a 50-year design life. The hazard factors in the Australian Standard have not been updated since its previous version AS 1170.4:1993 and are based on the work of Gaull et al. (1990), who used data of the Australian Geological Survey Organisation dated back to 1856. All areas in Australia are assumed to be seismically active for design purposes, with the hazard factor generally ranging between $Z = 0.05$ and $Z = 0.13$, with the exception of the Meckering region in

Western Australia, where the hazard factor ranges between $Z = 0.14$ and $Z = 0.22$, and the Macquarie Island, located halfway between New Zealand and Antarctica, where the hazard factor is equal to $Z = 0.60$.

In NZS 1170.5:2004, the hazard factor Z corresponds to 0.5 times the spectral acceleration (5 % damping) for a structure period $T = 0.5$ s and soil subclass C, considering a design earthquake with a return period of 500 years (Fig. 1c, d). The minimum value across New Zealand is $Z = 0.13$, to ensure no collapse of structures even in areas of low seismicity, i.e., every structure is designed to survive the 84-percentile strong motion of a magnitude $M = 6.5$ normal-faulting earthquake at source-to-site distance of 20 km, a seismic scenario corresponding to the low-seismicity areas of New Zealand. The hazard factor at the high-seismicity major cities (e.g., Wellington, Napier, Hastings) is of the order of $Z = 0.40$, with the maximum value considered in the Standard being $Z = 0.60$.

The probability factor (AS 1170.4:2007) or return period factor (NZS 1170.5:2004) R , listed in Table 3, is used to scale the hazard factor to the required annual probability of exceedance, for the design limit state under consideration. In AS 1170.4:2007, the annual probability of exceedance is correlated with the design working life and the importance level of the structure, with the

Structural Design Codes of Australia and New Zealand: Seismic Actions, Table 3 Probability factor (AS 1170.4:2007) or return period factor (NZS 1170.5:2004)

Annual probability of exceedance	R
1/2,500	1.8
1/2,000	1.7
1/1,500	1.5
1/1,000	1.3
1/800	1.25
1/500	1.0
1/250	0.75
1/200	0.70
1/100	0.50
1/50	0.35
1/25	0.25
1/20	0.20

latter provided in AS/NZS 1170.0:2002 (Appendix F). The design annual probability of exceedance applies to the ultimate limit state only: According to AS 1170.4:2007, structures of importance levels 1–3 (i.e., all structures except ones carrying critical post-disaster functions and exceptional structures) de facto satisfy the serviceability limit state requirements when designed in accordance to the Standard. A special study needs to be carried out for critical post-disaster structures only (importance level 4), to ensure that they remain operational after a seismic event equivalent to the ultimate limit state design event for ordinary importance level 2 structures. The design annual probability of exceedance for structures and buildings (importance level 2) with a working life of 50 years is 1/500 and corresponds to a 10 % probability of exceedance during the design life of the structure. For major structures affecting crowds and associated with “very great” economic, social, and environmental consequences of failure (importance level 3), the annual probability of exceedance is reduced to 1/1,000 for structures with a design working life of 50 years and to 1/2,500 for structures with a design working life of 100 years.

The required annual probability of exceedance for structures designed according to NZS 1170.5:2004 is provided again in AS/NZS

1170.0:2002 (Table 3.3 of AS/NZS 1170.0:2002); however, in the New Zealand Standard, it is correlated with the design (serviceability or ultimate) limit state: The annual probability of exceedance for the common serviceability limit state SLS1 (requirement for no repairs on structural and nonstructural components) is 1/25 for all structures. The special serviceability limit state SLS2 applies to structures carrying critical post-disaster functions only (importance level 4) and is associated with an annual probability of exceedance of 1/500 for design working life of 50 years. A special hazard study is required to define the SLS2 actions for structures of importance level 4 with design working life of 100 years or more.

As far as the ultimate limit state is concerned, the design annual probability of exceedance is the same as in AS 1170.4:2007, for structures classified to importance levels 2 and 3. Note that the product $Z \cdot R$ in NZS 1170.5:2004 need not exceed $Z \cdot R = 0.70$ for ultimate limit state analyses but must be higher than $Z \cdot R = 0.20$ when an annual probability of exceedance 1/2,500 is considered. These $Z \cdot R$ bounds correspond to the higher and lower seismicity regions of New Zealand, respectively: The upper bound matches the 84-percentile near-fault strong motion due to a $M = 8.1$ event from the major Alpine Fault that runs along the South Island, divided by a margin of safety equal to 1.5 likely to result from applying the code design provisions.

Near-Fault Factor

The near-fault factor $N(T, D)$ is introduced in NZS 1170.5:2004 to account for near-source effects on the strong motion during the activation of a strike-slip fault: a) forward directivity, resulting in high peak velocities and displacements, and b) polarization of the long-period motions in the near-source region, where medium- to long-period pulses tend to be stronger in the direction perpendicular to the strike of the fault. Near-fault effects in NZS 1170.5:2004 are considered for eleven (11) major strike-slip faults classified as “class A” faults according to the Californian Category A fault criteria (Petersen et al. 2000), capable of producing earthquakes with magnitude $M = 7.0$

Structural Design Codes of Australia and New Zealand: Seismic Actions, Table 4 Maximum values of the near-fault factor $N_{\max}(T)$ for different structure periods

NZS 1170.5:2004		Linear interpolation functions	
Structure period, T (sec)	$N_{\max}(T)$	Structure period, T (sec)	$N_{\max}(T)$
≤ 1.5	1.0	≤ 1.5	1.0
2	1.12	$1.5 < T < 4$	$0.24 T + 0.64$
3	1.36		
4	1.60	$4 \leq T < 5$	$0.12 T + 1.12$
≥ 5	1.72	≥ 5	1.72

or greater and having slip rates of 5 mm/year of greater. The near-fault factor $N(T, D)$ must be considered during the derivation of the medium-to long-period band of the elastic response spectra for sites located within a distance D less than 20 km from the traces of the major strike-slip faults listed in NZS 1170.5:2004 and applies to annual probability of exceedance less than 1/250:

$$N(T, D) = N_{\max}(T) \quad \text{for } D \leq 2 \text{ km} \quad (3.1)$$

$$N(T, D) = 1 + (N_{\max}(T) - 1) \cdot (20 - D) / 18 \quad \text{for } 2 \text{ km} < D \leq 20 \text{ km} \quad (3.2)$$

$$N(T, D) = 1.0 \quad \text{for } D > 20 \text{ km} \quad (3.3)$$

where the factor $N_{\max}(T)$ is provided as a function of the structure period T in Table 4 and Fig. 3a. Linear interpolation functions are provided for intermediate period values, as proposed in NZS 1170.5:2004. In addition, a comparison of the effect of near-fault correction (Eqs. 3.1, 3.2, and 3.3) on the spectral shape factors for dynamic analyses is illustrated in Fig. 3b, for different distances from the fault.

Vertical Design Actions

According to AS 1170.4:2007, vertical earthquake actions generally need not to be considered in design. For the design of mechanical and electrical components, the vertical earthquake forces are taken equal to 50 % of the horizontal forces.

However, a provision is included stating that when the dynamic analysis requires the consideration of vertical earthquake forces, both upward and downward motions need to be considered and the vertical spectral shape factor shall be taken equal to

$$C_v(T) = 0.5 \cdot C_h(T_v) \quad (\text{AS 1170.4 : 2007}) \quad (4)$$

where T_v is the vertical period of vibration. In NZS 1170.5:2007 on the other hand, when vertical design actions need to be considered in the analyses (e.g., time history analyses), the elastic response spectrum for vertical loading is taken equal to 70 % of the corresponding horizontal spectrum, as

$$C_v(T) = 0.7 \cdot C_h(T_v) \quad (\text{NZS 1170.5 : 2004}) \quad (5)$$

where $T_v = 0$ for the design of the structure as a whole, or equal to the vertical period of the element under consideration, for the design of parts and components. Note that the vertical component of strong earthquake motion is usually rich in high-frequency content; thus, peak ground acceleration and spectral values in the near-source region may exceed the horizontal values (NZS 1170.5 Supp 1:2004, Niazi and Bozorgnia 1992; Ambrassey and Simpson 1996). In light of this, NZS 1170.5 Supp 1:2004 recommends that when the distance of the site from the fault trace is less than $D = 10$ km, the vertical design actions be considered equal to the horizontal design actions for structure period $T \leq 0.30$ s. Strong motion recordings from recent earthquakes, such as the Christchurch 2011 earthquake, provided further evidence in support of the above, as will be discussed later in this entry.

Structural Ductility and Structural Performance Factor-Inelastic Design Spectrum

Derivation of the (inelastic) design spectrum requires the correction of the elastic response spectrum to account for the ability of the

Structural Design Codes of Australia and New Zealand: Seismic Actions, Fig. 3 (a) Variation of the near-fault factor $N_{max}(T)$ with the structure period, T , and (b) comparison of spectral shape factors corrected for

near-fault effects for a rock site (soil subclass A and B) at a distance $D \leq 2$ km, $D = 10$ km, and $D > 20$ km from a major active fault (5 % damping)

particular structure to dissipate seismic energy via nonlinear response. Apart from the structural ductility factor, μ , which is related to the level of inelastic demand that can be reliably sustained by the structure, AS 1170.4:2007 and NZS 1170.5:2004 introduce the structural performance factor S_p to reduce the elastic design seismic actions. The structural performance factor is employed to quantify a number of effects that are not explicitly taken into account in state-of-practice structural analysis procedures by simply scaling the design loads. Such effects include (NZS 1170.5 Supp 1:2004):

- (a) Excitation effects: The estimated seismic loads correspond to a peak ground acceleration value, which may be reached only during a single loading cycle and therefore is unlikely to lead to significant damage (“effective” ground acceleration concept).
- (b) Individual structural elements typically feature a higher capacity than modeled during the analysis of the structure, due to higher material strength, strain hardening, strain rate effects, etc.
- (c) The total structural capacity is typically higher than predicted, due to redundancy

effects or the contribution of nonstructural elements (e.g., in fill walls) which is not taken directly into account in typical analysis models.

- (d) The energy dissipation of the structure is typically higher than assumed, due to damping introduced from nonstructural elements and soil-foundation interaction effects.

The ductility factor μ for the ultimate limit state is calculated in accordance with the appropriate material standard, where such data are provided. Contrary to NZS 1170.5:2004, where reference is made to material standards only and a special study is required otherwise, maximum ductility factors for typical structural systems are provided directly in AS 1170.4:2007 (Table 5). Alternatively, for a specific structure, μ and S_p can be determined via a nonlinear static pushover analysis. Note also that AS 1170.4:2007 applies only to structures with ductility factor $\mu \leq 3$, and when a higher ductility factor is considered, the design must be performed in compliance with NZS 1170.5:2004 provisions (Table 5).

While NZS 1170.5:2004 does not refer explicitly to ductility factor values for the ultimate limit state, for serviceability limit state analyses of

Structural Design Codes of Australia and New Zealand: Seismic Actions, Table 5 Ductility factor μ and structural performance factor S_p for different structural systems and specific structure types (After AS 1170.4:2007)

^aThe design of structures with $\mu > 3$ should be in accordance to NZS 1170.5:2004^bValues from AS 3700:2001

common structures (SLS1), it is provisioned that $1.0 \leq \mu \leq 1.25$, and for critical post-disaster structures (SLS2), it is provisioned that $1.0 \leq \mu \leq 2.0$. Furthermore, the ductility factor for vertical actions is always considered to be $\mu = 1.0$.

Note that in NZS 1170.5:2004, the inelastic horizontal design spectra are not derived by directly multiplying the elastic spectra by $(1/\mu)$. Instead, to account for the transition between equal displacement theory (which is valid for longer structure periods) and equal energy theory

(valid for shorter structure periods), a transition point is defined at $T_1 = 0.7$ s for soil subclasses A to D and at $T_1 = 1.0$ s for soil subclass E, where T_1 is the largest translation period of vibration along the direction under consideration. So, the factor to derive the inelastic response spectra is estimated as:

For subsoil classes A, B, C, and D:

$$k_\mu = \mu \quad \text{for } T_1 \geq 0.7 \text{ s} \quad (6.1)$$

$$k_\mu = 1 + (\mu - 1)T_1/0.7 \quad \text{for } T_1 < 0.7 \text{ s} \quad (6.2)$$

For subsoil class E:

$$k_\mu = \mu \quad \text{for } T_1 \geq 1.0 \text{ s or } \mu < 1.5 \quad (6.3)$$

$$k_\mu = 1.5 + (\mu - 1.5)T_1 \quad \text{for } T_1 < 1.0 \text{ s and } \mu \geq 1.5 \quad (6.4)$$

For the purpose of calculating k_μ , the largest translation period of vibration T_1 is not taken less than 0.4 s.

The structural performance factor S_p in AS 1170.4:2007 is provided in Table 5. In NZS 1170.5:2004, the structural performance factor is taken equal to $S_p = 0.7$ for ultimate limit state analyses, except for low-ductility structures with $1.0 < \mu < 2.0$, where S_p is calculated as:

$$S_p = 1.3 - 0.3\mu \quad (7)$$

For ultimate limit state verification of structures against sliding or overturning, S_p is taken equal to $S_p = 1.0$. For serviceability limit state SLS1 and SLS2 analyses, S_p is taken equal to $S_p = 0.7$, except otherwise dictated by the relevant material standard.

In accordance to the above, the inelastic design response spectrum in AS 1170.4:2007 is defined as

$$C_d(T) = \frac{C(T)S_p}{\mu} \quad (8)$$

and in NZS 1170.5:2004 as

$$C_d(T) = \frac{C(T)S_p}{k_\mu} \quad (\text{for horizontal actions}) \quad (9.1)$$

$$C_d(T) = C_v(T)S_p \quad (\text{for vertical actions}) \quad (9.2)$$

Actions for Dynamic Time History Analyses

In addition to actions applicable to common equivalent static and modal dynamic analyses, AS 1170.4:2007 and, mainly, NZS 1170.5:2004 include certain provisions for the determination of the appropriate design actions when dynamic time-domain analyses are to be performed. While in AS 1170.4:2007 there is a vague requirement that the response spectra of the actual acceleration time histories used shall “approximate” the design spectrum of Eq. 8, NZS 1170.5:2004 prescribes a more elaborate and explicit procedure for the selection and scaling of ground motion records.

Ground motion accelerographs to be used for time-domain analyses according to NZS 1170.5:2004 shall consist of both horizontal components of the recording; the vertical component may have to be considered too, for the analysis of structures sensitive to vertical strong ground motion. The above imply that the procedure refers to three-dimensional analyses, yet an adaptation to two-dimensional models is feasible, by considering only one horizontal component of each ground motion record as, e.g., in ASCE/SEI 7-10. A “family” of no less than three records must be employed in each time history analysis.

The selected acceleration records must be consistent with the local seismotectonic regime (expected magnitude, fault rupture mechanism, source-to-site distance, etc.). When the site is located near a major fault, i.e., $N(T, D) > 1$ (Eqs. 3.1, 3.2, and 3.3), then one set of the records must have a forward directivity component. Simulated, artificial accelerographs may be used too, when appropriate real acceleration recordings are not available. Each record shall be scaled by a “record scale factor” k_1 to

Structural Design Codes of Australia and New Zealand: Seismic Actions, Fig. 4 (a) Comparison of the 2011 Christchurch strong motion recordings elastic response spectra (5 % damping, horizontal components) with the design NZS 1170.5:2004 elastic design spectra

for the city of Christchurch and soil subclass D, (b) scaled elastic response spectra of the same strong motion recordings to match the NZS 1170.5:2004 design spectra for largest structure translation period $T_1 = 1$ s and $S_p = 1$

match the target design spectrum over the period range of interest and by a “family scale factor” k_2 to ensure that the energy content of at least one record in the family exceeds that of the design spectrum over the period range of interest. The target design spectrum is defined as

$$SA_{\text{target}} = \left(\frac{1 + S_p}{2} \right) C(T) \quad (10)$$

where the spectral shape factor $C(T)$ is calculated from Eq. 1 and S_p is the structural performance factor defined in the section “**Structural Ductility and Structural Performance Factor-Inelastic Design Spectrum.**”

In order to present the procedure of scaling ground motion records according to NZS 1170.5:2004, the horizontal components of three typical strong ground motion recordings from the 2011 Christchurch $M = 6.3$ earthquake were used. These records were scaled to match the target ultimate limit state spectrum of NZS 1170.5:2004 for a common structure (importance level 2) located in Christchurch, founded on subsoil class D (soft soil). According to NZS 1170.5:2004, for a structure of

importance level 2 in Christchurch with a design life of 50 years, $Z \cdot R = 0.22$ g and $N(T, D) = 1$, i.e., no near-fault effects, need to be taken into account due to possible rupture of the Port Hills Fault that is believed to have caused the 2011 earthquake. Assuming for simplicity that $S_p = 1$, the target spectrum is plotted in Fig. 4.

Strong motion recordings during the Christchurch 2011 earthquake exceeded by far the design peak ground acceleration at the ground surface of class D soft soils implied by NZS 1170.5:2004 (0.246 g) and reached maximum values of 1.67 g in the horizontal direction and 2.20 g in the vertical direction at the Heathcote Valley Primary School Station (HVSC) (www.geonet.org.nz). Here a family of three near-field recordings on soft to very soft soil are used, with peak horizontal ground accelerations ranging from 0.34 to 0.67 g (Table 6).

The elastic response spectra of the horizontal components of these three recordings are plotted in Fig. 4a, in comparison with the design response spectra of NZS 1170.5:2004. A band-pass filter in the frequency ranges of 0.10–0.25 Hz and 24.5–25.5 Hz was applied to the time histories

CHHC	D	6	0.345	0.364	0.601

used to derive the spectra. It is clear that the spectral values of these typical records are above the design spectra across practically the whole range of important structural periods, an indication of the severity of the Christchurch earthquake.

Scaling of ground motion records to match the target design spectrum via the scale factor k_1 was performed while taking into account a structure period range that depends on the largest translational period of the structure in the direction of interest, T_1 . The period range of interest is defined as $0.4 T_1 \leq T \leq 1.3 T_1$, with the product $0.4 T_1$ not taken less than 0.4 s. Notice that this band of significant periods is considerably narrower compared to the corresponding one prescribed in EN-1998-1, which is $0.2 T_1 \leq T \leq 2.0 T_1$, or even ASCE/SEI 7-10, where the corresponding range is $0.2 T_1 \leq T \leq 1.5 T_1$. For the case at hand, it was assumed that $T_1 = 1$ s, and the period range of interest is denoted by the yellow band in Fig. 4.

The best-fit scale factor k_1 of each horizontal ground motion component was determined as the value minimizing the function $\log(k_1 SA_{\text{component}}/SA_{\text{target}})$ over the period range of interest, in a least mean square sense. In other words, the aim was to find via an interactive procedure the k_1 value that minimizes the sum:

$$\int_{0.4T_1}^{1.3T_1} \left[\log \left(\frac{k_1 SA_{\text{component}}}{SA_{\text{target}}} \right) \right]^2 dT = \min \quad (11)$$

The selected recordings must satisfy a “similarity” criterion $0.33 < k_1 < 3.0$. Moreover, in order to verify that each selected record reasonably matches the target spectrum over the period range of interest, the following inequality quantifying the mean (over the period of interest) square difference of the scaled over the target spectral values must be satisfied:

$$D_1 = \sqrt{\frac{1}{(1.3 - 0.4)T_1} \cdot \int_{0.4T_1}^{1.3T_1} \left[\log \left(\frac{k_1 SA_{\text{component}}}{SA_{\text{target}}} \right) \right]^2 dT} \leq \log(1.5) \quad (12)$$

Although not a normative criterion, a stricter fit $D_1 \leq \log(1.3)$ is proposed for most cases, according to NZS 1170.5 Supp 1:2004.

The k_1 and D_1 factors for the records at hand are listed in Table 7, where it is depicted that the specific records are compatible with NZS 1170.5:2004 requirements. The component of each record with the lower k_1 value was nominated as “principal” (Fig. 4, Table 7), and this value of k_1 was used as the record scale factor.

The record family scale factor, k_2 , ensures that the principal component of at least one record spectrum (after being scaled by k_1) exceeds the target spectrum over the period range of interest. It is estimated as the maximum value of the ratio $SA_{\text{target}}/\max(SA_{\text{principal}}) \geq 1.0$ within the period range of interest, where $\max(SA_{\text{principal}})$ is the maximum spectral value between all the principal components of the family, at each period step considered for the derivation of the spectra. To confirm the selection of the principal and

Structural Design Codes of Australia and New Zealand: Seismic Actions, Table 7 Scaling factors for the considered typical strong motion records

Site code	Component	k_1	D_1	k_2
CBGS	N89W (principal)	0.608	0.070	1.05
	S01W	0.789	0.105	
PRPC	W (principal)	0.672	0.081	
	S	0.785	0.097	
CHHC	N01W	0.683	0.064	
	S89W (principal)	0.598	0.058	

secondary components, the record family scale factor must be within the range $1.0 < k_2 \leq 1.3$. If $k_2 > 1.3$, then either a different record must be selected or the selection of the principal/secondary components may be reversed, aiming to minimize the product $k_1 k_2$. This may be the case when all three principal components in a family feature low spectral values within a particular period band, while one of the secondary components is rich in frequency content within the same band; thus, although the scale factor k_1 may be greater for that particular strong motion component, the product $k_1 k_2$ may be lower. In the case at hand however, the family factor k_2 is within the desirable range (Table 7), a fact that can be confirmed visually from Fig. 4.

The above scaling procedure must be followed for all directions of interest, corresponding to different translational periods of the structure, T_1 , and thus a different period range of interest. Although more elaborate than the analogous procedure of EN-1998-1 or ASCE/SEI 7-10 for the time history representation of the seismic action, where it is simply required that no value of the mean elastic spectrum of all time histories used is less than 90 % (EN-1998-1) or 100 % (ASCE/SEI 7-10) of the corresponding value of the elastic response spectrum, the procedure prescribed in NZS 1170.5:2004 results in a more rational scaling of strong motion records, and in a closer match to the design spectrum, as it does not impose restrictions related only to lower-than-target spectral acceleration values found in EN-1998-1 and ASCE/SEI 7-10. As a result of

Structural Design Codes of Australia and New Zealand: Seismic Actions, Fig. 5 Comparison of the mean response spectrum (5 % damping) of the three principal components listed in Table 7 with the NZS 1170.5:2004 target spectrum for soil subclass D and $S_p = 1$. The period of interest band according to NZS 1170.5:2004 ($0.4 T_1 \leq T \leq 1.3 T_1$) and according to ASCE/SEI 7-10 ($0.2 T_1 \leq T \leq 1.5 T_1$) is also drawn

the above, if one embraced the more conservative EN-1998-1 and ASCE/SEI 7-10 provisions regarding the average response spectra from the three principal components, the specific scaling factors applied would not be acceptable, as their average spectrum is below 100 % (ASCE/SEI 7-10) and marginally below 90 % (EN-1998-1) of the target spectrum (Fig. 5).

Finally, note that NZS 1170.5:2004 (as also ASCE/SEI 7-10) bases the accelerograph scaling procedure on spectral values within the range of interest only and does not impose restrictions on the zero period spectral response acceleration values of the strong motion, as, e.g., EN-1998-1.

Summary

Seismic design action definitions in the Australian AS 1170.4:2007 and New Zealand NZS 1170.5:2004 Standards were presented in a concise way, focusing on the determination of the elastic and inelastic design response spectra to be used together with static and dynamic methods

of analysis. A short discussion against provisions of other modern seismic codes, such as EN-1998-1 and ASCE/SEI 7-10, was attempted to point out certain key differences in particular clauses. Although Australian and New Zealand Standards embrace most of the recent developments on earthquake engineering, such as accounting for near-source effects on strong motion (but not topography effects as, e.g., EN-1998-1), any seismic code is not a “static” document, but rather a “dynamic” one, and evolves with lessons learned from recent major earthquakes that are included in future revisions as, e.g., the increase of the hazard factor Z for the Christchurch area from $Z = 0.22$ g to $Z = 0.30$ g in the latest compliance document of the New Zealand Building Code (Department of Building and Housing 2011).

Introduction

In civil engineering, the design of structures has always been governed by fulfilling the needs of both safety and economy. Ideally, the designer would want to minimize cost while simultaneously maximizing safety. To a large extent, these objectives are in conflict; therefore, suitable compromises need to be found. A well-established tool for finding this set of best compromises is Pareto optimization. Figure 1 illustrates the trade-off between two conflicting objectives, both of which should be minimized. Reducing one objective automatically implies increasing the other one. Good compromises are to be found on the Pareto front.

Mathematically, this can be expressed as follows. Given a multi-objective minimization problem with m scalar-valued objective functions $f_k(\mathbf{x})$

$$f_k : D_{\mathbf{x}} \subset \mathbb{R}^n \rightarrow \mathbb{R} \quad (1)$$

a point $\mathbf{x}^*$ is called nondominated if (Ngatchou et al. 2008)

$$\begin{aligned} f_k(\mathbf{x}^*) &\leq f_k(\mathbf{x}) \forall k \forall \mathbf{x} \in D_{\mathbf{x}} \text{ and} \\ \exists \ell : f_\ell(\mathbf{x}^*) &< f_\ell(\mathbf{x}) \forall \mathbf{x} \in D_{\mathbf{x}} \end{aligned} \quad (2)$$

The Pareto set, i.e., the set of all nondominated solutions of an m objective problem can be constructed by assembling all solutions $\mathbf{x}_\alpha$ of all aggregated optimization problems of the form

$$f_\alpha = \sum_{k=1}^m \alpha_k f_k(\mathbf{x}) \rightarrow \text{Min.}! \quad (3)$$

in which α_k are positive coefficients. For more involved problems, alternative method based on multi-objective genetic algorithms (MOGA) such as non-dominated sorting genetic algorithms (NSGA) (Ngatchou et al. 2008) may be more appropriate. Applications of these approaches can be found, e.g., in Liu and Frangopol (2005) and Furuta and Kameda (2006).

Traditionally, however, in structural engineering, the abovementioned compromise has been realized by setting minimum target safety levels

Structural Optimization Under Random Dynamic Seismic Excitation, Fig. 1 Pareto front for the case of two conflicting objectives to be minimized

(as specified, e.g., by design codes) and aiming for the economically best solution satisfying the safety requirements. Mathematically, this corresponds to a *constrained* optimization problem. Due to many uncertainties involved in the construction process as well as in the environmental loads acting on a structure, the optimization problem cannot be treated deterministically. Figure 2 shows a simple example of a stochastic optimization problem in which the design variables contain uncertainties (e.g., due to the manufacturing or construction tolerances) and the objective (cost) function contains uncertainties (e.g., due to price fluctuations on the markets), and finally, the safety constraint function contains uncertainties (e.g., due to randomness of environmental loads such as earthquakes or storms).

Optimization Methodology

In a deterministic setting, a constraint optimization problem involves an objective function $f(\mathbf{x})$ and several constraint functions $g_k(\mathbf{x})$, $k = 1 \dots m$. Then the problem can be formulated as

$$\mathbf{x}^* = \operatorname{argmin} f(\mathbf{x}); g_k(\mathbf{x}) \leq 0; k = 1 \dots m \quad (4)$$

Since the cost function f will typically be random, any optimization will have to be formulated on the basis of expected values or probabilities

Structural Optimization Under Random Dynamic Seismic Excitation, Fig. 2 Simple example for a stochastic optimization problem

derived from the cost function. In this way, the objective function R for the optimization can be formulated, e.g., in terms of the mean value $\bar{f}$ and standard deviation σ_f , as

$$R = \bar{f} + k\sigma_f \quad (5)$$

In this form, a multiple of standard deviation of the cost function is added to the mean values to form the objective function. The case $k = 0$ corresponds to game theory (suitable for, e.g., large portfolio management, fair gambling), whereas $k > 0$ implies a so-called *risk-averse* strategy.

Such a strategy is commonly employed when large losses cannot be compensated by long-term averaging (strong asymmetry).

Also, the constraint functions $g_k(\mathbf{x})$ will be random. Therefore, it is helpful to use the probability of constraint violation as new constraint, i.e., subject to the minimization of R to

$$P[g_k(\mathbf{x}^*)] > 0] \leq \varepsilon \quad (6)$$

In safety-related constraints, the probability level ε may be very small, e.g., $\varepsilon = 10^{-5}$. Hence, it is absolutely mandatory to provide computationally efficient methods for computing such small probabilities. This need is even more pronounced as the application of optimization algorithm required the repeated computation of small failure probabilities (whenever the algorithm changes the design variables).

Structural Optimization Under Random Dynamic Seismic Excitation, Fig. 3 Safety margin for constraints in a stochastic optimization problem

In traditional structural design, this is realized by introducing a safety margin (usually expressed in terms of partial safety factors) into the otherwise deterministic formulation of the constraints (cf. Fig. 3).

Computational Tools

The reduction of the large computational effort can be tackled in various ways, such as:

- Reduce and simplify the structural model, e.g., by modal reduction (Clough and Penzien 1993) or proper orthogonal decomposition (Bamer and Bucher 2012).
- Reduce the probabilistic description, e.g., by equivalent linearization (Roberts and Spanos 2003) or tail-equivalent linearization (Fujimura and Kiureghian 2007).
- Approximate the input-output relation of the system by a meta-model (Bucher and Macke 2005).
- Approximate the input-failure probability relation by a meta-model (Gasser and Schuëller 1997).
- Compute the input-failure probability relation by efficient Monte Carlo methods (Bucher 2009a).

In the following, the response surface method and a specific Monte Carlo method (asymptotic sampling) will be explained in some detail.

Response Surface Method

The response surface method has been a topic of extensive research in many different application areas since the influential paper by Box and Wilson in 1951 (Box and Wilson 1951). A fairly complete review on existing techniques and research directions of the response surface methodology can be found in Hill and Hunter (1966), Mead and Pike (1975), Myers et al. (1989), and Myers (1999). One of the earliest suggestions to utilize the response surface method for structural reliability assessment was made in Rackwitz (1982). Here Lagrangian interpolation surfaces and second-order polynomials are rated as useful response surfaces. Moreover, the importance of reducing the number of basic variables and error checking is emphasized. Polynomials of different orders in combination with regression analysis are proposed in Faravelli (1989), in which fractional factorial designs are utilized to obtain a sufficiently large number of support points. The absolutely essential validation of the chosen response surface model is done by means of analysis of variance.

In Ouyornprasert et al. (1989), it has been pointed out that for reliability analysis, it is most important to obtain support points for the response surface very close to or exactly at the limit state $g(\mathbf{x}) = 0$. This finding has been further extended in Kim and Na (1997) and Zheng and Das (2000). In Brenner and Bucher (1995), the response surface concept has been applied to problems involving random fields and nonlinear structural dynamics. Besides polynomials of different orders, piecewise continuous functions such as hyperplanes or simplexes can also be utilized as response surface models.

Assume that an appropriate response surface model $q(\cdot)$ has been chosen to represent the experimental data. Then, for estimating the values of the parameters θ in the model, the method of maximum likelihood can be utilized. Under the assumptions of a Gaussian distribution of the random error terms ε , the method of maximum likelihood can be replaced by the more common method of least squares (Box and Draper 1987). In the latter case, the parameters θ are determined in such a way that the sum of squares of the differences between the value of

Structural Optimization Under Random Dynamic Seismic Excitation, Fig. 4 Response surface and data points

the response surface $q(\theta; \mathbf{x}^{(k)})$ and the measured response $z^{(k)}$ at the m points of experiment

$$\mathbf{x}^{(k)} = (x_1^{(k)}, \dots, x_n^{(k)})', \quad k = 1, 2, \dots, m \quad (7)$$

becomes as small as possible. In other words, the sum of squares function

$$s(\theta) = \sum_{k=1}^m \left(z^{(k)} - q(\theta; \mathbf{x}^{(k)}) \right)^2 \quad (8)$$

has to be minimized. This corresponds to a minimization of the variance of the random error terms ε . The minimizing choice of θ is called a *least squares estimate* and is denoted by $\hat{\theta}$.

The above regression problem becomes more simple to deal with when the response surface model is linear in its parameters θ . Let us assume that the response surface is given by (Fig. 4)

$$\eta = \theta_1 q_1(\mathbf{x}) + \theta_2 q_2(\mathbf{x}) + \dots + \theta_p q_p(\mathbf{x}) \quad (9)$$

The least squares estimate of the parameter vector is given by

$$\hat{\theta} = (\mathbf{Q}'\mathbf{Q})^{-1}\mathbf{Q}'\mathbf{z} \quad (10)$$

This estimator is unbiased, i.e.,

$$\mathbf{E}[\hat{\theta}] = \theta \quad (11)$$

A detailed discussion is given by (Bucher and Macke 2005).

Structural Optimization Under Random Dynamic Seismic Excitation,

Fig. 5 Schematic sketch of first-passage problem

Monte Carlo Simulation

First-Passage Problem

Generally, the probability of failure P_F in an n -dimensional space of random variables $X_1, \dots, X_n$ can be computed as

$$P_F = \int \cdots \int_{D_F} f_{X_1, \dots, X_n}(x_1, \dots, x_n) dx_1 \cdots dx_n \quad (12)$$

In this equation, $f_{X_1, \dots, X_n}(x_1, \dots, x_n)$ denotes the joint probability function of the random variables $X_1, \dots, X_n$, and D_F denotes the failure domain, i.e., the region of the n -dimensional random variable space in which failure occurs. Typically, this is denoted in terms of a scalar limit state function $g(\cdot)$ attaining negative values, i.e., $D_F = \{(X_1, \dots, X_n) \mid g(X_1, \dots, X_n) \leq 0\}$. For applications in time-dependent problems as those arising structural dynamics, the appropriate formulation leads to the first-passage problem. Here the failure domain is typically written as

$$D_F = \left\{ (X_1, \dots, X_n) \mid \max_{1 \leq k \leq N} h_k(X_1, \dots, X_n) \geq \xi \right\} \quad (13)$$

In this equation, $h(\cdot)$ denotes a response quantity of interest, and ξ is a critical threshold value of this response. The random variables X_i usually denote the random excitation (e.g., earthquake or wind) which is discretized in time. A schematic sketch is shown in Fig. 5. Note that due to the

principle of causality, the values of h at point k in time can only depend on the basic variables $X_1 \dots X_k$ (i.e., on those in the past put to the present as expressed by the index k) and not on those in the future.

The generalized safety index (or reliability index) β is defined by

$$\beta = \Phi^{-1}(1 - P_F) = \Phi^{-1}[F_H(h)] \quad (14)$$

Here $\Phi^{-1}(\cdot)$ is the inverse standardized Gaussian distribution function. Without loss of generality, it is assumed that the random variables X_i are Gaussian and that they are independent and identically distributed (i.i.d.) with zero mean and unit standard deviation.

Since the failure probabilities to be computed are usually very small (e.g., $PF = 10^{-5}$), it is not feasible to evaluate the integral in Eq. 12 using standard numerical integration procedures. This is due to the fact that the number of integration points required to perform, e.g., Gaussian integration in dimension n , grows exponentially with n . Monte Carlo methods do not have this dependence on the dimension; however, crude or plain Monte Carlo simulation requires a number of samples roughly larger than $\frac{10}{P_F}$. This, again, may lead to prohibitively large computational effort.

Asymptotic Sampling Method

The asymptotic sampling method as described in Bucher (2009a, b) exploits the asymptotic

behavior of the failure probability expressed in terms of the reliability index β when changing the standard deviation of the basic random variables. If the original standard Gaussian random variables are replaced by variables with non-unit standard deviations $\sigma = \frac{1}{f}$, then the computed reliability index will depend on the choice of f . As a first simple case, consider a linear function of the basic random variables X_k , say

$$g(\mathbf{X}) = \sum_{k=1}^N a_k X_k \quad (15)$$

with arbitrary real-valued coefficients a_k . The random variable $Y = g(\mathbf{X})$ will then be Gaussian with a zero mean and a variance

$$\sigma_Y^2 = \sum_{k=1}^N a_k^2 \quad (16)$$

The distribution function $F_Y(y)$ of this variable will therefore be given by

$$F_Y(\xi) = \Phi\left(\frac{\xi}{\sigma_Y}\right) = \Phi\left(\frac{\xi}{\sqrt{\sum_{k=1}^N a_k^2}}\right) \quad (17)$$

Upon changing the standard deviation of all basic variables from unity to a value of $1/f$, the standard deviation of Y changes by the same amount. Thus, the distribution function changes to

$$F_Y(\xi) = \Phi\left(\frac{\xi f}{\sqrt{\sum_{k=1}^N a_k^2}}\right) \quad (18)$$

from which the generalized reliability index according to Eq. 14 is immediately found as

$$\beta = \frac{\xi f}{\sqrt{\sum_{k=1}^N a_k^2}} \rightarrow \frac{\beta}{f} = \frac{\xi}{\sqrt{\sum_{k=1}^N a_k^2}} \quad (19)$$

This means that for a linear function of Gaussian variables, the scaled reliability index β/f is invariant with respect to the choice of f .

For the general case, this is not true. There is, however, an asymptotic property which ensures similar behavior for many nonlinear cases. As stated by Breitung (1984) and Gollwitzer and Rackwitz (1988), the reliability index asymptotically depends linearly on f or in scaled notation

$$\lim_{f \rightarrow \infty} \frac{\beta(f)}{f} = \text{const.} \quad (20)$$

In order to exploit this asymptotic relation, Bucher (2009b) suggested to utilize the formulation

$$\frac{\beta}{f} = A + \frac{B}{f^2} \quad (21)$$

in which the coefficients A and B are determined from a regression analysis using the values of β as estimated from several Monte Carlo runs with different values of f . It should be mentioned that the asymptotic sampling method is a representative of a very recent family of methods exploiting the dependency of the failure probability on a scaling parameter of the standard deviation of the input variables. A different approach to this is given by Naess and Gaidai (2008) and Naess et al. (2010). For a comparative review and synthesis of these two approaches, it is referred to Qin et al. (2012).

Optimal Design of Seismic Isolation Systems

Definition of Problem

In order to ensure structural safety and integrity in earthquake conditions, it may be useful or even necessary to equip structures with protective devices. One possible choice is seismic isolation devices.

The basic scenario in which such devices are utilized is shown in Fig. 6.

In this scenario, a structure is subjected to an earthquake described by the ground acceleration $a(t)$. Its effect on the structure is to be mitigated

Structural Optimization Under Random Dynamic Seismic Excitation, Fig. 6 Structure and friction-based seismic isolation device

by a device which limits the transfer of forces from the ground to the structure. One such device consists of a combined friction and spring element, in which the spring can also be replaced by a re-centering force due to gravity effects (so-called friction pendulum systems, see, e.g., Roussis and Constantinou (2006)). The device has two characteristic parameters, one is the maximum force transmitted by friction (described by the friction coefficient μ) and the other is the re-centering (or restoring) spring stiffness constant (described by the effective radius of curvature R) (Fig. 7). Both parameters should be chosen such as to ensure the desired protective effect for the structure and the integrity of the isolation device itself.

The question of optimal design for stiffness and friction of seismic isolation systems has been addressed previously in the literature (e.g., Constantinou and Tadjbakhsh (1983), Iemura et al. (2007), Jangid (2005)). The method of equivalent linearization in conjunction with a random process model for the earthquake excitation tuned to the El Centro record was used in Jangid (1996). Here, a full nonlinear dynamic analysis will be used as a basis for the computation of the structural response. The ground motion is modeled as a nonstationary (i.e., evolutionary) random process; hence, the response should be characterized in suitable probabilistic terms.

As the main function, if the seismic isolation is to keep the effect of the ground acceleration from the superstructure, it is obvious that a “soft”

Structural Optimization Under Random Dynamic Seismic Excitation, Fig. 7 Simple sketch for friction pendulum system

isolator will be good for that purpose. On the other hand, the isolator itself can have only limited displacements due to constructive reasons. This means that the isolator should be “stiff” enough. Hence, the targets (objectives) of the optimal design of a seismic isolation device are in conflict with each other. As mentioned above, the determination of the Pareto set allows the preselection of suitable candidates for the final decision-making process.

The relevant quantities for the Pareto optimization are the maximum displacement x_D of the friction device (this should be small in order to ensure safety of the supports) and the maximum structural displacement x_S (measured relative to the device, this should be small to ensure seismic isolation). As the quantities are random, characteristic values (i.e., mean value plus three times the respective standard deviation) are chosen for the objectives.

structural displacement (*right*) depending on design parameters R and μ

Structural Optimization Under Random Dynamic Seismic Excitation, Fig. 9 Convergence of particle swarm optimization method to one point in the Pareto set

Selected Results

In order to prepare the optimization, the characteristic values for x_D and x_S are computed for 100 randomly selected combinations of the design variables R and μ . At each sample point, the structural system is analyzed for 100 randomly generated earthquakes (using a nonstationary Kanai-Tajimi model (Bucher 2009c)), and the characteristic values for x_D and x_S are computed using sample statistics. These

discrete values are utilized to form response surface approximations which by inherent smoothing largely eliminate the sampling uncertainty inherent in Monte Carlo methods. The resulting response surfaces are shown in Fig. 8.

An aggregated objective function R is then generated as

$$R = \alpha x_D + (1 - \alpha) x_S \quad (22)$$

**Structural Optimization
Under Random Dynamic
Seismic Excitation,
Fig. 10** Final Pareto set

in which α is a real number in the interval $[0, 1]$. Solving the aggregated problem results in one point of the Pareto set. The convergence of this optimization using a particle swarm optimizer is shown in Fig. 9.

Finally, the results of aggregated optimization runs for different values of α yield the Pareto set as shown in Fig. 10.

It turns out that the Pareto set contains very large friction coefficients which are very difficult to realize in practice. Hence, the optimal solutions may not be accessible.

Energy dissipation in dynamic analysis; Finite element analysis; Implicit performance function; Nonlinear analysis; Risk management; Seismic loading; Structural reliability; Time-domain dynamic analysis; Time-domain reliability analysis

Introduction

The estimation of structural reliability has matured over the years. It has been accepted by the profession that if the risk in engineering design cannot completely be eliminated, it needs to be managed appropriately. The issue has attracted added significance since the basic design philosophy has changed from human safety to structural safety. This is in response to limit enormous amount of damage caused to infrastructures during recent earthquakes in China, Chile, Haiti, India, Iran, Japan, the USA, and other parts of the world. The word “structure” is used here in a generic sense. It represents real engineered systems including structures in a nuclear power plant, multistory buildings, onshore and offshore structures, soil–pile interaction problems in offshore mooring systems, aerospace structures, computer

packaging systems, systems represented by finite elements, etc. Most of the discussions made here are appropriate for different forms of dynamic including seismic loadings.

The estimation of the probability of failure, expressed in terms of risk or reliability, implied that it needs to be estimated just before failure indicating a very complicated process a structure has to go through before failure. The appropriate risk management requires an acceptable reliability method considering all major loads and load combinations that may act on the structures during their lifetime, modeling the structures appropriately satisfying the underlying physics at the time of failure and analyzing their nonlinear behavior as realistically as possible just before failure.

If the performance functions or limit state functions are explicit, i.e., if they can be expressed as explicit functions of all the random variables present in the formulation and the performance requirements, there are several methods with various degrees of sophistication that are available (Haldar and Mahadevan 2000a). The most commonly used procedures are the first-order and second-order reliability method commonly known as FORM/SORM. They are also referred to as the Rackwitz-Fiessler (1976) algorithm. Although not always necessary, for the most efficient implementation of the procedures require the performance functions are available in explicit forms. The algorithms are iterative in nature and the gradients of performance or limit state functions are required to estimate the coordinates of the most probable failure point (MPFP) and the corresponding reliability index and failure probability. However, their applicability in estimating the reliability of real structural systems could be very limited. For routine applications of FORM/SORM, the derivatives of the performance functions are difficult to obtain even for a simple structure like a two-dimensional small frame. Furthermore, risk analysis methods currently available were developed for relatively simple systems with numerous assumptions which cannot be satisfied for large realistic structural systems. For such systems, the limit states are expected to be implicit, and for

dynamic nonlinear problems, they are also to be a function of time. In response to questions on future research directions in the risk evaluation techniques, Rackwitz (2000) commented that the use of FORM/SORM complemented by Monte Carlo simulations (MCS) would be the next frontier. Several recent studies reflected this idea and simulation has become an integral part of reliability evaluation studies.

Challenges in the Reliability Estimation for Seismic Loading

Reliability estimation for dynamic or seismic loading is evolving. The probability of failure implies that it needs to be estimated just before failure developing various sources of nonlinearities. The finite element method (FEM) is commonly used by the deterministic community to study nonlinear problems where dynamic loadings are applied in time domain. This clearly indicates that an FEM-based general purpose reliability evaluation method, parallel to the deterministic analysis, is necessary.

The most sophisticated deterministic dynamic analysis of structures requires that the load should be applied in time domain. This is one of the major challenges in the reliability analysis for seismic loading. The classical random vibration-based approaches were used in the past for this purpose; however, they did not provide information acceptable to the deterministic community. The classical random vibration-based approaches have numerous limitations including the loads which are applied in the form of power spectral density functions essentially appropriate for linear structural behavior, the uncertainty in the linear or nonlinear structural behavior which may need to be incorporated in approximate ways, several performance-enhancing features currently introduced in structures which cannot be incorporated in appropriate ways, etc. The most severe weakness is that the seismic loading cannot be applied in time domain.

Structural elements (beams, columns, connections, etc.) are generally designed first for

strength according to design guidelines given in codes satisfying some underlying reliability requirements, although unknown to most designers. However, the overall system reliability in strength considering the reliabilities of all the elements remains unknown. It is not addressed in codes since it is difficult to estimate and can only be assessed based on numerous idealistic assumptions (brittle or ductile behavior, dependency of failure of elements, consideration of nonlinear limit states, etc.) (Haldar and Mahadevan 2000a). Moreover, the design satisfying strength requirements may not satisfy the global performance or serviceability requirement, e.g., excessive lateral deflection, a major cause of structural failure for seismic loading. Serviceability requirements also may control the seismic design in most cases and should not be ignored (Huh and Haldar 2002).

Physics-Based Dynamic Behavior: Connection Conditions

Structural members are connected to each other using various types and forms of connections, specifically for steel structures. These connections are routinely modeled as fully restrained (FR). However, extensive experimental studies indicate that they are essentially partially restrained (PR) connections with different rigidities. In a deterministic analysis, PR connections add a major source of nonlinearity by decreasing the overall stiffness of a frame. In a dynamic analysis, it changes the dynamic properties of the structures and adds a major source of energy dissipation. In reliability analysis, it also adds a major source of uncertainty. Thus, the reliability of steel frames with PR connections and subjected to seismic excitation is expected to be quite different than that of frames with FR connections. The implications of the presence of PR connections and the uncertainty in modeling them are essential for the reliability analysis.

Static Versus Dynamic or Seismic Analyses: Improved FEM-Based Formulation

The modeling of structures to extract response information under the static and dynamic application of loadings is expected to be very different.

Under dynamic or seismic loading, the structural response will depend on many factors including the changes in the structural dynamic properties (stiffness, frequency, damping, etc.) and the corresponding response amplification as the loading progresses from linear to nonlinear stages; the sophistication in the physics-based structural modeling, i.e., FR versus PR connections and support conditions; the various sources of energy dissipation intentionally introduced in the system to improve its behavior; etc.

One basic limitation of reliability analysis under seismic loading is the incapability of handling structural behavior appropriately. Because the analysis is based on tracking the uncertainty propagating through the steps of deterministic analysis (Haldar and Mahadevan 2000b), the efficiency of the deterministic FEM is extremely important. It has been reported in the literature (Kondoh and Atluri 1987; Shi and Atluri 1988; Haldar and Nee 1989) that the assumed stress-based FEM has many advantages over the commonly used displacement-based FEM, particularly for nonlinear analysis of frame structures capable of producing large deformation. In the assumed stress-based FEM, the tangent stiffness can be expressed in an explicit form, the stresses of an element can be obtained directly, fewer elements are required to describe a large deformation configuration, and integration is not required to obtain the tangent stiffness. Different sources of nonlinearity, especially due to the presence of partially restrained (PR) connections, can be incorporated without losing the basic simplicity. It is very accurate and efficient in analyzing nonlinear responses. Some of its essential features in the context of the dynamic problems are discussed very briefly in the following sections.

Unified Stochastic Finite Element Method (SFEM)

As discussed earlier, to capture a realistic structural behavior, an FEM-based formulation is desirable. When uncertainty in the variables in the formulation is considered, it leads to the concept of stochastic finite element method (SFEM) (Haldar and Mahadevan 2000b).

Without losing any generality, the limit state function can be expressed in terms of the set of basic random variables $\mathbf{x}$ (e.g., loads, material properties, and structural geometry), the set of displacements $\mathbf{u}$, and the set of load effects $\mathbf{s}$ (except the displacements) such as internal forces, stresses, etc. The displacement $\mathbf{u} = \mathbf{QD}$, where $\mathbf{D}$ is the global displacement vector and $\mathbf{Q}$ is a transformation matrix. The limit state function can be expressed as $g(\mathbf{x}, \mathbf{u}, \mathbf{s}) = 0$. For reliability computation, it is convenient to transform $\mathbf{x}$ into the standard normal space $\mathbf{y} = \mathbf{y}(\mathbf{x})$ such that the elements of $\mathbf{y}$ are statistically independent and have a standard normal distribution. An iterative algorithm can be used to locate the design point or MPFP on the limit state function using the first-order approximation. During each iteration, the structural response and the response gradient vectors are calculated using finite

element models. The following iteration scheme can be used for finding the coordinates of the design point:

$$\mathbf{y}_{i+1} = \left[\mathbf{y}_i^t \alpha_i + \frac{g(\mathbf{y}_i)}{|\nabla g(\mathbf{y}_i)|} \right] \alpha_i \quad (1)$$

where

$$\nabla g(\mathbf{y}) = \left[\frac{\partial g(\mathbf{y})}{\partial y_1}, \dots, \frac{\partial g(\mathbf{y})}{\partial y_n} \right]^t \quad \text{and} \quad \alpha_i = -\frac{\nabla g(\mathbf{y}_i)}{|\nabla g(\mathbf{y}_i)|} \quad (2)$$

To implement the algorithm, the gradient $\nabla g(\mathbf{y})$ of the limit state function in the standard normal space can be derived as (Haldar and Mahadevan 2000b):

$$\nabla g(\mathbf{y}) = \left[\frac{\partial g(\mathbf{y})}{\partial \mathbf{s}} \mathbf{J}_{s,x} + \left(\mathbf{Q} \frac{\partial g(\mathbf{y})}{\partial \mathbf{u}} + \frac{\partial g(\mathbf{y})}{\partial \mathbf{s}} \mathbf{J}_{s,D} \right) \mathbf{J}_{D,x} + \frac{\partial g(\mathbf{y})}{\partial \mathbf{x}} \right] \mathbf{J}_{y,x}^{-1} \quad (3)$$

where $\mathbf{J}_{i,j}$'s are the Jacobians of transformation (e.g., $\mathbf{J}_{s,x} = \partial \mathbf{s} / \partial \mathbf{x}$) and y_i 's are statistically independent random variables in the standard normal space. The evaluation of the quantities in Eq. 3 will depend on the problem under consideration (linear or nonlinear, two or three dimensional, etc.) and the performance functions used. The essential numerical aspect of SFEM is the evaluation of three partial derivatives, $\partial g / \partial \mathbf{s}$, $\partial g / \partial \mathbf{u}$, and $\partial g / \partial \mathbf{x}$ and four Jacobians, $\mathbf{J}_{s,x}$, $\mathbf{J}_{s,D}$, $\mathbf{J}_{D,x}$, and $\mathbf{J}_{y,x}$. They can be evaluated by procedures suggested by Haldar and Mahadevan (2000b) for linear and nonlinear, two- or three-dimensional structures. Once the coordinates of the design point $\mathbf{y}^*$ are evaluated with a preselected convergence criterion, the reliability index β can be evaluated as:

$$\beta = \sqrt{(\mathbf{y}^*)^t (\mathbf{y}^*)} \quad (4)$$

The probability of failure, P_f , can be calculated as:

$$P_f = \Phi(-\beta) = 1.0 - \Phi(\beta) \quad (5)$$

where Φ is the standard normal cumulative distribution function. Equation 5 can be considered as a notational failure probability. When the reliability index is larger, the probability of failure will be smaller. The author and his team published numerous papers to validate the above procedure for static application of the loading.

Dynamic Governing Equation for SFEM

The nonlinear dynamic equilibrium equation can be expressed at time $t + \Delta t$ as:

$$\begin{aligned} & \mathbf{M}^{t+\Delta t} \ddot{\mathbf{D}}^{(k)} + {}^t\mathbf{C}^{t+\Delta t} \dot{\mathbf{D}}^{(k)} + {}^t\mathbf{K}^{(k)} \mathbf{D}^{(k)} \\ &= {}^{t+\Delta t}\mathbf{F}^{(k)} - {}^{t+\Delta t}\mathbf{R}^{(k-1)} - \mathbf{M}^{t+\Delta t} \ddot{\mathbf{D}}_g^{(k)} \end{aligned} \quad (6)$$

where $\mathbf{M}$ is the mass matrix, ${}^t\mathbf{C}$ is the viscous damping coefficient matrix at time t , ${}^t\mathbf{K}^{(k)}$ is the global tangent stiffness matrix of the k^{th} iteration

at time t , ${}^{t+\Delta t}\Delta\mathbf{D}^{(k)}$ is the incremental displacement vector of the k^{th} iteration at time $t + \Delta t$, ${}^{t+\Delta t}\mathbf{F}^{(k)}$ is the external load vector of the k^{th} iteration at time $t + \Delta t$, ${}^{t+\Delta t}\mathbf{R}^{(k-1)}$ is the internal force vector of the $(k-1)^{\text{th}}$ iteration at time $t + \Delta t$, and ${}^{t+\Delta t}\ddot{\mathbf{D}}_g^{(k)}$ is the seismic ground acceleration vector of the k^{th} iteration at time $t + \Delta t$.

The damping matrix ${}^t\mathbf{C}$ in Eq. 6 is considered to be viscous. In a realistic seismic analysis of frames, the amount of damping energy to be generated will depend on the non-yielding and yielding state of the material and the hysteretic behavior if the material yields. For mathematical simplicity, the effect of non-yielding energy dissipation is generally represented by equivalent viscous damping varying between 0.1 % and 7 % of the critical damping (Leger and Dussault 1992). Among many alternatives, Rayleigh-type damping is utilized in this study. It can be represented as:

$${}^t\mathbf{C} = \alpha\mathbf{M} + \gamma{}^t\mathbf{K} \quad (7)$$

where ${}^t\mathbf{K}$ is the tangent stiffness matrix and α and γ are proportional constants which can be evaluated from the natural frequencies of the structure. Since Rayleigh-type damping is proportional to mass and stiffness matrixes, it is more appropriate for nonlinear behavior as it incorporates information on changes in the stiffness values.

Numerical Procedures

The following numerical procedures can be followed to implement SFEM concept for seismic or dynamic loading. The step-by-step direct integration numerical procedure using the Newmark- β method, with parameters $\eta = 1/2$ and $\beta_N = 1/4$, can be used to solve Eq. 6. The iterative scheme can be expressed as:

$${}^t\mathbf{K}_D {}^{t+\Delta t}\Delta\mathbf{D}^{(k)} = {}^{t+\Delta t}\mathbf{F}^{(k)} - {}^{t+\Delta t}\mathbf{R}^{(k-1)} \quad (8)$$

where

$${}^{t+\Delta t}\mathbf{F}^{(k)} = {}^{t+\Delta t}\mathbf{F}^{(k-1)} + {}^{t+\Delta t}\Delta\mathbf{F}_D^{(k)} \quad (9)$$

and ${}^t\mathbf{K}_D$ is the dynamic tangent stiffness matrix and can be shown to be:

$${}^t\mathbf{K}_D = f_1\mathbf{M} + f_2{}^t\mathbf{K} \quad (10)$$

${}^{t+\Delta t}\mathbf{F}^{(k-1)}$ and ${}^{t+\Delta t}\Delta\mathbf{F}_D^{(k)}$ are the modified external force and its incremental vector, respectively. The modified external force vector can be expressed as:

$${}^{t+\Delta t}\mathbf{F}^{(k-1)} = {}^{t+\Delta t}\mathbf{F}^{(k-1)} + {}^{t+\Delta t}\mathbf{P}^{(k-1)} - \mathbf{M}{}^{t+\Delta t}\ddot{\mathbf{D}}^{(k-1)} \quad (11)$$

And ${}^{t+\Delta t}\mathbf{R}^{(k-1)}$ is the internal force vector of the system. The term ${}^{t+\Delta t}\mathbf{P}^{(k-1)}$ in Eq. 11 is the modified force vector contributed by the displacement, velocity, and acceleration at time t and the displacement at time $t + \Delta t$ and can be written as

$$\begin{aligned} {}^{t+\Delta t}\mathbf{P}^{(k-1)} = \mathbf{M} & \left[f_1{}^t\ddot{\mathbf{D}} + f_3{}^t\dot{\mathbf{D}} + f_4{}^t\ddot{\mathbf{D}} - f_1{}^{t+\Delta t}\ddot{\mathbf{D}}^{(k-1)} \right] \\ & + {}^t\mathbf{K} \left[f_5{}^t\mathbf{D} + f_6{}^t\dot{\mathbf{D}} + f_7{}^t\ddot{\mathbf{D}} - f_5{}^{t+\Delta t}\mathbf{D}^{(k-1)} \right] \end{aligned} \quad (12)$$

The incremental external force term ${}^{t+\Delta t}\Delta\mathbf{F}_D^{(k)}$ can be shown to be:

$${}^{t+\Delta t}\Delta\mathbf{F}_D^{(k)} = {}^{t+\Delta t}\Delta\mathbf{F}^{(k)} - \mathbf{M}{}^{t+\Delta t}\Delta\ddot{\mathbf{D}}_g^{(k)} \quad (13)$$

The coefficients, f_i 's, are constants and can be evaluated (Haldar and Nee 1989) in terms of η , α , β_N , γ , and Δt as:

$$\begin{aligned} f_1 &= \frac{1}{\beta_N\Delta t^2} + \frac{\eta\alpha}{\beta_N\Delta t}, \quad f_2 = \frac{\eta\gamma}{\beta_N\Delta t} + 1, \\ f_3 &= \frac{1}{\beta_N\Delta t} + \frac{\eta\alpha}{\beta_N} - \alpha, \\ f_4 &= \left(\frac{1}{2\beta_N} - 1 \right) + \eta\alpha \left(\frac{1}{2\beta_N} - \frac{1}{\eta} \right) \Delta t, \\ f_5 &= \frac{\eta\alpha}{\beta_N\Delta t}, \quad f_6 = \frac{\eta\gamma}{\beta_N} - \gamma, \quad f_7 = \left(\frac{\eta\gamma}{2\beta_N} - \gamma \right) \Delta t \end{aligned} \quad (14)$$

Equation 8 now can be solved using the modified Newton-Raphson method. Once the displacements are obtained, the member forces can be calculated accordingly.

Consideration of PR Connections in the Finite Element Formulation

The presence of partial connection rigidity needs to be incorporated into the deterministic analysis of structures to capture their behavior. In general, the relationship between the moment M , transmitted by the connection, and the relative rotation angle θ is used to represent the flexible behavior. Among the many alternatives (Richard model, piecewise linear model, polynomial model, exponential model, B-spline model, etc.), the Richard four-parameter moment–rotation model is chosen here to represent the flexible behavior of a connection. It can be expressed as (Richard and Abbott 1975):

$$M = \frac{(k - k_p)\theta}{\left(1 + \left|\frac{(k - k_p)\theta}{M_0}\right|^N\right)^{1/N}} + k_p\theta \quad (15)$$

where M is the connection moment, θ is the relative rotation between the connecting elements, k is the initial stiffness, k_p is the plastic stiffness, M_0 is the reference moment, and N is the curve shape parameter. These parameters are identified in Fig. 1.

Although an ordinary beam-column element is used to represent a PR connection element for numerical analyses, its stiffness needs to be updated at each iteration since the stiffness representing the partial rigidity depends on θ . This can be accomplished by updating the Young's modulus as:

$$E_C(\theta) = \frac{l_C}{I_C} K_C(\theta) = \frac{l_C}{I_C} \frac{\partial M(\theta)}{\partial \theta} \quad (16)$$

where l_C , I_C , and $K_C(\theta)$ are the length, the moment of inertia, and the tangent stiffness of the connection element, respectively. $K_C(\theta)$ is calculated using Eq. 15 and can be shown to be:

$$K_C(\theta) = \frac{dM}{d\theta} = \frac{(k - k_p)}{\left(1 + \left|\frac{(k - k_p)\theta}{M_0}\right|^N\right)^{\frac{N+1}{N}}} + k_p \quad (17)$$

The Richard model discussed up to now represents only the monotonically increasing loading portion of the M – θ curves. However, the unloading and reloading behavior of the M – θ curves is also essential for any nonlinear seismic analysis. This subject was extensively addressed in the literature (Colson 1991; El-Salti 1992). They theoretically developed the unloading and reloading parts of the M – θ curves using the Masing rule. A general class of Masing models can be defined with a virgin loading curve expressed as:

$$f(M, \theta) = 0 \quad (18)$$

and its unloading and reloading curve can be described by the following equation:

$$f\left(\frac{M - M_a}{2}, \frac{\theta - \theta_a}{2}\right) = 0 \quad (19)$$

where (M_a, θ_a) is the load reversal point as shown in Fig. 1.

Using the Masing rule and the Richard model represented by Eqs. 15 and 17, the unloading and reloading behavior of a PR connection can be generated as:

$$M = M_a - \frac{(k - k_p)(\theta_a - \theta)}{\left(1 + \left|\frac{(k - k_p)(\theta_a - \theta)}{2M_0}\right|^N\right)^{1/N}} - k_p(\theta_a - \theta) \quad (20)$$

and

$$K_C(\theta) = \frac{dM}{d\theta} = \frac{(k - k_p)}{\left(1 + \left|\frac{(k - k_p)(\theta_a - \theta)}{2M_0}\right|^N\right)^{\frac{N+1}{N}}} + k_p \quad (21)$$

If (M_b, θ_b) is the next load reversal point, as shown in Fig. 1, the reloading relation between M and θ can be obtained by simply replacing (M_a, θ_a) with (M_b, θ_b) in Eqs. 20 and 21. Thus, the proposed method uses Eqs. 15 and 17 when the connection is loading and Eqs. 20 and 21 when

Structural Reliability Estimation for Seismic Loading, Fig. 1 M - θ curve using the Richard model, Masing rule, and uncertainty (Huh and Haldar 2002)

the connection is unloading and reloading. This represents hysteretic behavior at the PR connections.

The basic FEM formulation of the structure remains unchanged, and thus the incorporation of the PR connection can be successfully accomplished.

Pre- and Post-Northridge PR Connections

During the Northridge earthquake of 1994, several connections in steel frames fractured in a brittle and premature manner. A typical connection, shown in Fig. 2, was fabricated with the beam flanges attached to the column flanges by full penetration welds (field welded) and with the beam web bolted (field bolted) to single plate shear tabs (Richard and Radau 1998), denoted hereafter as the pre-NC.

In the post-Northridge design practices, the thrusts were to make the connections more flexible than the pre-NC and to move the location of formation of any plastic hinge away from the connection and to provide more ductility to increase the energy absorption capacity. Several improved connections can be found in the literature including cover-plated connections, spliced beam

connections, side-plated connections, bottom haunch connections, connections with vertical ribs, and connections with a reduced beam sections (RBS) or dog boned (FEMA 350–3 2000). Seismic Structural Design Associates, Inc. (SSDA) proposed a unique proprietary slotted web (SSDA SlottedWebTM) moment connection (Richard et al. 1997), as shown in Fig. 3, denoted hereafter as the post-NC. The author was given access to some of the actual SSDA full-scale test results. Using the four parameters Richard model discussed earlier, Mehrabian et al. (2005) proposed a mathematical model to represent moment-relative rotation (M - θ) curves for this type of connections. Once (M - θ) curves are available, they can be used for the reliability evaluation, as discussed in the previous section. This is very important that this type of performance-enhancing feature is incorporated in any reliability evaluation.

Uncertainties in the Connection Model

A considerable amount of the uncertainty in the connection behavior comes from the uncertainties in the manufacturing and assembling processes and from the mathematical modeling (Haldar and Mahadevan 2000a). Deterministic prediction of connection behavior, based on either empirical formulations or single test data, is likely to overestimate the strength and stiffness. In practice, parameters in a typical M - θ curve are estimated from experimental results using a curve-fitting technique. Therefore, deterministic curves do not account for the scatter in the connection behavior. To consider the uncertainty in modeling the behavior of PR connections, the four parameters in the Richard model can be considered to be the basic random variables as shown in Fig. 1, along with other load- and resistance-related random parameters.

Seismic Reliability Evaluation for Large Structures

Considering all the challenges discussed above, a robust reliability evaluation technique for large

Structural Reliability Estimation for Seismic Loading, Fig. 2 A typical pre-NC (Mehrabian et al. 2005)

Structural Reliability Estimation for Seismic Loading, Fig. 3 A typical post-NC (Mehrabian et al. 2005)

structural systems may not be available at this time. In the presence of such vacuum, one may decide a simple Monte Carlo simulation (MCS) to address the presence of uncertainty. It is observed that one deterministic analysis of a large structure excited by seismic loading applied in time domain satisfying different sources of energy dissipation and satisfying underlying physics may take over 10 h of computer time.

If one decides only say 10,000 cycles of MCS, it will take about 100,000 h or about 11.4 years of continuous running of a computer. Obviously, it will be impractical.

Eliminating the basic MCS as a realistic alternative for large structural systems with relatively moderate probability of failure events, the available computational approaches can be broadly divided into two categories: (i) the

sensitivity-based stochastic finite element method (SFEM) analysis and (ii) the response surface method (RSM). This led to the development of sensitivity-based SFEM formulation (Haldar and Mahadevan 2000b). The other alternative is RSM (Box et al. 1978). The primary purpose of applying RSM in reliability analysis is to approximate the original complex and implicit limit state function using a simple and explicit polynomial (Bucher and Bourgund 1990; Yao and Wen 1996; Khuri and Cornell 1996). The three basic weaknesses of RSM that need to be addressed before applying it for structural reliability evaluations are the following: (1) it cannot incorporate distribution information of random variables even when it is available; (2) if the response surface is not generated in the failure region, it may not be directly applicable or robust; and (3) for large systems, it may not give the optimal sampling points. Thus, a basic RSM-based reliability method may not be acceptable.

At present, a second-order polynomial without and with cross terms are generally used to generate response surfaces. Recently, Li et al. (2001) proposed high-order response surface method (HORSM). The method employs Hermite polynomials and the one-dimensional Gaussian points as sampling points to determine the highest power of each variables. In recent past, several methods with the general objective of approximately developing multivariate expressions for response surface for mechanical engineering applications were proposed. One such method is the high-dimensional model representation (HDMR) (Alis and Rabitz 2001; Rao and Chowdhury 2009; Sobol 2003; Wei and Rahman 2007). It is also referred to as “decomposition method,” “univariate approximation,” “bivariate approximation,” “S-variate approximation,” etc. HDMR captures the high-dimensional relationships between sets of input and output model variables in such a way that the component functions of the approximation are ordered starting from a constant and adding terms such as first order, second order, and so on. The concept appears to be reasonable if higher-order variable correlations are weak,

allowing the physical model to be captured by the first few lower-order terms.

Another major work is known as the explicit design space decomposition (EDSD). It can be used when responses can be classified into two classes, e.g., safe and unsafe. The classification is performed using explicitly defined boundaries in space. A machine learning technique known as support vector machines (SVM) (Basudhar et al. 2008; Layman et al. 2007) is used to construct the boundaries separating distinct classes. The failure regions corresponding to different modes of failure are represented with a single SVM boundary, which is refined through adaptive sampling.

The HORSM, HDMR, and EDSD-SVM approaches use MCS to estimate the underlying reliability. They may not be suitable for reliability evaluation of large structural systems where dynamic loadings need to be applied in time domain and several important features like PR connections, several sources of nonlinearities and energy dissipation features must be explicitly analytically incorporated in the formulation satisfying the underlying physics.

Proposed New Method

The proposed reliability evaluation method for large structural systems is developed in two stages. In the first stage, the two weaknesses of RSM, i.e., the consideration of distributional information of the random variables present in the formulation and identifying the location of the failure region, are addressed by integrating it with FORM/SORM. This approach will lead to a hybrid approach consisting of SFEM, FORM/SORM, and RSM. In the second stage, the efficiency of the method is improved by using several advanced factorial schemes so that the response surface can be generated with fewer sampling points.

Proposed Method: Stage 1

Considering the fact that a higher-order polynomial may result in an ill-conditional system of equations for unknown coefficients and exhibit

an irregular behavior outside of the domain of samples, their utilization in generating RSM has received relatively little attention (Gavin and Yau 2008; Rajashekhar and Ellingwood 1993). For complicated problems considered by the research team of the author, a second-order polynomial, without and with cross terms, is considered to be appropriate. They can be expressed as:

$$\hat{g}(\mathbf{X}) = b_0 + \sum_{i=1}^k b_i X_i + \sum_{i=1}^k b_{ii} X_i^2 \quad (22)$$

$$\hat{g}(\mathbf{X}) = b_0 + \sum_{i=1}^k b_i X_i + \sum_{i=1}^k b_{ii} X_i^2 + \sum_{i=1}^{k-1} \sum_{j>i}^k b_{ij} X_i X_j \quad (23)$$

where X_i ($i = 1, 2, \dots, k$) is the i th random variable and b_0 , b_i , b_{ii} , and b_{ij} are unknown coefficients to be determined. The numbers of coefficient necessary to define Eqs. 22 and 23 are $p = 2k + 1$ and $p = (k + 1)(k + 2)/2$, respectively. The coefficients can be fully defined by estimating deterministic responses at intelligently selected data points called experimental sampling points. The concept behind a sampling scheme can be expressed as:

$$X_i = X_i^C \pm h_i \sigma_{x_i} x_i \quad (24)$$

where X_i^C and σ_{x_i} are the coordinates of the center point and the standard deviation of a random variable X_i , respectively, and h_i is an arbitrary factor that defines the experimental region.

Sampling points are selected around the center point. The selection of the center point and experimental sampling points around it are crucial factors in establishing the efficiency and accuracy of the proposed iterative method. The center point is selected to be the coordinates of the checking points as the iteration continues. In the context of iterative scheme of FORM/SORM, the initial center point $\mathbf{x}_{C_1}$ is selected to be the mean values of the random variable X_i 's. Then, using the responses obtained from the deterministic FEM evaluations for all the experimental sampling points around the center point, the response surface $\hat{g}_1(\mathbf{X})$ can be generated explicitly in terms of the random variables $\mathbf{X}$. Once a closed-form expression for the limit state function is obtained, the coordinates of the checking point $\mathbf{x}_{D_1}$ can be estimated using FORM/SORM, using all the statistical information on the X_i 's, eliminating one major deficiency of RSM. The response can be evaluated again at the checking point $\mathbf{x}_{D_1}$, and a new center point $\mathbf{x}_{C_2}$ can be selected using linear interpolation from the center point $\mathbf{x}_{C_1}$ to $\mathbf{x}_{D_1}$ such that $g(\mathbf{X}) = 0$, i.e.,

$$\mathbf{x}_{C_2} = \mathbf{x}_{C_1} + (\mathbf{x}_{D_1} - \mathbf{x}_{C_1}) \frac{g(\mathbf{x}_{C_1})}{g(\mathbf{x}_{C_1}) - g(\mathbf{x}_{D_1})} \quad \text{if } g(\mathbf{x}_{D_1}) \geq g(\mathbf{x}_{C_1}) \quad (25)$$

$$\mathbf{x}_{C_2} = \mathbf{x}_{D_1} + (\mathbf{x}_{C_1} - \mathbf{x}_{D_1}) \frac{g(\mathbf{x}_{D_1})}{g(\mathbf{x}_{D_1}) - g(\mathbf{x}_{C_1})} \quad \text{if } g(\mathbf{x}_{D_1}) < g(\mathbf{x}_{C_1}) \quad (26)$$

A new center point $\mathbf{x}_{C_2}$ then can be used to develop an explicit performance function for the next iteration. This iteration scheme can be repeated until a preselected convergence criterion of $(\mathbf{x}_{C_{i+1}} - \mathbf{x}_{C_i})/\mathbf{x}_{C_i} \leq \varepsilon$ is satisfied. ε can be considered to be $[0.05]$. In the final iteration, the information on the most recent center point

can be used to formulate the final response surface. FORM/SORM can then be used to calculate the reliability index and the corresponding coordinates of the MPFP.

It is to be noted that since increasing efficiency is a major objective, random variables with low-sensitivity indexes (Haldar and Mahadevan 2000a)

can be considered as deterministic at their mean values without compromising the accuracy of the reliability estimation.

To select experimental sampling points around the center point, saturated design (SD) and central composite design (CCD) are the two most promising schemes. SD is less accurate but more efficient since it requires only as many sampling points as the total number of unknown coefficients to define the response surface. CCD is more accurate but less efficient since a regression analysis is needed to evaluate the unknown coefficients for the response surface. Also, a second-order polynomial with cross terms (Eq. 23) must be used for CCD.

To illustrate the computational effort required for the reliability evaluation of a large structural system, suppose the total number of significant random variables, after making some of them deterministic at their mean values, present in the formulation is $k = 50$. The total number of coefficients necessary to define Eq. 22 will be $2 \times 50 + 1 = 101$ and to define Eq. 23 will be $(50 + 1)(50 + 2)/2 = 1326$. It can also be shown that if Eq. 22 and SD scheme are used to generate the response surface, the total number of sampling points, essentially the total number of deterministic FEM-based time-domain nonlinear response analyses will be 101. However, if Eq. 23 and a full SD scheme are used, the corresponding deterministic analyses will be 1326. If Eq. 23 and CCD scheme are used, the corresponding deterministic analyses will be $2^{50} + 2 \times 50 + 1 > 1.1258999 \times 10^{15}$. Obviously, some of these alternatives may not be meaningful.

Since the proposed algorithm is iterative and the basic SD and CCD require different amounts of computational effort, considering efficiency without compromising accuracy, several schemes can be followed. Among the numerous schemes considered by the research team, one basic and two promising schemes are:

Scheme 0 – SD using second-order polynomial without the cross terms throughout all the iterations.

Scheme 1 – Implement SD using Eq. 22 for the intermediate iterations and SD using Eq. 23 for the final iteration.

Scheme 2 – Implement SD using Eq. 22 for the intermediate iterations and CCD using Eq. 23 for the final iteration.

The efficiency and accuracy of the above schemes will be discussed with the help of an example.

Proposed Method: Stage 2

The above two schemes may be major improvements but still may not be able to estimate the reliability of large structural systems. They may require fewer deterministic evaluations but still they could be in thousands. Their efficiency can be improved significantly by reducing the deterministic evaluations in hundreds in the following way.

Scheme M1: To improve the efficiency of Scheme 1, the cross terms (edge points), $k(k - 1)$, are suggested to be added only for the most important variables in the last iteration. Since the proposed algorithm is an integral part of FORM/SORM, all the random variables in the formulation can be arranged in descending order of their sensitivity indexes $\alpha(X_i)$, i.e., $\alpha(X_1) > \alpha(X_2) > \alpha(X_3) \dots \dots > \alpha(X_k)$. The sensitivity of a variable X , $\alpha(X)$, is the directional cosines of the unit normal vector at the design point. In the last iteration, the cross terms are added only for the most sensitive random variables, m , and the corresponding reliability index is calculated. The total number of FEM analyses required for Scheme 1 and M1 are $(k + 1)(k + 2)/2$ and $2k + 1 + m(2k - m - 1)/2$, respectively. For an example, suppose for a large structural system, $k = 50$ and $m = 3$. The total number of required FEM analyses will be 1326 and 245, respectively, for the two schemes; a significant improvement in the efficiency without compromising the accuracy.

Illustrative Examples

To illustrate the different procedures discussed here for the seismic risk evaluation of a structure, the following illustrative examples are presented.

Structural Reliability Estimation for Seismic Loading, Fig. 4 A three-story three-bay SMRF structure (Haldar et al. 2012)

Structural Reliability Estimation for Seismic Loading, Fig. 5 Earthquake time history used in this study

Reliability of Steel Frames in the Presence of Reinforced Concrete Shear Wall: Seismic Loading is Applied in Time Domain

A three-story three-bay steel frame, as shown in Fig. 4, is considered (Haldar et al. 2012). Section sizes of beams and columns, using A36 steel, are also shown in the figure. The gravity loads acting on the second, third, and roof are given in the figure. A building is supposed to consist of several such frames. It was excited by a seismic time history shown in Fig. 5.

The four parameters of the Richard model are calculated by PRCONN (Richard 1993), a commercially available computer program for both pre-NC and post-NC connections. For the

example under consideration, considering the sizes of columns and beams, three types of connection are necessary. They are denoted as types A, B, and C, hereafter. Four Richard parameters for both pre-NC and post-NC connections are summarized in Table 1.

Limit States of Performance Functions

Both strength and serviceability limit states are used for structural reliability estimation.

Strength limit states: They mainly depend on the failure mode to be considered. Most of the elements in the structural system considered are beam columns, i.e., they are subjected to both axial load and bending moment at the same time.

^akN · cm/rad^bkN · cm

For design purposes, interaction equations are generally used to consider the combined effect of axial load and bending moment. The interaction equations suggested by the American Institute of Steel Construction's *Load and Resistance Factor Design* manual (AISC 2005) for two-dimensional structures are used for this illustrative example. They can be expressed as:

$$\frac{P_u}{\phi P_n} + \frac{8}{9} \left(\frac{M_{ux}}{\phi_b M_{nx}} \right) \leq 1.0; \quad \text{if } \frac{P_u}{\phi P_n} \geq 0.2 \quad (27)$$

$$\frac{P_u}{2\phi P_n} + \left(\frac{M_{ux}}{\phi_b M_{nx}} \right) \leq 1.0; \quad \text{if } \frac{P_u}{\phi P_n} < 0.2 \quad (28)$$

where ϕ and ϕ_b are the resistance factors, P_u is the required tensile/compressive strength, P_n is the nominal tensile/compressive strength, M_{ux} is the required flexural strength, and M_n is the nominal flexural strength. P_n and M_{nx} can be calculated using AISC's LRFD code (AISC 2005).

Serviceability limit states: For seismic loading, the design may be controlled by the serviceability, e.g., inter-story drift or the overall lateral displacement. The general form of a serviceability limit state can be represented as:

$$g(\mathbf{X}) = \delta_{\text{allow}} - y_{\text{max}}(\mathbf{X}) = \delta_{\text{allow}} - \hat{g}(\mathbf{X}) \quad (29)$$

where δ_{allow} is the allowable inter-story drift or overall lateral displacement specified in codes and $y_{\text{max}}(\mathbf{X})$ is the corresponding maximum inter-story drift or overall lateral displacement estimated from the analysis.

Reliability Evaluations of Frames with Different Connection Conditions and Without RC Shear Wall

The statistical information on all the random variables for the illustrative example is summarized in Table 2. The allowable displacement at the top of the frame, δ_{allow} , is considered to be $h/400$, where h is the height of the frame. For this example, δ_{allow} is 2.97 cm. The corresponding serviceability limit state is defined by Eq. 29 (Huh and Haldar 2011). The probabilities of failure of the frame for the lateral deflection at the top of the frame for serviceability limit state and the strength limit state of the weakest members are first estimated assuming all the connections are of FR type, considered routinely in the profession. The results are summarized in Table 3 using the proposed method. To verify the results, 20,000 MCS for the serviceability and 30,000 MCS for the strength limit states were carried out.

The results clearly indicate that the bare steel frame will not satisfy the serviceability requirement. Then, the reliabilities of the frame are estimated assuming all the connections are post-NC

and pre-NC types and the results are summarized in Table 4. The behavior of the frame in the presence of FR and post-NC for both serviceability and strength limit states are very similar. This was also observed during the full-scale experimental investigations establishing the advanced features of the proposed method. In any case, the lateral stiffness of the frame needs to be increased.

Reliability Evaluations of Frames with Different Connection Conditions with RC Shear Wall

To increase the lateral stiffness, the steel frame is strengthened with a reinforced concrete (RC) shear wall at the first floor level, as shown in Fig. 6. Obviously, the RC shear wall will increase the complexity in the problem.

Structural Reliability Estimation for Seismic Loading, Fig. 6 Steel frame with RC shear wall in the first floor (Haldar et al. 2012)

However, if it is placed properly, it will increase the lateral stiffness of the frame.

For the steel and concrete dual system, all the steel elements in the frame are modeled as beam-column elements. A four-node plane stress element is introduced for the shear wall in the frame. To consider the presence of RC shear wall, two additional parameters, namely, the modulus of elasticity, E_C , and the Poisson ratio of concrete, ν , are necessary in the deterministic formulation. The tensile strength of concrete is small compared to its compressive strength and cracking may develop at a very early stage of loading. The behavior of an RC shear wall is expected to be significantly different before and after cracking. It was observed that the degradation of the stiffness of the shear walls occurs after cracking and can be considered effectively by reducing the modulus of elasticity of the shear walls (Lefas et al. 1990). The same concept is used in this study. The shear wall is assumed to develop cracks when the tensile stress in concrete exceeds the prescribed value. The rupture strength of concrete, f_r , is assumed to be $f_r = 7.5 \times \sqrt{f'_c}$, where f'_c is the compressive strength of concrete. After the tensile stress of each shear wall exceeds the prescribed tensile stress of concrete, the degradation of the shear wall stiffness is assumed to be reduced to 40 % of the original stiffness (Lefas et al. 1990). The uncertainty in all the variables considered for the bare steel frame will remain the same. However, two additional sources of uncertainty, namely, in E_C and ν , need to be considered (Lee and Haldar 2003), as given in Table 2.

The frame is again excited by the same earthquake time history as shown in Fig. 2. The probabilities of failure for the combined dual system in the presence of FR, post-NC, and pre-NC connections are calculated using the proposed algorithm for the strength and serviceability limit states. The results are summarized in Table 4. The results indicate that the presence of shear wall at the first floor level significantly improves both the serviceability and strength behavior of the steel frame. If the probabilities

of failure need to be reduced further, RC shear walls can be added in the second and/or third floor. Again, this improved behavior can be observed and quantified by carrying out about a hundred deterministic evaluations instead of thousands of MCS. The improved behavior of the frame in the presence of RC shear wall is expected; however, the proposed algorithm can quantify the amount of improvement in terms of probability of failure considering all major sources of uncertainty. This is a significant development. The information will help to make decision as what to do next in the design.

Summary

Structural reliability estimation for seismic loading, specifically for large structural systems, is evolving. An overview of the existing state of the art is given. For wider acceptance, it is necessary to estimate reliability by applying the seismic loading in time domain, considering special features recently being introduced to improve seismic response behavior and explicitly considering all major sources of nonlinearity and uncertainty. A new method is suggested incorporating all these features. Several seismic risk evaluation procedures are illustrated with examples.

Introduction

Perhaps, no other discipline within engineering has to deal with as much uncertainty as the field of earthquake engineering (Der Kiureghian 1996). To begin with, the occurrence of earthquakes in time and space is completely random in nature, and this leads to a large amount of uncertainty while predicting the intensities of ground motions resulting from earthquakes. Further, it is challenging to precisely assess the load-carrying capacity of the structural system of interest, due to the inherent variability across different structural members that constitute the overall structural system. It is necessary to analyze all of these different sources of uncertainty and assess the safety of the structure by accounting for such sources of uncertainty. Structural safety assessment is important both during the design of the structural system and for analyzing its performance while the system is under operation, particularly before and after earthquakes.

Engineering design is usually a trade-off between maximizing safety levels and minimizing cost. It is necessary to account for the uncertainty in anticipated loading conditions and the different sources of uncertainty regarding the structural system while assessing safety during system design. Traditional design approaches simplify the problem by treating the uncertain quantities to be deterministic and account for

the inherent uncertainty through the use of empirical safety factors, also referred to as deterministic safety factors. These empirical safety factors do not provide any information on how the different uncertain quantities influence the overall structural safety. Therefore, it is difficult to design a system with a uniform distribution of safety levels among the different components using empirical safety factors (Haldar and Mahadevan 2000). Further, during the design stage, deterministic safety factors do not provide adequate information to achieve optimal use of the available resources to maximize safety. For these reasons, it is necessary to use probabilistic approaches that rigorously account for the different sources of uncertainty and directly aid in the design of the structural system. Probabilistic approaches directly calculate the probability that the structural system may fail by probabilistically analyzing the load-carrying capacity of the structure and the actual loading on the structure. The safety of the structure is defined in terms of the converse of the probability of failure, which in turn is used to compute the so-called reliability metric that measures the probabilistic reliability of the structure. In fact, probabilistic methods provide a systematic framework to analyze the different sources of uncertainty, quantify their individual contributions to the overall structural safety, and aid in efficient design by choosing design parameters that maximize the reliability of the structure.

During the operation of the structural system, particularly before and after earthquakes, it is important to assess the safety of the structure and make decisions regarding repairs and replacements that are necessary for maintenance, rehabilitation, and structural retrofitting. The quality of the structural components may have degraded over the course of the operation of the structure, and therefore, the load-carrying capacity of the structures may have changed over the course of time. Therefore, it is important to reassess structural safety by recalculating the structural demands and load-carrying limits and reestimating the reliability of the structure.

Since the advantages of probabilistic assessment of structural safety have become evident

during the past two decades, several design guidelines and codes are being revised to incorporate probabilistic analysis. Examples of such revision include the American Institute of Steel Construction Load and Resistance Factor Design (1994) specifications and the European and Canadian structural design specifications. The use of probabilistic analysis in these codes is expected to provide more information about system behavior, the influence of the various uncertain quantities on system performance, and the interaction between the different system components. Therefore, the engineering design community has been increasingly resorting to the use of probabilistic reliability assessment techniques over the past few years. This has further been aided by the advent of high power computing technology that supports the use of advanced computational techniques for probabilistic analysis.

This entry discusses the fundamental concepts of structural reliability analysis in the context of earthquake engineering and provides an overview of the various mathematical tools that may be used to assess the safety and reliability of different types of structural systems. The rest of this entry is organized as follows. The fundamental problem of reliability analysis is formally defined and mathematically presented in section “[Structural Reliability Analysis](#).” The various sources of uncertainty are discussed, and the challenges involved in reliability calculation are outlined. Section “[Simulation-Based Methods](#)” discusses different types of simulation techniques for structural reliability analysis; while simulation techniques rely on high computational power, they are generally accurate and serve as benchmark solutions for comparison against other computational methods. Section “[First-Order Reliability Methods](#)” discusses a class of analytical techniques, popularly known as first-order reliability methods, to calculate structural reliability. While analytical methods are based approximations, they are computationally far cheaper than simulation-based approaches. The aforementioned methods are first illustrated using a structural beam in section “[Numerical Example I: Structural Beam](#)” and using a structural

frame in section “[Numerical Example 2: Structural Frame](#).” Section “[Advanced Concepts in Structural Reliability](#)” reviews a few advanced methods for reliability assessment, thereby providing an overview of the state of the art in the topic of structural reliability analysis.

Structural Reliability Analysis

The fundamental formulation of structural reliability analysis is based on the fact that a structural failure occurs when the loading demand on the structure is greater than its load-carrying capacity. Conventionally, the load-carrying capacity of the structure is equivalent to the resistance offered by the structure and is denoted by R . The loading applied on the structure is denoted by S . The classical formulation of reliability analysis is based on the following equation:

$$G \equiv R - S \quad (1)$$

If the load-carrying capacity is larger than the applied loading, $G = R - S > 0$, and the structure is considered to be safe. If the load-carrying capacity is smaller than the applied loading, $G = R - S < 0$, and the structure is considered to have failed. The equation $G = 0$ represents the condition when the applied loading is equal to the resistance offered, and this equation is popularly known as the limit state equation in structural reliability analysis. Further, the function G is also referred to as the performance function.

If the loading on the structure (S) were to be known precisely and if the load-carrying capacity (R) of a structure could be estimated precisely, then R and S would become completely deterministic. It would then be possible to design a structure whose load-carrying capacity would be greater than the anticipated loading, and design would become a trivial problem. However, since R and S are mostly uncertain, particularly in earthquake engineering, it becomes challenging to ascertain whether the structure is safe or not.

Sources of Uncertainty

It is important to understand the reason why R and S are uncertain in practical structural systems. The uncertainty in S , i.e., the applied/anticipated loading conditions, can be explained from the fact a given structure does not experience the same amount of loading at all possible time instants. In the context of earthquake engineering, the occurrences of earthquakes and their intensities are random, and therefore, the structural loading that is resultant of these earthquakes is also random.

The resistance offered by a structural member, i.e., R , is also random due to several reasons. The resistance offered by a structural member depends on several quantities, including its material and geometric properties. For example, the maximum bending moment that can be applied on a beam is a function of its yield stress (material property) and the sectional modulus (geometric property). There are two types of uncertainty that contribute to the overall uncertainty in R . First, the material and geometric properties that govern the value of R may themselves be uncertain due to natural variability across nominally identical members of the same type. Second, the functional dependence between these quantities and R may not be precisely known; though a physics-based model may be developed to represent this functional relationship, it may not be accurately representative of the actual carrying capacity of the structure. The latter issue is commonly known as model uncertainty and has been an important topic of research during the past few years.

Some researchers classify the different types of uncertainty into aleatory and epistemic (Der Kiureghian and Ditlevsen 2009). Aleatory uncertainty refers to those types of uncertainty that are inherent in nature and, therefore, irreducible by definition. For example, the variability in material properties, variability in earthquake loading, etc. are all irreducible in nature. Epistemic uncertainty refers to those types of uncertainty that may be reduced when more information is available. For example, when an improved model can be used to predict the response of a structure, then the uncertainty regarding the model prediction would decrease, thereby decreasing the overall uncertainty.

Structural Seismic Reliability Analysis, Fig. 1 Region of overlap between R and S

Nevertheless, it is clear as to why R and S need to be treated as uncertain variables. Therefore, they need to be represented as probability distributions. Let $f_R(r)$ and $f_S(s)$ denote the probability density functions (PDF) of R and S , respectively, as shown in Fig. 1. Note that r and s are generic realizations of the random variables R and S , respectively. While some realizations of R and S may render the structure safe (whenever $r > s$), some other realizations of R and S may correspond to structural failure. The most important aspect of structural reliability analysis is to calculate the probability of structural failure based on the probability distributions of R and S .

Calculation of Failure Probability

From the preceding discussion, it can be easily seen that the probability of the event $G < 0$ is directly equal to the probability of structural failure, and this can be mathematically written as

$$P_f = P(R < S) = P(G < 0) \quad (2)$$

Using principles of probability, Eq. 2 can be rewritten as (Ditlevsen and Madsen 1996):

$$P_f = \int_{R < S} f_R(r) f_S(s) ds dr \quad (3)$$

The reliability of the structure is the converse of failure probability and is equal to $1 - P_f$. Typically, good design practices ensure that

$\mu_R > \mu_S$, where μ_R and μ_S denote the means of R and S , respectively. However, due to the uncertainty in R and S , there is small region of overlap between the densities of R and S , and in this region of overlap, structural failure will occur because $R < S$. Therefore, the probability content in this region of overlap is equal to P_f , and in fact, this region is the domain of integration in Eq. 3. The goal in design is to minimize this region of overlap, and this may be accomplished either by moving μ_R and μ_S apart from each other or by reducing σ_R and σ_S , where σ_R and σ_S denote the standard deviations of R and S , respectively. There is a design cost related with each of these activities; while it may be cost-wise prohibitive to eliminate this region of overlap, good design practices advocate minimizing the probability of failure subject to certain cost constraints. That is why it is important to be able to accurately estimate the value of failure probability.

Analytical, closed-form expressions are available for P_f only in the special case when both R and S are normally distributed, i.e., when R and S follow Gaussian distributions as $N(\mu_R, \sigma_R)$ and $N(\mu_S, \sigma_S)$, respectively. In this case, G follows the distribution $N(\mu_R - \mu_S, \sqrt{\sigma_R^2 + \sigma_S^2})$, and P_f can be evaluated as

$$P_f = P(G < 0) = \Phi\left(-\frac{\mu_R - \mu_S}{\sqrt{\sigma_R^2 + \sigma_S^2}}\right) \quad (4)$$

In order to delve deeper into this computation, consider the transformation of the Gaussian variables R and S into standard normal distributions (with zero mean and unit standard deviation) as follows:

$$R' = \frac{R - \mu_R}{\sigma_R} \quad (5)$$

$$S' = \frac{S - \mu_S}{\sigma_S} \quad (6)$$

Now, both R' and S' follow the Gaussian distribution $N(0, 1)$. This coordinate space is referred to as the reduce coordinate system or the standard normal coordinate system. Rewrite the limit

Structural Seismic Reliability Analysis, Fig. 2 Linear performance function

state equation in Eq. 1 in terms of the transformed variables as

$$G \equiv \sigma_R R' - \sigma_S S' + \mu_R - \mu_S = 0 \quad (7)$$

Since the performance function G is linear, the limit state equation corresponds to a straight line in the $R' - S'$ coordinate axis, as shown in Fig. 2. This straight line divides the plane into two regions. The first region corresponds to $G > 0$ and is known as “safe region,” while the second region corresponds to $G < 0$ and is known as the “unsafe region.”

It is apparent from Fig. 2 that if the limit state line is closer to the origin in the reduced coordinate system, the failure region is larger, and if it is away from the origin, the failure region is smaller. Hence, it is intuitive that the distance of this straight line to the origin is of importance and this can be computed using basic trigonometry as

$$\beta = \frac{\mu_R - \mu_S}{\sqrt{\sigma_R^2 + \sigma_S^2}} \quad (8)$$

Comparing Eq. 8 and Eq. 4, it can be easily seen that

$$\beta = \Phi^{-1}(-P_f), \quad (9)$$

where Φ^{-1} denotes the inverse of the standard normal cumulative distribution function (Haldar and Mahadevan 2000).

The minimum distance point on the limit state is referred to as the checking point or the design point or the most probable point (MPP); since this coordinate axis consists of standard normal variables, the closer a point is to the origin, the higher is the probability of the maximum, and hence, the most probable point is called so. The minimum distance β is popularly known as the Hasofer-Lind Reliability Metric (Hasofer and Lind 1974). The lower the value of P_f , the higher is the value of β and vice versa. Sometimes, in design applications, a target reliability value is specified, and the component or the structure is designed to meet this target value.

Having discussed the computation of failure probability by considering R and S to be Gaussian variables, it is necessary to understand that the probability distributions of R and S may not be readily available, in many structural applications. In fact, they may not even follow Gaussian distributions. It may be necessary to estimate their probability distributions based on the probability distributions of those quantities that influence R and S . An alternate approach is to redefine the limit state directly in terms of these quantities, as explained in the following subsection.

Generalized Definition of the Limit State

Consider that the performance of a structure is defined by generic set of quantities, given by $\mathbf{X}$, where $\mathbf{X} = \{X_i, i = 1 \text{ to } n\}$. The loading on the structure (S) and load-carrying capacity (R) can be expressed in terms of these generic set of quantities, and without loss of generality, the limit state in Eq. 1 can be rewritten as

$$G(\mathbf{X}) = 0 \quad (10)$$

The structure is said to be safe when $G(\mathbf{X}) > 0$, and the structure is said to have failed when $G(\mathbf{X}) < 0$. Limit states in earthquake engineering are of different types and correspond to different types of failures. Limit state related to the serviceability of the structure is used to check whether the deflections of structural

components are within acceptable limits, whether the stresses are lower than yield stress, etc. Limit states related to the safety of the structure are also known as ultimate limit states and are used to check whether accelerations are smaller than acceptable thresholds, whether the stress on the structure is lower than the ultimate stress, etc. Depending upon the criteria of design, a single limit state or a combination of states may be chosen. The majority of this entry deals with situations consisting of single limit states. When multiple limit states need to be simultaneously evaluated, it is necessary to resort to system reliability techniques (Mahadevan et al. 2001; Mahadevan and Raghoeamachar 2000), as later explained in section “[Advanced Concepts in Structural Reliability](#)” of this entry.

Consider a limit state equation that is based on a specific functional performance of the structure. Using the corresponding limit state equation, the structural failure probability can be calculated as

$$P_f = \int_{G(\mathbf{X}) < 0} f_{\mathbf{X}}(\mathbf{x}) d\mathbf{x}, \quad (11)$$

where $f_{\mathbf{X}}(\mathbf{x})$ denotes the joint probability density function of $\mathbf{X}$. If $\mathbf{X}$ consists of independent quantities, then the joint probability density function can be expressed as the product of the individual probability densities of X_i ($i = 1 \text{ to } m$).

Note that, in general, G may be nonlinear unlike Eq. 1, and therefore, the concepts explained in section “[Calculation of Failure Probability](#)” cannot be readily extended to this case. Further, underlying random variables, i.e., $\mathbf{X}$, may not follow Gaussian distributions at all. In order to overcome these challenges, researchers have developed a suite of computational methods to efficiently evaluate the integral in Eq. 11 and compute the failure probability. While some of these methods are based on simulation, other methods are based on linearizing G and, hence, popularly known as first-order reliability methods. These computational methods are discussed in sections “[Simulation-Based Methods](#)” and “[First-Order Reliability Methods](#),” respectively.

Simulation-Based Methods

The most intuitive approach to structural reliability analysis is to make use of simulation, i.e., repeatedly evaluate the performance function G for multiple realizations of the random variable $\mathbf{X}$, and use the results of these multiple evaluations to calculate the failure probability. Simulation techniques rely on the ability to generate pseudorandom numbers using computer programs and may require several thousand evaluations of G in order to produce meaningful results.

In any simulation-based approach, there are two steps. The first step is to randomly generate samples of $\mathbf{X}$, based on the joint probability density function $f_{\mathbf{X}}(\mathbf{x})$. The second step is to evaluate the function G for each of the randomly generated samples. While the former is a statistical problem, the latter is a modeling problem. Mathematical models (which may either be based on physics or which may be constructed using observed data) can be constructed to represent G , but it is necessary to resort to advanced statistical methods to generate random samples.

Generation of random samples is particularly easy when the various quantities in $\mathbf{X}$ are independent of each other. Then, random samples can be generated for each individual X_i . Several computer programs are capable of generating pseudorandom numbers that are uniformly distributed on the interval $[0, 1]$. Once a pseudorandom number (u_i) can be generated using a computer code, then the corresponding random sample of X_i may be generated by inverting the cumulative distribution function of X_i as

$$x_i = F_{X_i}^{-1}(u_i) \quad (12)$$

This procedure is repeated multiple times to obtain random samples of X_i . Then, the entire procedure is repeated for all the quantities in $\mathbf{X}$ to obtain multiple samples of $\mathbf{X}$.

When the quantities in $\mathbf{X}$ are dependent on one another, one approach is to use the full conditional distributions of the quantities in $\mathbf{X}$, i.e., probability densities such as $f_{X_i|X_j}(x_i|x_j)$, where $i \neq j$. Then, the conditional cumulative

distribution functions are used in Eq. 12 to successively generate one sample for each X_i . However, such information on conditional distributions may be difficult to obtain, in practice. Therefore, it is necessary to rely on correlation structure of $\mathbf{X}$ to generate correlated samples. The most popular approach to generate correlated samples using the covariance matrix of $\mathbf{X}$ is, perhaps, using the Nataf model (Liu and Der Kiureghian 1986). Alternatively, Cholesky decomposition (Haldar and Mahadevan 2000) or principal component analysis (Cox and Hinkley 1974) may also be used for such transformation. All of these methods are based on transforming the random variable $\mathbf{X}$ from the original, correlated coordinate space to an uncorrelated coordinate space using linear transformation techniques. An appropriate transformation matrix is computed, and using this matrix, it is possible to uniquely transform the variables from the correlated space to the uncorrelated space and vice versa. While generating correlated normal variables, it must be noted that it is challenging to accurately satisfy both the marginal distributions of the individual variables and the covariance matrix. In fact, it is not possible to uniquely define the joint probability density function using information on marginal distributions and the covariance matrix (Bickel and Doksum 1977). It must also be cautioned that correlation is able to capture only one type of dependence among variables, i.e., linear dependence. Other types of dependence cannot be captured using the aforementioned transformation techniques.

Having developed a mechanism to generate samples of $\mathbf{X}$, there are several types of simulation techniques that may be used to evaluate the failure probability. Some of the important techniques are briefly explained in this section.

Monte Carlo Sampling

Monte Carlo sampling (MCS) is the most straightforward approach to evaluate failure probability P_f . First, it is necessary to generate N random samples of $\mathbf{X}$, and then, the function G needs to be evaluated for every random sample $\mathbf{X}$. Recall that structural failure occurs when $G < 0$. Out of N evaluations of G , let N_f denote

the number of simulations in which $G < 0$. Then, an estimate of the probability of failure can be calculated as

$$P_f = \frac{N_f}{N} \quad (13)$$

Theoretically, an infinite number of samples are necessary to accurately estimate the probability of failure. Since only a finite number of samples are being used here, there is an uncertainty regarding the estimated value of P_f . This uncertainty can be expressed in terms of the variance of P_f as

$$\text{Variance of } P_f = \sqrt{\frac{P_f(1 - P_f)}{N}} \quad (14)$$

Thus, it can be seen that, for a given number of samples, the accuracy in the estimation of P_f increases proportional to the square root of the number of samples; for example, if the number of samples is quadrupled, then the accuracy is doubled.

The choice of the value of N is very critical in Monte Carlo analysis. As it can be seen from Eq. 14, the accuracy depends on the number of samples used. Further, in many engineering applications, the true probability of failure could be smaller than 10^{-5} . Therefore, on average, only 1 out of 100,000 samples would correspond to failure. Thus, at least 100,000 samples are necessary to observe failure. For a reliable estimate of failure probability, at least 10 times, this minimum (one million samples, in this case) is usually recommended. Sometimes, if G consists of a complex computer code (e.g., a finite element analysis), it may not be computationally feasible to evaluate G a million times. In such cases, it is necessary to resort to other alternative techniques for structural reliability estimation.

Importance Sampling

The basic idea of importance sampling is to deliberately select those samples of $\mathbf{X}$ that result in structural failure, instead of sampling them as per their original density $f_X(\mathbf{x})$. For this purpose, a new sampling density function $h_X(\mathbf{x})$ is defined so

that most samples derived out of this density function will lead to failure. Samples are drawn from $h_X(\mathbf{x})$ and corrected based on their original densities, while computing the failure probability. Therefore, $h_X(\mathbf{x})$ is popularly known as the proposal density function.

In order to mathematically derive the expression for failure probability, consider the definition of P_f as per Eq. 11. Note that the domain of integration is specifically over the failure region, defined by $G < 0$. Consider a mathematical indicator function as follows:

$$I_g(\mathbf{x}) = \begin{cases} 0, & \text{if } G(\mathbf{x}) > 0 \\ 1, & \text{if } G(\mathbf{x}) < 0 \end{cases} \quad (15)$$

Using this indicator function, the expression for failure probability can be rewritten as

$$P_f = \int I_g(\mathbf{x}) f_X(\mathbf{x}) d\mathbf{x} \quad (16)$$

Note that the domain of integration has now been explicitly rolled into the indicator function and need not be specified as integral limits. Now, multiplying and dividing by $h_X(\mathbf{x})$,

$$P_f = \int \left[I_g(\mathbf{x}) \frac{f_X(\mathbf{x})}{h_X(\mathbf{x})} \right] h_X(\mathbf{x}) d\mathbf{x} \quad (17)$$

If samples of $\mathbf{X}$ are drawn from $h_X(\mathbf{x})$, then the right-hand side of the above equation is simply the expectation of $I_g(\mathbf{x}) \frac{f_X(\mathbf{x})}{h_X(\mathbf{x})}$. Such an expectation over N samples can be computed numerically as

$$P_f = \frac{1}{N} \sum_{i=1}^N I_g(\mathbf{x}^i) \frac{f_X(\mathbf{x}^i)}{h_X(\mathbf{x}^i)} \quad (18)$$

The accuracy of the estimate of P_f obtained through importance sampling depends on the choice of $h_X(\mathbf{x})$. Several researchers have explored importance sampling in detail and studied its accuracy (Melchers 1989). In fact, the concept of importance sampling is also used in several other engineering applications such as particle filtering (Arulampalam et al. 2002), while tracking the behavior of dynamic systems.

Stratified Sampling

In this sampling approach, the overall domain of X is divided into multiple sub-domains, and samples are drawn from each sub-domain independently. The process of dividing the overall domain into multiple sub-domains is referred to as stratification. This method is applicable when subpopulations within the overall population are significantly different and when certain subpopulations contribute more to the failure probability than others.

Let the overall failure domain be divided into m mutually exclusive regions, denoted by Ω_i , where $i = 1$ to m . Each of these regions has its own probability, denoted by $P(\Omega_i)$. The unique feature of this method is that different number of samples may be chosen for each region; let N_i denote the number of samples in each region. Then, the failure probability can be expressed as

$$P_f = \sum_{i=1}^m \left[P(\Omega_i) \frac{1}{N} \sum_{j=1}^{N_i} I_g(\mathbf{x}^j) \right], \quad (19)$$

where $\mathbf{x}^j$ is the j th sample. An advantage of stratified sampling is that no particular region of the overall domain would be neglected during sampling.

Other Sampling Techniques

While it is almost impossible to explain all sampling approaches in detail, a few important techniques are briefly explained in this section, without delving into the details of implementation. Adequate references are provided for all of these techniques to instigate further reading on these topics.

While importance sampling requires far fewer number of samples than Monte Carlo sampling to estimate the failure probability, it is challenging to select an appropriate proposal density function because the region of “importance” (where more samples are likely to indicate structural failure) is usually unknown. **Adaptive sampling** is an advanced sampling technique where the efficiency of importance sampling is continuously improved by updating the proposal density function based on the information obtained after

evaluating G for a few samples. Two classes of adaptive sampling methods are multimodal sampling (Karamchandani et al. 1989) and curvature-based sampling (Wu 1992). It has been reported by researchers that adaptive sampling techniques can accurately estimate the failure probability using 100–400 samples, while traditional Monte Carlo techniques may require several hundreds of thousands of samples.

Recall that Eq. 14 provided an estimate for the variance P_f . Using the so-called variance reduction techniques, it is possible to reduce this variance and thereby obtain an improved estimate of P_f . Such techniques are called variance reduction techniques (Kalos and Whitlock 2008) and are commonly used while estimating P_f . One such technique is popularly called the **conditional expectation method**; in this method, a control variable is selected and the variance of P_f is reduced by removing the random fluctuations of this control variable which was not conditioned. In another technique, popularly known as the technique of **antithetic variates**, negative correlation is purposefully induced between successive samples to decrease the variance of the estimated mean value. It is also common to use the technique of antithetic variates in combination with the conditional expectation method (Haldar and Mahadevan 2000).

There are other sampling methods such as the Latin hypercube sampling (Iman 2008) method or the unscented transform sampling methods (Daigle and Sankararaman 2013). These sampling techniques are more well suited to compute the overall statistics of G , rather than to estimate $P_f = P(G < 0)$. While the Latin hypercube sampling approach focuses on covering the entire domain of X accurately, the unscented transform sampling method focuses on estimating the central moments of G .

Summary

This section discussed a variety of simulation techniques to estimate structural reliability. Topics such as Monte Carlo sampling, importance sampling, and stratified sampling were discussed in detail, and some other advanced topics such as adaptive sampling, variance

reduction techniques in sampling, etc. were briefly explained. The topic of structural reliability estimation using sampling has always been an important research topic, and researchers are constantly developing new methods to mitigate the computational challenges and estimate the failure probability as accurately as possible, using as fewer evaluations of G as possible.

First-Order Reliability Methods

This section discusses a class of methods known as the first-order reliability methods to compute the probability of failure of structural systems. These methods are based on the first-order Taylor's series expansion of the performance function $G(\mathbf{X})$. The first-method, known as the first-order second-moment (FOSM) method, focuses on approximating the mean and standard deviation of G and uses this information to compute P_f . Then, the FOSM method is extended to the advanced FOSM method in two steps: first, the methodology is developed for the case where all the variables in $\mathbf{X}$ are Gaussian (normal) and, second, the methodology is extended to the general case of non-normal variables.

First-Order Second-Moment Method

First, consider the generic performance function $G(\mathbf{X})$, and let $f_{\mathbf{X}}(\mathbf{x})$ denote the joint probability density function of $\mathbf{X}$. Recall $\mathbf{X} = \{X_i, i = 1 \text{ to } n\}$, and let μ_{X_i} and σ_{X_i} denote the mean and standard deviation of X_i , respectively. Further, the covariance of X_i and X_j is denoted by $\text{Cov}(X_i, X_j)$. The first-order second-moment (shortly, referred to as FOSM) method approximates G to be a Gaussian distribution, using only the mean ($\mu_{\mathbf{X}}$) and covariance of $\mathbf{X}$.

Consider the first-order Taylor series expansion of $G(\mathbf{X})$ around $\mu_{\mathbf{X}}$ as

$$G = G(\mu_{\mathbf{X}}) + \sum_{i=1}^{i=n} (X_i - \mu_{X_i}) \left(\frac{\partial G}{\partial X_i} \right)_{\mu_{\mathbf{X}}} \quad (20)$$

Note that G is now a linear function of $\mathbf{X}$ with the partial derivatives as coefficients, and

therefore, it is straightforward to approximate its mean and variance as

$$\mu_G = G(\mu_{\mathbf{X}}) \quad (21)$$

$$\sigma_G^2 = \sum_{i=1}^{i=n} \sum_{j=1}^{j=n} \left(\frac{\partial G}{\partial X_i} \right)_{\mu_{\mathbf{X}}} \left(\frac{\partial G}{\partial X_j} \right)_{\mu_{\mathbf{X}}} \text{Cov}(X_i, X_j) \quad (22)$$

When the inputs to G are uncorrelated, then the expression for variance in Eq. 22 simplifies to

$$\sigma_G^2 = \sum_{i=1}^{i=n} \left(\frac{\partial G}{\partial X_i} \right)_{\mu_{\mathbf{X}}}^2 \sigma_{X_i}^2 \quad (23)$$

Once the mean and standard deviation of G is calculated, then G is approximated as a Gaussian distribution, with mean and standard deviation σ_G . Then, the failure probability can be calculated as

$$P_f = P(G < 0) = \Phi \left(-\frac{\mu_G}{\sigma_G} \right) \quad (24)$$

It is obvious that the failure probability calculated using the FOSM approach is accurate only in two cases: (1) when G is a linear function of $\mathbf{X}$ and the quantities in $\mathbf{X}$ are statistically independent normal random variables or (2) when G is a multiplicative function of $\mathbf{X}$ and the quantities in $\mathbf{X}$ are statistically independent lognormal random variables. In many practical examples, it is unlikely that all the variables are statistically independent normals or lognormals. Nor it is likely that G is an additive or multiplicative function of $\mathbf{X}$. In such cases, Eq. 24 is only approximate; however, it can be used to provide a rough idea of the level of risk or reliability.

Nevertheless, the FOSM approach has two important deficiencies. First, the method does not use the information regarding the variable $\mathbf{X}$ when available. The function G in Eq. 20 is linearized at the mean of $\mathbf{X}$. When G is nonlinear, significant error may be introduced by neglecting higher order terms. Second, and more importantly, the P_f calculated using Eq. 24 does not remain invariant for

different but mechanically equivalent formulations of the same performance function. For example, the following performance functions G_1 and G_2 are mechanically equivalent:

$$G_1 \equiv X_1 - X_2 \quad (25)$$

$$G_2 \equiv \frac{X_1}{X_2} < 1 \quad (26)$$

However, the FOSM approach, when implemented using these two performance functions, yields different values for $\frac{\mu_G}{\sigma_G}$ and hence different values of P_f . In other words, the same engineering problem can be formulated either in terms of strength or stress, but the FOSM approach should not lead to different results for different formulations. The lack of invariance is a serious problem and was recognized by the researchers in 1970s, and in order to overcome this problem, Hasofer and Lind (Hasofer and Lind 1974) proposed the advanced FOSM method.

Advanced FOSM for Normal Variables

First, consider the case where the quantities in $\mathbf{X}$ are independent normal variables. While it may be meaningful to use Taylor's series expansion to linearize G , there is no rationale behind choosing the point of linearization to be the mean of $\mathbf{X}$. It is necessary to choose a point of linearization such that the estimate P_f obtained after such linearization is directly related to the probability of failure of the structure.

Point of Linearization: Most Probable Point

Any point lying on the curve of demarcation would satisfy the equation $G(\mathbf{X}) = 0$. Since (1) this curve serves as the demarcation between the two zones given by $G > 0$ and $G < 0$ and (2) it is of interest to calculate the probability $P(G < 0)$, it is intuitive that it is important to identify a linear function which closely resembles the contour $G(\mathbf{x}) = 0$. Hence, the point of linearization must lie on this curve of demarcation; in other words, the point of linearization must satisfy the equation $G(\mathbf{x}) = 0$. This is

clearly different from the FOSM approach, where the mean μ_X was chosen as the point of linearization; in general, the mean μ_X will not satisfy this equation.

Therefore, the point of linearization should be located on the curve of demarcation. However, there are infinite points that satisfy this criterion, and it is important to select the appropriate one. Each of these infinite points has a likelihood of occurrence, and intuitively, the *point of maximum likelihood* is chosen as the point of linearization. This likelihood can be calculated using the probability density function of the underlying random variables. For a single normal random variable X with mean μ and standard deviation σ , the PDF is given by

$$f_X(x|\mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp \left[-\frac{(x - \mu)^2}{2\sigma^2} \right] \quad (27)$$

For example, when $\mu = 10$ and $\sigma = 1$, $x = 10$ is 1.65 times more likely to occur than $x = 9$. The maximum value of the likelihood function occurs at $x = \mu$; therefore, the farther x is away from the mean μ , the lower the likelihood of occurrence of x . If there is only one random variable X instead of $\mathbf{X}$, the mean μ_X cannot be chosen as the point of linearization since $G(\mu_X) \neq 0$, in general. Therefore, if there is a single input variable, the point of linearization is chosen in such a way that it satisfies the equation $G(x) = 0$ and the value of $\|x - \mu_X\|$ is minimum.

However, in a general structural reliability analysis problem, the input to G is a vector, i.e., $\mathbf{X} = \{X_1, X_2, \dots, X_i, \dots, X_n\}$, and each X_i has its own mean μ_{X_i} and standard deviation σ_{X_i} . The objective is to identify the point of maximum likelihood, which can be calculated by maximizing the joint probability density function of all the input random variables. If the variables are independent, then the joint density function of $\mathbf{X}$ is expressed as (when the variables are independent)

$$f_{\mathbf{X}}(\mathbf{x}) = \prod_{i=1}^n \frac{1}{\sigma_i\sqrt{2\pi}} \exp \left[-\frac{(x_i - \mu_i)^2}{2\sigma_i^2} \right] \quad (28)$$

It can be verified (by taking the logarithm) that the maximizer of the above function simultaneously minimizes

$$\delta = \sum_{i=1}^{i=n} \left(\frac{x_i - \mu_i}{\sigma_i} \right)^2 \quad (29)$$

Eq. 29 can be rewritten as

$$\delta = \sum_{i=1}^{i=n} u_i^2, \quad (30)$$

where

$$u_i = \frac{x_i - \mu_i}{\sigma_i} \quad (31)$$

If the above computation were performed for every realization x_i of the random variable X_i , then the corresponding u_i 's would be realizations of the standard normal variable U_i , i.e., $U_i \sim N(0,1)$. Therefore, Eq. 31 is referred to as the standard normal transformation, similar to that in Eq. 5 and Eq. 6. In the space containing standard normal variables, maximizing the likelihood of occurrence is equivalent to minimizing Eq. 30, which implies that the point of linearization is that point on the curve of demarcation, whose distance (measured in the standard normal space) from the origin is minimum. Since the point of linearization has the maximum likelihood of occurrence, it is popularly known as the Maximum Probable Point (MPP), as indicated in Fig. 3.

Computing Failure Probability

The next task is to expand $G(\mathbf{X})$ around the MPP and make use of the linear approximation. Let $\mathbf{x}^* = \{x_i^*, i = 1 \text{ to } n\}$ denote the most probable point in the original coordinate space and $\mathbf{u}^* = \{u_i^*, i = 1 \text{ to } n\}$ denote the corresponding point in the standard normal space. Then,

$$G = G(\mathbf{x}^*) + \sum_{i=1}^{i=n} (X_i - x_i^*) \left(\frac{\partial G}{\partial X_i} \right)_{\mathbf{x}^*} \quad (32)$$

Now, G is a linear combination of Gaussian variable X and, therefore, can be approximated to

Structural Seismic Reliability Analysis,
Fig. 3 Estimating MPP in FORM

be Gaussian with mean μ_G^* and standard deviation σ_G^* . The mean can be calculated as

$$\mu_G^* = \sum_{i=1}^{i=n} (\mu_{X_i} - x_i^*) \left(\frac{\partial G}{\partial X_i} \right)_{\mathbf{x}^*} \quad (33)$$

By definition of the standard normal transformation, it can be easily seen that (for all $i = 1$ to n)

$$x_i^* = \mu_{X_i} + u_i^* \sigma_{X_i} \quad (34)$$

$$\frac{\partial u_i}{\partial x_i} = \frac{1}{\sigma_{X_i}} \quad (35)$$

$$\left(\frac{\partial G}{\partial X_i} \right)_{\mathbf{x}^*} = \left(\frac{\partial G}{\partial u_i} \right)_{\mathbf{u}^*} \frac{\partial u_i}{\partial x_i} = \frac{1}{\sigma_{X_i}} \left(\frac{\partial G}{\partial u_i} \right)_{\mathbf{u}^*} \quad (36)$$

Substituting Eq. 34 and 36 in Eq. 33,

$$\mu_G^* = \sum_{i=1}^{i=n} (\mu_{X_i} - x_i^*) \left(\frac{\partial G}{\partial X_i} \right)_{\mathbf{x}^*} \quad (37)$$

Substituting Eq. 34 and 36 in Eq. 37,

$$\mu_G^* = \sum_{i=1}^{i=n} -u_i^* \times \left(\frac{\partial G}{\partial u_i} \right)_{\mathbf{u}^*} \quad (38)$$

Note that $\left(\frac{\partial G}{\partial u_i} \right)_{\mathbf{u}^*}$ refers to the i th term of the gradient vector ($\boldsymbol{\alpha}^* = \{\alpha_i^* = i = 1 \text{ to } n\}$) of G in

the standard normal space. Therefore, Eq. 38 can be rewritten as:

$$\mu_G^* = -(\mathbf{u}^*)^T(\boldsymbol{\alpha}^*) \quad (39)$$

Note that the vectors represented by $\mathbf{u}^*$ and $\boldsymbol{\alpha}^*$ are both perpendicular to the limit state equation and hence parallel to each other. However, they are of opposite directions; while $\mathbf{u}^*$ is directed away from the origin, the gradient vector $\boldsymbol{\alpha}^*$ is directed towards the origin, i.e., in the direction of increasing value of G . Therefore, the above vector multiplication is basically a dot product of collinear but opposite vectors, and hence,

$$\mu_G^* = \|\mathbf{u}^*\| \times \|\boldsymbol{\alpha}^*\| \quad (40)$$

Similarly, based on Eq. 32, the variance of G , denoted by $(\sigma_G^*)^2$, is calculated as

$$(\sigma_G^*)^2 = \sum_{i=1}^n \sigma_{X_i}^2 \times \left[\left(\frac{\partial G}{\partial X_i} \right)_{\mathbf{x}^*} \right]^2 \quad (41)$$

Substituting Eq. 36 in Eq. 41,

$$\begin{aligned} (\sigma_G^*)^2 &= \sum_{i=1}^n \sigma_{X_i}^2 \times \left[\left(\frac{\partial G}{\partial X_i} \right)_{\mathbf{x}^*} \right]^2 \left[\frac{\partial u_i}{\partial x_i} \right]^2 \\ &= \sum_{i=1}^n \left[\left(\frac{\partial G}{\partial u_i} \right)_{\mathbf{x}^*} \right]^2 \end{aligned} \quad (42)$$

Therefore,

$$\sigma_G^* = \sqrt{\sum_{i=1}^n \left[\left(\frac{\partial G}{\partial u_i} \right)_{\mathbf{x}^*} \right]^2} = \|\boldsymbol{\alpha}^*\| \quad (43)$$

Having estimated μ_G^* and σ_G^* , the reliability index and the value of P_f can be calculated as

$$\beta = \frac{\mu_G^*}{\sigma_G^*} = \|\mathbf{u}^*\| \quad (44)$$

$$P_f = \Phi(-\beta) \quad (45)$$

Therefore, the reliability index is simply equal to the minimum distance measured from the

Given PDFs of $\mathbf{X}$
 Minimize $\beta = \mathbf{u}^T \mathbf{u}$
 such that $G(\mathbf{x}) = 0$
 where standard normal $\mathbf{u} = T(\mathbf{x})$
 $P(G < 0) = \Phi(-\beta)$

Structural Seismic Reliability Analysis,
Fig. 4 Optimization in advanced FOSM

origin to the curve represented by the limit state equation, in the standard normal space. Note that Eq. 39 and Eq. 44 are correct only when $\beta > 0$, i.e., $P_f < 0.5$. Otherwise, the right-hand sides of these two equations need to be negated. Since the failure probability of structures is usually less than 0.1, the above equations hold in normal circumstances. The most general expression (appropriate sign incorporated) for β can be obtained by dividing the right-hand side of Eq. 39 by that of Eq. 43.

Algorithm for Structural Reliability Analysis

Having discussed the theory behind the advanced FOSM, the method is now presented as an algorithm to aid practitioners. The key of the advanced FOSM method is to identify the MPP by solving an optimization problem, as shown in Fig. 4.

In this optimization problem, the focus is to select that point on the limit state equation that is closest to the origin, in the standard normal space. In Fig. 4, T represents the standard normal transformation function from the original space ($\mathbf{x}$) to the standard normal space ($\mathbf{u}$). This optimization is solved using the Rackwitz-Fiessler (Fiessler et al. 1979) algorithm, an iterative procedure, as follows:

1. Initialize counter $j = 0$ and start with an initial guess for the most probable point (MPP), i.e., $\mathbf{x}^j = \{x_1^j, x_2^j, \dots, x_i^j, \dots, x_n^j\}$, a column vector.
2. Transform into standard normal space and calculate $\mathbf{u}^j = \{u_1^j, u_2^j, \dots, u_i^j, \dots, u_n^j\}$ using Eq. 31, a column vector.

3. Compute the gradient vector in the standard normal space, i.e., $\alpha = \{\alpha_1, \alpha_2, \dots, \alpha_n\}$, another column vector where

$$\alpha_i = \frac{\partial G}{\partial u_i} = \frac{\partial G}{\partial x_i} \times \frac{\partial x_i}{\partial u_i} = \frac{\partial G}{\partial x_i} \times \sigma_i \quad (46)$$

4. In the iterative procedure, the next point u^{j+1} is calculated using the following equation:

$$u^{j+1} = \frac{1}{\|\alpha\|} [\alpha^T u^j - G(x^j)] \frac{\alpha}{\|\alpha\|} \quad (47)$$

5. Transform back into original space, i.e., compute x^{j+1} , and continue starting from Step 3 until the iterative procedure converges. Using tolerance limits δ_1 and δ_2 , convergence can be checked if the following two criteria are satisfied: (i) the point lies on the curve of demarcation, i.e., $|G(x^j)| \leq \delta_1$, and (2) the solution does not change between two iterations, i.e., $|x^{j+1} - x^j| \leq \delta_2$.

Note that, since this approach is gradient based, the gradient vector at MPP is an indicator of which sources of uncertainty are the strongest contributors to structural failure. The higher the magnitude of the gradient in a direction that corresponds to a particular uncertain variable, the more important is that variable in the context of structural safety.

Until now, the discussion did not account for statistical among variables. If there is any statistical dependence, then it is necessary to transform the variables into uncorrelated standard normal space. The same type of transformations discussed earlier in section “[Simulation-Based Methods](#)” may be used for this purpose.

Advanced FOSM for Non-normal Variables

Now consider the case where the inputs X_i ($i = 1$ to n) have arbitrary probability distributions given by their CDFs as $F_{X_i}(x_i)$ ($i = 1$ to n). Now that X_i is not normally distributed, Eq. 31 cannot be used for standard normal transformation. Therefore, it is necessary to calculate u_i from a given x_i meaningfully, so that u_i represents

a realization of the standard normal variable. The only difference from the implementation of the advanced FOSM algorithm is the transformation step and the gradient computation which is dependent on the choice of transformation.

One simple transformation is based on probability integral transform concept as

$$u_i = \Phi^{-1}(F_{X_i}(X_i = x_i)), \quad (48)$$

where $\Phi^{-1}(\cdot)$ refers to the inverse of the standard normal distribution function (Haldar and Mahadevan 2000). Now, the calculation of the gradient in the standard normal space is different from Eq. 46 and can be derived directly using Eq. 48. First, decompose Eq. 48 into two parts as

$$v_i = F_{X_i}(X_i = x_i) \quad (49)$$

$$u_i = \Phi^{-1}(v_i) \quad (50)$$

Then, each element of the gradient vector $\alpha = \{\alpha_1, \alpha_2, \dots, \alpha_n\}$ can be calculated as

$$\alpha_i = \frac{\partial G}{\partial u_i} = \frac{\partial G}{\partial x_i} \times \frac{\partial x_i}{\partial v_i} \times \frac{\partial v_i}{\partial u_i} = \frac{\partial G}{\partial x_i} \times \frac{\phi(u_i)}{f_{X_i}(x_i)}, \quad (51)$$

where $\phi(\cdot)$ refers to the standard normal density function and $f_{X_i}(x_i)$ is the PDF of the i th input variable X_i .

In addition to the above procedure, there are also other transformation techniques. For example, a two-parameter transformation procedure estimates the mean μ_i and standard deviation σ_i of the normal distribution by equating the CDF and PDF values of the distribution of X and the normal distribution. Then, Eq. 31 can be used to calculate u_i from x_i . Note that the mean μ_{X_i} and standard deviation σ_{X_i} are dependent on the value of x_i . Similarly, Chen and Lind (Chen and Lind 1983) proposed a three-parameter transformation procedure by introducing a third parameter, a scale factor which is estimated by matching the slope of the probability density function in addition to the PDF and CDF values. Further, when

the inputs are correlated or statistically dependent, it is necessary to transform them to *uncorrelated* standard normal space. Haldar and Mahadevan (Haldar and Mahadevan 2000) describe methods for such transformation. It must be noted that any transformation must be accompanied by suitably computing the derivatives in the standard normal space, and Eq. 46 must be appropriately replaced.

Sometimes, the variable X may follow arbitrary distributions and be correlated. In that case, it is still necessary to transform these variables to uncorrelated standard normal space (Liu and Der Kiureghian 1986; Haldar and Mahadevan 2000). This is usually performed in two steps: first, the variables are converted to uncorrelated space and then transformed to standard normal space where optimization is performed to estimate MPP.

Summary

The section discussed the use of first-order reliability methods in order to estimate the reliability of structures. First, the first-order second-moment (FOSM) method was presented and then extended to the advanced FOSM method. The concept of most probable point (MPP) was introduced. It was derived that the distance from the origin to the MPP, in standard normal space, is equal to the safety index or reliability index, denoted by β . Information regarding the gradient at the MPP can be used to identify the sources of uncertainty that are significant contributors to the failure of the structure.

The inverse of the advanced FOSM algorithm is commonly employed in design. This procedure is known as inverse-FORM and is used to select a design parameter (which is input as unknown quantity to the performance function G) so that a target reliability index may be attained. Details of the inverse-FORM methodology can be found in several research articles (Der Kiureghian et al. 1994) and textbooks (Haldar and Mahadevan 2000).

Numerical Example I: Structural Beam

This section illustrates the estimation of structural reliability through an illustrative example that has

been extended from a case study discussed by Haldar and Mahadevan (Haldar and Mahadevan 2000). This numerical example consists of a steel beam that is suggested to carry an applied deterministic bending moment M that follows a Gaussian distribution whose mean is equal to 1,500 kip-in and standard deviation is equal to 75 kip-in. The yield stress (Y) of steel is considered to be a lognormal variable with mean equal to 38 ksi and standard deviation equal to 3.8 ksi. The plastic section modulus (Z) is known to be a normal random variable with mean equal to 54 in³ and standard deviation equal to 2.7 in³. The goal is to compute the structural reliability of this beam.

The resistance offered by this beam (maximum loading possible) can be expressed as the product of yield stress (Y) and plastic section modulus (Z). The structure will fail if the resistance is smaller than the applied bending moment (M). Therefore, the limit state equation is

$$G = YZ - M \quad (52)$$

The structure is said to fail when $G < 0$.

First, the problem is solved using Monte Carlo simulation. It is possible to directly generate samples of M and Z since they follow Gaussian distributions. However, in order to generate samples from the lognormally distributed Y , its distribution parameters (the mean and standard deviation of the corresponding normal distribution) need to be estimated. The location parameter λ_Y is calculated to be equal to 3.632611 and the scale parameter ζ_Y is calculated to be equal to 0.0997513. It is trivial to code Monte Carlo simulation in a programming environment such as MATLAB. For this numerical example, the MATLAB codes would be

1. $N = 50,000,000$
2. $M = \text{randn}(N,1)*75 + 1,500$
3. $Z = \text{randn}(N,1)*2.7 + 54$
4. $Y = \text{icdf}('logn', \text{rand}(N,1), 3.632611, 0.0997513)$
5. $G = Y.*Z - M$
6. $N_f = \text{length}(\text{find}(G < 0))$
7. $P_f = N_f/N$

Structural Seismic Reliability Analysis,
Table 1 Advanced FOSM method: implementation

Quantity	Iteration I	Iteration II	Iteration III
Y	38	30.6	30.81
Z	54	51.4	51.1
M	1,500	1,552.5	1,573.7
G	552	19.21	−0.08
μ_Y	37.81	37.07	37.11
μ_Z	54	54	54
μ_M	1,500	1,500	1,500
σ_Y	3.79	3.05	3.07
σ_Z	2.7	2.7	2.7
σ_M	75	75	75
u_Y	0.05	−2.13	−2.05
u_Z	0	−0.96	−1.08
u_M	0	0.7	0.98
α_Y	54	51.41	51.08
α_Z	38	30.57	30.81
α_M	−1	−1	−1
α_{u_Y}	204.69	156.78	156.97
α_{u_Z}	102.06	82.53	83.18
α_{u_M}	−75	−75	−75
New u_Y	−1.9	−2.05	−2.05
New u_Z	−0.96	−1.08	−1.09
New u_M	0.70	0.98	0.98
β	2.24	2.52	2.52

As seen from the above code, a very large number of samples have been used and the resultant P_f is calculated to be equal to 0.0059. Since the number of samples is high, this serves a benchmark solution to verify the solutions from FOSM and advanced FOSM methods.

The same numerical example can also be solved using the first-order second-moment method, by linearizing the limit state equation at the mean of the variables. The distribution information of the variables is not used. In this approach, $\mu_G = 38 \times 54 - 1,500 = 552$, and $\sigma_G^2 = (3.8 \times 54)^2 + (2.7 \times 38)^2 + (75)^2$ which yields $\sigma_G = 241.37$. Therefore, $\beta = 2.287$, and hence, $P_f = 0.011$. Evidently, this is extremely erroneous because of the inaccuracy of the FOSM method.

Finally, the numerical example is solved using the advanced FOSM method, by estimating the most probable point (MPP), as shown in Table 1. The initial guess for the MPP is $Y = 38$, $Z = 54$,

and $M = 1,500$. In this table, μ_Y , μ_Z , μ_M , and σ_Y , σ_Z , σ_M denote the equivalent normal mean and standard deviation in each iteration. Obviously, since Z and M are originally normal variables, their means and standard deviations do not change. The coordinate values in the standard normal space are denoted by u_Y , u_Z , and u_M . The derivatives in the original space are denoted by σ_Y , σ_Z , and σ_M , and these are multiplied by the equivalent normal standard deviation to calculate the derivatives in the standard normal space, denoted by σ_{u_Y} , σ_{u_Z} , and σ_{u_M} , respectively. The coordinate values after the derivative-based update is given by “New u_Y ,” “New u_Z ,” and “New u_M .” These are transformed back to the original space using the previously computed equivalent normal mean and standard deviation, and the new values of Y , Z , and M are the starting values for the next iteration. This procedure is continued until the optimization converges.

It is seen that, after three iterations, the value of G is close to zero, and there is no significant change in the value of $\beta = 2.52$ that corresponds to $P_f = 0.0059$, which is in excellent agreement with the Monte Carlo simulation approach. Note that the FOSM approach required only 12 evaluations of G to estimate this failure probability. As explained earlier, the gradient in the standard normal space is an indicator of those sources of uncertainty that are the strongest contributors to structural failure. In this case, the yield stress (Y) is found to be the most important contributor since it has the highest gradient.

Numerical Example 2: Structural Frame

This section illustrates the calculation of structural reliability using the model of a simple two-story frame, as shown in Fig. 5.

This two-story frame has six parameters, m_1 , m_2 , k_1 , k_2 , D_1 , D_2 , that represent the masses, stiffness, and damping parameters of the two stories of the structural frame. Except the masses ($m_1 = 136$ and $m_2 = 66$ kg), all of the other quantities are uncertain. Further, the inputs to the system are forces (lateral excitations) at the two levels given by $A_1 \sin(\omega_1 t)$ and $A_2 \sin(\omega_1 t)$.

Structural Seismic Reliability Analysis, Fig. 5 (a) Structural frame, (b) mechanical model

Structural Seismic Reliability Analysis, Table 2 Statistics of uncertain quantities

Parameter	Value	Std. Dev.	Unit
k_1	30,700	1,500	N/m
k_2	44,300	2,000	N/m
D_1	307	30	Ns/m
D_2	443	40	Ns/m
A_1	75	5	N
A_2	100	5	N
ω_1	9	0.5	s ⁻¹
ω_2	9	0.5	s ⁻¹

All the uncertain quantities are assumed to follow Gaussian distributions, and their statistics are provided in Table 2.

In this example, the maximum displacement of the second story during the first 5 s of loading is the quantity of interest, and the structure is said to have failed due to serviceability reasons if this maximum displacement exceeds 35 mm.

First, the response of the system (u_2 , in this case) needs to be computed based on the fundamental equations:

$$m_1 \ddot{u}_1 + (D_1 + D_2) \dot{u}_1 - D_2 \dot{u}_2 + (k_1 + k_2) u_1 - k_2 u_2 = A_1 \sin(\Omega_1 t) \quad (53)$$

$$m_2 \ddot{u}_2 - D_2 \dot{u}_1 + D_2 \dot{u}_2 - k_2 u_1 + k_2 u_2 = A_2 \sin(\Omega_2 t) \quad (54)$$

Once u_2 is computed, its maximum value is computed, and the limit state G is defined as

$$G = \max(u_2) - 0.035 \quad (55)$$

The probability of failure is directly evaluated using Monte Carlo sampling (10,000 samples), and P_f is observed to be equal to 0.0028.

Note that sinusoidal loading functions were used in this example so that the response of structural frame may be easily computed using well-known equations structural dynamics. In order to study the response of a structure to an earthquake, the appropriate earthquake loading needs to be used, and the equations of structural dynamics need to be solved using numerical techniques. Then the maximum deflection would be calculated and used to construct the limit state for reliability analysis. Since the scope of this article is to familiarize the readers with reliability methods, simpler numerical examples were considered for illustrative purposes.

Advanced Concepts in Structural Reliability

In addition to the first-order reliability methods and simulation-based techniques, there are other types of techniques and methods that have become popular for structural reliability analysis, over the past two decades. The purpose of this section is to provide an overview of some of these approaches and list appropriate references that would aid in-depth understanding of these methods.

Second-Order Reliability Methods

Recall that $G(X)$ is a generic function and the class of first-order reliability methods focus on linearizing G using the first-order Taylor's series expansion. Several researchers have developed computational methods to improve the estimates provided by the first-order reliability methods. In particular, second-order reliability methods focus on quadratic approximations of the limit state (Fiessler et al. 1979). Breitung (1984) estimated closed-form analytical expressions for P_f , using the principal curvatures of the limit state at the MPP. While Breitung's method was based on a parabolic approximation, Tvedt (Tvedt 1990) developed a generalized second-order approximation to the limit state to compute the failure probability. Der Kiureghian et al. (1987) approximated the limit state using two different semi-parabolas around the MPP and used the analytical expressions developed by Breitung (1984).

Subset Simulation

The topic of subset simulation addresses structural reliability calculation using sampling. Recall that, since failure probabilities are generally small, it is necessary to consider a large number of samples to estimate the failure probability accurately. The basic idea of subset simulation is to express the failure probability as a product of larger conditional failure probabilities by introducing intermediate failure events (Au and Beck 2001). As a result, the original problem of calculating a small failure probability, which is computationally demanding, is reduced to calculating a sequence of conditional probabilities, which can be readily and efficiently estimated by means of simulation. This approach has been applied to structural reliability analysis of frames subjected to seismic excitation (Au and Beck 2001).

Surrogate Modeling

Another class of methods for structural reliability analysis relies on approximating the performance function $G(X)$ using different types of mathematical tools. This class of methods is referred to as surrogate modeling techniques (sometimes, as

response surface methods) since they use a few evaluations of $G(X)$ (referred to as training points) to construct a mathematical function that approximates the original G . Obviously, the surrogate model will not be able to match the value of G at values of X , and therefore, this imparts additional uncertainty to the problem. Once a surrogate model is constructed, then Monte Carlo simulation may be used to compute the failure probability. Since the surrogate model is simple to evaluate, it is easy to use a million samples of X during Monte Carlo sampling.

Commonly used surrogate modeling approaches include regression techniques (Haldar and Mahadevan 2000), polynomial chaos expansion (Najm 2009), kriging (Stein 1999), etc. Each of these methods uses different types of basis functions, and one may approximate G better than the other, and it is necessary to choose a suitable surrogate model based on the application of interest.

Efficient Global Reliability Analysis

While conventional surrogate modeling approaches focus on approximating the performance function $G(X)$ over the entire domain of X , the technique of efficient global reliability analysis (Bichon et al. 2008) argues that it is not necessary for such approximation. It is sufficient to approximate the function $G(X)$ near the limit state equation, i.e., around the region where $G(X) = 0$. This method uses a few training points that lie near the curve represented by the limit state equation to construct a Gaussian process surrogate model (Rasmussen 2004) and continues updating this surrogate model using additional training points until the resultant surrogate model sufficiently approximates the performance function $G(X)$ around the curve represented by the limit state equation. Finally, Monte Carlo simulation can be used along with the final surrogate model; it is sufficient to know whether $G > 0$ or $G < 0$, and the numerical value of G is not significant. Since this method approximates G only near the limit state curve, it is well suited to find the sign of G and hence provides estimates of P_f with reasonable accuracy.

System Reliability Methods

Sometimes, a structural system may consist of multiple structural components, each of which has its own limit state. In a series system, the failure of any one component implies the failure of the entire structural system. In a parallel system, it is imperative that all the components fail individually to imply that the system has failed. The probability of system failure can be expressed as a union of component-level failures in the former case, while it is expressed as an intersection of component-level failures in the latter case. Methods for predicting system reliability have been studied by several researchers and documented in several research articles (Hohenbichler and Rackwitz 1983; Cruse et al. 1994) and textbooks (Ditlevsen and Madsen 1996; Haldrar and Mahadevan 2000). Sometimes, even a single structural component may have multiple limit states; methods for system reliability methods are applicable even to such situations since it is necessary to evaluate probability of union or intersection of different events that correspond to failure across multiple limit states.

Summary

This entry introduced the concept of structural reliability analysis, in the context of earthquake engineering, and reviewed several fundamental concepts that may be used to assess the safety of structural systems. There are several sources of uncertainty that affect the performance of structural systems, and therefore, the safety of structural systems is uncertain. It is important to constantly perform structural safety assessment for the purposes of analysis and design and estimate the probability that the structure may fail due to the applied loading. In general, structural failure occurs when the applied loading is greater than the load-carrying capacity (resistance) of the structure. Since both the load-carrying capacity and the actual loading may be uncertain, the safety of the structure also becomes uncertain. This concept was explored in detail by considering Gaussian distributions for the loading and the

resistance quantities, mathematical expressions for failure probability were derived, and the concepts of limit state and reliability index were introduced.

In many structural systems, the loading and the resistance may be functions of various quantities such as material and geometric properties, and this led to the explanation of the generalized limit state function. The quantification of failure probability was explained in detail using simulation-based approaches and first-order reliability methods. These methods were also illustrated using two different numerical examples, one consisting of a beam and the other consisting of a structural system. Finally, an overview of advanced reliability concepts such as the second-order reliability method, efficient global reliability analysis, system reliability techniques, etc. was provided, thereby explaining the state of the art in the field of structural reliability analysis.

Structures with Nonviscous Damping, Modeling, and Analysis

Sondipon Adhikari

College of Engineering, Swansea University,
Swansea, UK

Introduction

The role of damping is vitally important in predicting dynamic response of structures, such as building and bridges subjected to earthquake loads. Noise and vibration are not only uncomfortable to the users of these complex dynamical systems but also may lead to fatigue, fracture, and even failure of such systems. Increasing use of composite structural materials, active control, and damage-tolerant systems in the aerospace and automotive industries has led to renewed demand for energy absorbing and high damping materials. Effective applications of such materials in complex engineering dynamical systems require robust and efficient analytical and numerical methods. Due to the superior damping characteristics, the dynamics of viscoelastic materials and structures have received significant attention over the past two decades. This chapter is aimed at developing computationally efficient and physically insightful approximate numerical methods for linear dynamical systems with nonviscous damping.

A key feature of nonviscously damped systems is the incorporation of the time history of the state variables in the equation of motion. Here we use the Biot model (Biot 1958) which

allows one to incorporate a wide range of functions in the frequency domain by means of summation of simple “pole residue forms.” Several authors have considered this model due to its simplicity and generality (see, e.g., Adhikari 2013a, b; Muravyov 1998; Muravyov and Hutton 1997; Zhang and Zheng 2007). The equation of motion of an n -degree-of-freedom linear visously damped system can be expressed by coupled differential equations as

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \int_0^t \mathcal{G}(t-\tau)\dot{\mathbf{u}}(\tau) + \mathbf{K}\mathbf{u}(t) = \mathbf{f}(t). \quad (1)$$

Here $\mathbf{u}(t) \in \mathbb{R}^n$ is the displacement vector; $\mathbf{f}(t) \in \mathbb{R}^n$ is the forcing vector; $\mathbf{M}, \mathbf{K} \in \mathbb{R}^{n \times n}$ are respectively the mass matrix and stiffness; and $\mathcal{G}(t)$ is the matrix of damping kernel functions. In general $\mathbf{M}$ is a positive definite symmetric matrix and $\mathbf{K}$ is a nonnegative definite symmetric matrix. In the special case when $\mathcal{G}(t) = \mathbf{C}\delta(t)$, where $\delta(t)$ is the Dirac delta function, it reduces to the classical viscous damping case with a damping matrix $\mathbf{C}$. Therefore, Eq. 1 can be viewed as the generalization of the conventional visously damped systems.

The natural frequencies ($\omega_j \in \mathbb{R}$) and the mode shapes ($\mathbf{x}_j \in \mathbb{R}^n$) of the corresponding undamped system can be obtained (Meirovitch 1997) by solving the matrix eigenvalue problem

$$\mathbf{K}\mathbf{x}_j = \omega_j^2 \mathbf{M}\mathbf{x}_j, \quad \forall j = 1, 2, \dots, n. \quad (2)$$

The undamped eigenvectors satisfy an orthogonality relationship over the mass and stiffness matrices, that is,

$$\mathbf{x}_k^T \mathbf{M}\mathbf{x}_j = \delta_{kj} \quad (3)$$

and

$$\mathbf{x}_k^T \mathbf{K}\mathbf{x}_j = \omega_j^2 \delta_{kj}, \quad \forall k, j = 1, 2, \dots, n \quad (4)$$

where δ_{kj} is the Kronecker delta function. We construct the modal matrix

$$\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n] \in \mathbb{R}^n. \quad (5)$$

The modal matrix can be used to diagonalize system (1) provided the damping matrix $\mathcal{G}(t)$ is simultaneously diagonalizable with $\mathbf{M}$ and $\mathbf{K}$. This condition, known as the proportional damping, originally introduced by Lord Rayleigh (1877) in 1877 in the context of viscous damping, is still in wide use today. The mathematical condition for proportional damping can be obtained from the commutative behavior of the system matrices (Adhikari 2001; Caughey and O’Kelly 1965). This can be expressed as $\mathcal{G}(t)\mathbf{M}^{-1}\mathbf{K} = \mathbf{K}\mathbf{M}^{-1}\mathcal{G}(t)$. The concern of this chapter is when this condition is not met, the most likely case for many practical applications. In particular, due to the recent developments in actively controlled structures and the increasing use of composite and smart materials, the need to consider general nonproportionally damped linear dynamic systems is more than ever before.

For nonproportionally damped systems, the nonviscous modal damping matrix

$$\mathcal{G}'(t) = \mathbf{X}^T \mathcal{G}(t) \mathbf{X} \quad (6)$$

is not a diagonal matrix. Such problems can be solved using a spectral approach similar to the undamped or proportionally damped system by transforming Eq. 1 into a state-space form (Wagner and Adhikari 2003). The state-space approach is not only computationally more expensive; it also lacks the physical insight provided by the classical normal mode-based approach. Therefore, many authors have developed approximate methods in the original space (Adhikari 1999a, b).

The eigenvalue problem corresponding to system (1) can be expressed as

$$[s_j^2 \mathbf{M} + s_j \mathbf{G}(s_j) + \mathbf{K}] \mathbf{u}_j = 0, \quad \forall j = 1, 2, \dots, m \quad (7)$$

where $s_j \in \mathbb{C}$ are the eigenvalues and $\mathbf{u}_j \in \mathbb{C}^n$ are the eigenvectors. The matrix $\mathbf{G}(s)$ is the Laplace transfer of $\mathcal{G}(t)$.

In general m is more than $2n$, that is, $m = 2n + p$; $p \geq 0$. Thus, although the system has n degrees of freedom, the number of eigenvalues is

more than $2n$. This is a major difference between the nonviscously damped systems and the viscously damped systems where the number of eigenvalues is exactly $2n$, including any multiplicities. When the eigenvalue s_j appears in complex conjugate pairs, $\mathbf{u}_j$ also appears in complex conjugate pairs, and when s_j is real, $\mathbf{u}_j$ is also real. Corresponding to the $2N$ complex conjugate pairs of eigenvalues, the n eigenvectors together with their complex conjugates will be called *elastic modes*. These modes are related to the n modes of vibration of the structural system. Physically, the assumption of “ $2N$ complex conjugate pairs of eigenvalues” implies that all the elastic modes are oscillatory in nature, that is, they are subcritically damped. The modes corresponding to the “additional” p eigenvalues will be called *nonviscous modes*. These modes are induced by the nonviscous effect of the damping mechanism. For stable passive systems, the nonviscous modes are overcritically damped (i.e., negative real eigenvalues) and not oscillatory in nature. Nonviscous modes, or similar to these, are known by different names in the literature of different subjects, for example, “wet modes” in the context of ship dynamics (Bishop and Price 1979) and “damping modes” in the context of viscoelastic structures (McTavish and Hughes 1993). Determination of the eigenvectors is considered next.

In this work we consider complex conjugate eigensolutions only as for stable systems such eigenvalues are of great practical importance. Using the eigensolutions, the frequency response function (FRF) can be obtained (see, for example, Adhikari (2002)) as

$$\mathbf{H}(i\omega) = \sum_{j=1}^n \left[\frac{\gamma_j \mathbf{u}_j \mathbf{u}_j^T}{i\omega - s_j} + \frac{\gamma_j^* \mathbf{u}_j^* \mathbf{u}_j^{*T}}{i\omega - s_j^*} \right] + \sum_{j=2n+1}^m \frac{\gamma_j \mathbf{u}_j \mathbf{u}_j^T}{i\omega - s_j} \quad (8)$$

where $\gamma_j = \frac{1}{\mathbf{u}_j^T [2s_j \mathbf{M} + d\mathbf{G}/ds|_{s=s_j}] \mathbf{u}_j}$.

Here $(\bullet)^*$ denotes complex conjugation, $(\bullet)^T$ denotes matrix transposition, and $(\bullet)'$ denotes differentiation with respect to s . This equation shows that if the complex eigensolutions s_j and $\mathbf{u}_j$ can be

obtained efficiently, the dynamic response can be obtained exactly using Eq. 8. In this chapter an iterative approach is developed to obtain the complex eigensolutions of nonproportionally damped systems from the undamped eigensolutions.

Iterative Approach for the Elastic Modes

Considering the proportional damping assumption, recently few methods (Adhikari and Pascual 2009, 2011) have been proposed to obtain the eigenvalues of nonviscously damped systems. So far, only perturbation type of approaches (Adhikari 2002) is available to obtain the eigenvectors for the general nonproportionally damped systems. This type of approaches may be suitable for the case on small nonproportionality. For the general case, only computationally expensive state-space approach (Wagner and Adhikari 2003) is currently available. Here a novel iterative method is proposed as an alternative to the state-space approach to obtain the elastic modes of general nonviscously damped systems.

For distinct undamped eigenvalues (ω_l^2) , $\mathbf{x}_l$, $\forall l = 1, \dots, n$, form a complete set of vectors. For this reason, $\mathbf{u}_j$ can be expanded as a complex linear combination of $\mathbf{x}_l$. Thus, an expansion of the form

$$\mathbf{u}_j = \sum_{l=1}^n \alpha_l^{(j)} \mathbf{x}_l \quad (9)$$

may be considered. Without any loss of generality, we can assume that $\alpha_j^{(j)} = 1$ (normalization) which leaves us to determine $\alpha_j^{(i)}$, $\forall i \neq j$. Substituting the expansion of $\mathbf{u}_j$ into the eigenvalue Eq. 7, one obtains the approximation error for the j -th mode as

$$\varepsilon_j = \sum_{l=1}^n s_j^2 \alpha_l^{(j)} \mathbf{M} \mathbf{x}_l + s_j \sigma_l^{(j)} \mathbf{G}(s_j) \mathbf{x}_l + \alpha_l^{(j)} \mathbf{K} \mathbf{x}_l. \quad (10)$$

We use a Galerkin approach to minimize this error by viewing the expansion (9) as a projection in the basis functions $\mathbf{x}_l \in \mathbb{R}^n$, $\forall l = 1, 2, \dots, n$.

Therefore, we make the error orthogonal to the basis functions, that is,

$$\varepsilon_j \perp \mathbf{x}_l \quad \text{or} \quad \mathbf{x}_k^T \varepsilon_j = 0 \quad \forall k = 1, 2, \dots, n. \quad (11)$$

Using the orthogonality property of the undamped eigenvectors described by (3) and (4), one obtains

$$s_j^2 \alpha_k^{(j)} + s_j \sum_{l=1}^n \alpha_l^{(j)} G'_{kl}(s_j) + \omega_k^2 \alpha_k^{(j)} = 0, \quad \forall k = 1, \dots, n \quad (12)$$

where $G'_{kl}(s_j) = \mathbf{x}_k^T \mathbf{G}(s_j) \mathbf{x}_l$ are the elements of the modal damping matrix $\mathbf{G}'(s_j)$ defined in Eq. 6. The j -th equation of this set obtained by setting $k = j$ can be written as

$$\left(s_j^2 + s_j G'_{jj}(s_j) + \omega_j^2 \right) \alpha_j^{(j)} + s_j \sum_{l \neq j}^n \alpha_l^{(j)} G'_{jl}(s_j) = 0. \quad (13)$$

Recalling that $\alpha_j^{(j)} = 1$ and $\mathbf{G}'(s_j)$ is a symmetric matrix, this equation can be rewritten as

$$s_j^2 + s_j \underbrace{\left(G'_{jj}(s_j) + \sum_{l \neq j}^n \alpha_l^{(j)} G'_{lj}(s_j) \right)}_{\gamma_j} + \omega_j^2 = 0 \quad (14)$$

$$\gamma_j = G'_{jj}(s_j) + \mathbf{b}_j^T \mathbf{a}_j \quad (15)$$

$$\mathbf{b}_j = \left\{ G'_{1j}(s_j), G'_{2j}(s_j), \dots, \{j\text{-th term deleted}\}, \dots, G'_{nj}(s_j) \right\}^T \in \mathbb{R}^{(n-1)} \quad (16)$$

and

$$\mathbf{a}_j = \left\{ \alpha_1^{(j)}, \alpha_2^{(j)}, \dots, \{j\text{-th term deleted}\}, \dots, \alpha_n^{(j)} \right\}^T \in \mathbb{C}^{(n-1)}. \quad (17)$$

The vector $\mathbf{a}_j$ is unknown and can be obtained by excluding the $j = k$ case in Eq. 12. Excluding this case, one has

$$s_j^2 \alpha_k^{(j)} + s_j \left(G'_{kj}(s_j) + \alpha_k^{(j)} G'_{kk}(s_j) + \sum_{l \neq k \neq j}^n \alpha_l^{(j)} G'_{kl}(s_j) \right) + \omega_k^2 \alpha_k^{(j)} = 0 \quad (18)$$

or $\left(s_j^2 + \omega_k^2 + G'_{kk}(s_j) \right) \alpha_k^{(j)} + s_j \sum_{l \neq k \neq j}^n G'_{kl}(s_j) \alpha_l^{(j)} = -s_j G'_{kj}(s_j), \quad \forall k = 1, \dots, n; k \neq j.$

These equations can be combined into a matrix form as

$$[\mathbf{P}_j - \mathbf{Q}_j] \mathbf{a}_j = \mathbf{b}_j. \quad (19)$$

In the above equation, the vectors $\mathbf{a}_j$ and $\mathbf{b}_j$ have been defined before. The matrices $\mathbf{P}_j$ and $\mathbf{Q}_j$ are defined as

$$\mathbf{P}_j = \text{diag} \left[\frac{s_j^2 + s_j G'_{11}(s_j) + \omega_1^2}{-s_j}, \dots, \{j\text{-th term deleted}\}, \dots, \frac{s_j^2 + s_j G'_{nn}(s_j) + \omega_n^2}{-s_j} \right] \in \mathbb{C}^{(n-1) \times (n-1)}, \quad (20)$$

and

$$\mathbf{Q}_j = \begin{bmatrix} 0 & G'_{12}(s_j) & \cdots & \{j\text{-th term deleted}\} & \cdots & G'_{1n}(s_j) \\ G'_{21}(s_j) & 0 & \vdots & \vdots & \vdots & G'_{2n}(s_j) \\ \vdots & \vdots & \vdots & \{j\text{-th term deleted}\} & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ G'_{n1}(s_j) & G'_{n2}(s_j) & \cdots & \{j\text{-th term deleted}\} & \cdots & 0 \end{bmatrix} \in \mathbb{R}^{(n-1) \times (n-1)}. \quad (21)$$

From Eq. 19, $\mathbf{a}_j$ should be obtained by solving the set of linear equations. Because $\mathbf{P}_j$ is a diagonal matrix, one way to do this is by using the Neumann expansion method (Adhikari 1999a). Using the Neumann expansion, we have

$$\begin{aligned} \mathbf{a}_j &= [\mathbf{I}_{n-1} - \mathbf{P}_j^{-1} \mathbf{Q}_j]^{-1} \{\mathbf{P}_j^{-1} \mathbf{b}_j\} \\ &= [\mathbf{I}_{n-1} + \mathbf{R}_j + \mathbf{R}_j^2 + \mathbf{R}_j^3 + \cdots] \mathbf{a}_{j0} \end{aligned} \quad (22)$$

where $\mathbf{I}_{n-1}$ is a $(n-1) \times (n-1)$ identity matrix:

$$\mathbf{R}_j = \mathbf{P}_j^{-1} \mathbf{Q}_j \in \mathbb{C}^{(n-1) \times (n-1)} \quad \text{and} \quad \mathbf{a}_{j0} = \mathbf{P}_j^{-1} \mathbf{b}_j \in \mathbb{C}^{(n-1)}. \quad (23)$$

Because $\mathbf{P}_j$ is a diagonal matrix, its inversion can be carried out analytically, and subsequently, the closed-form expressions of the elements of $\mathbf{a}_j$ can be obtained. Keeping one term in the series (22), the first-order expression of the elements of $\mathbf{a}_j$ can be obtained as

$$\mathbf{a}_j \equiv \{\alpha_k^{(j)}\}_{\forall k \neq j} = -\frac{s_j G'_{kj}(s_j)}{\omega_k^2 + s_j^2 + s_j G'_{kk}(s_j)}. \quad (24)$$

Similarly, the second-order expression of the elements of $\mathbf{a}_j$ can be obtained as

$$\begin{aligned} \mathbf{a}_j \equiv \{\alpha_k^{(j)}\}_{\forall k \neq j} &= -\frac{s_j G'_{kj}(s_j)}{\omega_k^2 + s_j^2 + s_j G'_{kk}(s_j)} \\ &+ \sum_{\substack{l=1 \\ l \neq j \neq k}}^n \frac{s_j^2 G'_{kl}(s_j) G'_{lj}(s_j)}{(\omega_k^2 + s_j^2 + s_j G'_{kk}(s_j)) (\omega_l^2 + s_j^2 + s_j G'_{ll}(s_j))}. \end{aligned} \quad (25)$$

The vector $\mathbf{a}_j$ obtained using this way can be substituted back in the expression of the eigenvalues in (14), which in turn can be solved for s_j as

$$s_j = -\left(\gamma_j \pm i\sqrt{4\omega_j^2 - \gamma_j^2}\right)/2. \quad (26)$$

However, the vectors $\mathbf{a}_j$ and $\mathbf{b}_j$ are also a function of s_j . As a result γ_j in Eq. 15 becomes a

function of s_j . This forms the basics of the iterative approach as from Eq. 26, one can write

$$\begin{aligned} s_j^{(r+1)} &= -\gamma_j(s_j^{(r)})/2 \pm i\sqrt{\omega_j^2 - \gamma_j^2(s_j^{(r)})}/4; \\ r &= 0, 1, 2, \dots \end{aligned} \quad (27)$$

For every iteration step, the vectors $\mathbf{a}_j$ and $\mathbf{b}_j$ get updated based on new values of s_j using

Eq. 24 or Eq. 25 depending on the order of terms retained in the series (22). The iteration can be started with the equivalent proportional viscous damping assumption (Udwadia 2009), namely,

$$s_j^{(0)} = -G'_{jj}(i\omega_j)/2 \pm i\sqrt{\omega_j^2 - G'^2_{jj}(i\omega_j)/4}. \quad (28)$$

The iteration can be stopped when the successive values of s_j or $\mathbf{a}_j$ do not change significantly. Once the final values of $\alpha_k^{(j)}, \forall k$ are obtained, the j -th complex mode $\mathbf{u}_j$ can be obtained from the series (9).

The necessary and sufficient conditions for the convergence of the proposed method are difficult to obtain. Below we give a sufficient condition.

Proposition 1 *A sufficient condition for the convergence of the proposed iterative method is that $|\mathbf{G}'(s_j)|$ is a diagonally dominant matrix $\forall j \in [1, 2n]$.*

Proof During the iteration process, the value of s_j changes for different iteration steps. We aim to derive the condition for the convergence of series (22) for an arbitrary value of s_j . This will guarantee the convergence of the iterative method, no matter what the value of s_j . The complex matrix power series (22) converges if, and only if, for all the eigenvalues $\sigma_l^{(j)}$ of the matrix $\mathbf{R}_j$, the inequality $|\sigma_l^{(j)}| < 1$ holds. Although this condition is both necessary and sufficient, checking convergence for all $j = 1, \dots, n$ is not feasible for every iteration step. So we look for a sufficient condition which is relatively easy to check and which ensures convergence for all $j = 1, \dots, n$.

For an arbitrary r -th iteration, let us denote the matrix $\mathbf{R}_j$ defined in Eq. 23 as $\mathbf{R}_j^{(r)}$. Suppose the value of s_j for the r -th iteration step is $s_j^{(r)}$. The kl -th element of the matrix $\mathbf{R}_j^{(r)}$ can be obtained as

$$R_{jkl}^{(r)} = \frac{-s_j^{(r)} G'_{kl}(s_j) (1 - \delta_{kl})}{\omega_k^2 + s_j^{(r)^2} + s_j^{(r)} G'_{kk}(s_j)}, \quad \forall k, l \neq j. \quad (29)$$

Since a matrix norm is always greater than or equal to its maximum eigenvalue, it follows from the inequality $|\sigma_l^{(j)}| < 1$ that the convergence of the series is guaranteed if $\|\mathbf{R}_j^{(r)}\| < 1$. Writing the sum of absolute values of entries of $\mathbf{R}_j^{(r)}$ results in the following inequality as the required sufficient condition for the convergence

$$\sum_{k=1}^n \sum_{l=1}^n \left| \frac{s_j^{(r)} G'_{kl}(s_j)}{\omega_k^2 + s_j^{(r)^2} + s_j^{(r)} G'_{kk}(s_j)} \right| (1 - \delta_{lk}) < 1. \quad (30)$$

Dividing both the numerator and denominator by $s_j^{(r)}$, the above inequality can be written as

$$\sum_{k=1}^n \sum_{l=1}^n \left| \frac{G'_{kl}(s_j)}{1/s_j^{(r)} (\omega_k^2 + s_j^{(r)^2}) + G'_{kk}(s_j)} \right| < 1. \quad (31)$$

Taking the maximum for all $k \neq j$, this condition can further be represented as

$$\max_{k \neq j} \frac{\sum_{l=1}^n |G'_{kl}(s_j)|}{\left| 1/s_j^{(r)} (\omega_k^2 + s_j^{(r)^2}) + G'_{kk}(s_j) \right|} < 1. \quad (32)$$

It is clear that (32) always holds if

$$\sum_{l=1}^n |G'_{kl}(s_j)| < |G'_{kk}(s_j)|, \quad \forall k \neq j \quad (33)$$

which in turn implies that for all $j = 1, \dots, n$, the inequality $\|\mathbf{R}_j^{(r)}\| < 1$ holds if $|\mathbf{G}'(s_j)|$ is a diagonally dominant matrix. It is important to note that the diagonal dominance of $|\mathbf{G}'(s_j)|$ is only a sufficient condition and the lack of it does not necessarily prevent convergence of the proposed iterative method.

Summary of the Algorithm

We give a simple iterative algorithm to implement the idea developed in the previous section. We select a tolerance between the differences of the successive values of s_j , denoted

by ε_m . A small value, say $\varepsilon_m = 0.001$, can be selected for numerical calculations. Considering that the undamped eigensolutions (ω_j and x_j) and the modal damping matrix $\mathbf{G}'(s_j)$ are known, the complex eigensolutions (s_j and $\mathbf{u}_j$) can be obtained using the following iterative algorithm:

```

for  $j = 1, 2, \dots, n$  do
  Initialize  $\varepsilon = 100, r = 0$ 
   $s_j^{(r)} = -G'_{jj}(i\omega_j)/2 \pm i\sqrt{\omega_j^2 - G'^2_{jj}(i\omega_j)}/4$ 
  while  $\varepsilon > \varepsilon_m$  do
     $\mathbf{b}_j = \{G'_{1j}(s_j^{(r)}), G'_{2j}(s_j^{(r)}), \dots, \{j\text{-th term deleted}\}, \dots, G'_{nj}(s_j^{(r)})\}^T$ 
     $\mathbf{a}_j \equiv \{\alpha_k^{(j)}\}_{\forall k \neq j} = -\frac{s_j^{(r)} G'_{kj}(s_j^{(r)})}{\omega_k^2 + s_j^{(r)2} + s_j^{(r)} G'_{kk}(s_j^{(r)})}$ 
     $\gamma_j = G'_{jj}(s_j) + \mathbf{b}_j^T \mathbf{a}_j$ 
     $s_j^{(r+1)} = -\gamma_j(s_j^{(r)})/2 \pm i\sqrt{\omega_j^2 - \gamma_j^2(s_j^{(r)})}/4$ 
     $\varepsilon = |s_j^{(r+1)} - s_j^{(r)}|/|s_j^{(r)}|$ 
     $r = r + 1$ 
  end while
   $\mathbf{u}_j = \sum_{k=1}^n \alpha_k^{(j)} \mathbf{x}_k$ 
end for

```

The algorithm is outlined for the first-order expression of $\alpha_k^{(j)}$ given by Eq. 24. However, the extension to the second- or higher-order expressions is straightforward. One simply needs to change the expression of $\mathbf{a}_j$ in this algorithm. If the higher-order terms are used, then less number of steps in the iteration is needed. Once the complex eigensolutions s_j and $\mathbf{u}_j$ are obtained using this method for all j , the dynamic response such as the frequency response function can be obtained exactly using Eq. 8. Next we illustrate this new method using a numerical example.

Numerical Illustration: A 3-DOF System with Exponential Nonviscous Damping

We consider a three-degree-of-freedom nonviscous and nonproportionally damped system from Adhikari (2013a). The system is shown in Fig. 1. Three masses, each of mass m_u , are connected by

springs of stiffness k_u . The nonviscous damping elements of the system are shown in the figure. The equation of motion of this model system can be represented by Eq. 1. The mass and the stiffness matrices of the system are given by

$$\mathbf{M}_1 = \begin{bmatrix} m_u & 0 & 0 \\ 0 & 2m_u & 0 \\ 0 & 0 & m_u \end{bmatrix} \quad \text{and} \quad \mathbf{K} = \begin{bmatrix} 2k_u & -k_u & 0 \\ -k_u & 2k_u & -k_u \\ 0 & -k_u & 2k_u \end{bmatrix}. \quad (34)$$

The matrix of damping kernel functions can be expressed in the time domain as

$$\mathcal{G}(t) = C_1 \mu_1 e^{-\mu_1 t} + C_2 \mu_2 e^{-\mu_2 t}. \quad (35)$$

The coefficient matrices of this double-exponential model are given by

Structures with Nonviscous Damping, Modeling, and Analysis, Fig. 1 A three-DOF model system with nonviscous damping, the shaded bars represent the

nonviscous damping elements. $c_i, i = 1, 2$ are the damping constants and $g_i(t - \tau) = \mu_i e^{-\mu_i(t-\tau)}$, $i = 1, 2$ are the nonviscous damping functions

$$\mathbf{C}_1 = \begin{bmatrix} c_1 & 0 & 0 \\ 0 & c_1 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad \{\omega_1, \omega_2, \omega_3\} = \{0.4315, 1.1547, 1.2616\} \quad (36)$$

$$\mathbf{C}_2 = \begin{bmatrix} 0 & 0 & 0 \\ 0 & c_2 & -c_2 \\ 0 & -c_2 & c_2 \end{bmatrix} \quad \text{and} \quad [\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3] = \begin{bmatrix} 0.1750 & -0.4082 & -0.3688 \\ 0.3012 & -0.0000 & 0.1429 \\ 0.1750 & 0.4082 & -0.3688 \end{bmatrix}. \quad (42)$$

Both the matrices have rank deficiency because one can easily verify that

$$r_1 = \text{rank}(\mathbf{C}_1) = 2 \leq 3 \quad (37)$$

and

$$r_2 = \text{rank}(\mathbf{C}_2) = 1 \leq 3. \quad (38)$$

The order of the system, that is, the number of eigenvalues

$$m = 2N + \sum \text{rank}(\mathbf{C}_i) = 6 + 3 = 9 \quad (39)$$

For the numerical calculation, we have assumed $m_u = 3.0$ kg, $k_u = 2.0$ N/m, $c_1 = 0.6$ Ns/m, $c_2 = 0.2$ Ns/m, $\mu_1 = 1.0$ s⁻¹, and $\mu_2 = 5.0$ s⁻¹. The matrix $\mathbf{G}(s)$, necessary for the implementation of the iterative method, can be obtained from (35) as

$$\mathbf{G}(s) = \mathbf{C}_1 \frac{\mu_1}{s + \mu_1} + \mathbf{C}_2 \frac{\mu_2}{s + \mu_2}. \quad (40)$$

The undamped eigenvalues and eigenvectors are obtained as

Note that the last two undamped eigenvalues are very close and therefore one would expect significant modal coupling. The complex conjugate eigenvalues obtained using the proposed iterative method is compared with the exact state-space method and the first-order perturbation method in Table 1. We have used the first-order expression of $\alpha_k^{(j)}$ given by Eq. 24 and considered the error tolerance to be $\varepsilon_m = 0.001$. For all the three eigenvalues, 3 iterations are used. The first-order perturbation results are obtained from Eq. 28. The percentage errors are calculated with respect to the exact state-space results as

$$\varepsilon = 100 \times \frac{|\text{exact} - \text{approximate}|}{|\text{exact}|}. \quad (43)$$

Using the proposed iterative method, errors corresponding to all the three modes are reduced compared to the first-order perturbation results.

Next we consider the complex eigenvectors of the system. The exact eigenvectors obtained using the state-space approach (Wagner and Adhikari 2003) are given by

Structures with Nonviscous Damping, Modeling, and Analysis, Table 1 The complex eigenvalues of the system obtained using the proposed method are compared with the exact state-space method and the first-order perturbation method. The numbers in the parenthesis represent the percentage error

Eigenvalue number	State space (exact)	First-order perturbation	Proposed iterative (three iterations)	Method
1	$-0.0335 \pm 0.4453i$	$-0.0323 \pm 0.4448i$ (0.2918)	$-0.0335 \pm 0.4453i$	(0.0003)
2	$-0.0386 \pm 1.1806i$	$-0.0373 \pm 1.1831i$ (0.2445)	$-0.0383 \pm 1.1810i$	(0.0450)
3	$-0.0420 \pm 1.2941i$	$-0.0427 \pm 1.2907i$ (0.2695)	$-0.0424 \pm 1.2911i$	(0.2321)

$$\mathbf{U}_{\text{Exact}} = \begin{bmatrix} 0.1721 - 0.0073i - 0.3519 - 0.0115i - 0.4397 + 0.0163i \\ 0.3014 - 0.0002i - 0.0305 - 0.0066i \quad 0.1410 + 0.0006i \\ 0.1769 + 0.0078i \quad 0.4632 - 0.0096i - 0.3019 - 0.0124i \end{bmatrix}. \quad (44)$$

The eigenvectors calculated using the expression of the first-order perturbation in (24) are given by

$$\mathbf{U}_{\text{1st}} = \begin{bmatrix} 0.1721 - 0.0073i - 0.3519 - 0.0115i - 0.4397 + 0.0163i \\ 0.3014 - 0.0001i - 0.0309 - 0.0058i \quad 0.1420 + 0.0020i \\ 0.1770 + 0.0077i \quad 0.4646 - 0.0115i - 0.2989 - 0.0139i \end{bmatrix}. \quad (45)$$

Using the propose iterative approach, the matrix of complex eigenvectors can be obtained as

$$\mathbf{U}_{\text{iter}} = \begin{bmatrix} 0.1721 - 0.0073i - 0.3519 - 0.0115i - 0.4397 + 0.0163i \\ 0.3013 - 0.0000i - 0.0305 - 0.0062i \quad 0.1421 + 0.0019i \\ 0.1769 + 0.0078i \quad 0.4623 - 0.0094i - 0.2994 - 0.0135i \end{bmatrix}. \quad (46)$$

The eigenvectors are normalized such that the first element is identical for all the three computational method. Therefore, the eigenvectors only differ in the second and the third elements. The absolute value of the errors for the first-order perturbation method and the iterative method is given by

$$\begin{aligned} \varepsilon_{\text{1st}} &= \begin{bmatrix} 0.0593 & 3.0320 & 1.2494 \\ 0.0340 & 0.5051 & 1.1030 \end{bmatrix} \quad \text{and} \\ \varepsilon_{\text{iter}} &= \begin{bmatrix} 0.0756 & 1.2961 & 1.2448 \\ 0.0085 & 0.1864 & 0.9141 \end{bmatrix}. \end{aligned} \quad (47)$$

In general, the iterative method gives lower error in the eigenvectors. In Fig. 2, errors in two

typical frequency response functions of the system calculated from Eq. 8 using the first-order perturbation and the iterative method are shown. The first-order perturbation method performs poorly across the frequency range. From these results, the relative accuracy of the proposed iterative method can be observed.

Conclusions

Due to the recent focus in sustainable earthquake-resistant design, there is a renewed interest to consider general nonviscous and nonproportionally damped linear dynamic systems as new

Structures with Nonviscous Damping, Modeling, and Analysis, Fig. 2 Percentage errors with respect to the exact state-space eigensolutions in a cross-FRF and the driving-point FRF of the system. Results from the first-order perturbation method and the proposed iterative method are shown

generation of materials are being used. State-space-based methods were normally applied to address such problems. These methods are computationally more expensive and often do not give the physical insight compared to the classical normal mode-based method. In this work a new iterative method has been proposed to obtain

the complex eigensolutions of a general nonviscous nonproportionally damped system from the undamped eigensolutions. It is assumed that all the eigenvalues are distinct and are real or appear in complex conjugate pairs. The proposed method exploits a mathematical construction where complex eigenvalues and eigenvectors

can be updated from their previous values in an iterative manner. A sufficient condition for the convergence of the proposed iterative method is derived. A simple algorithm is proposed to implement this method.

The applicability of the proposed method is investigated using an example with two nonviscous damping kernels. Acceptable accuracy has been observed. Using the iterative method developed here, it is possible to obtain the eigenvalues, eigenvectors, and consequently the dynamic response of nonproportionally damped systems by post-processing of the undamped eigenvalues and eigenvectors, which in turn can be obtained using a general-purpose finite element software. Future work is necessary to extend this method to systems with repeated eigenvalues.

Subset Simulation Method for Rare Event Estimation: An Introduction

Konstantin M. Zuev

Department of Computing and Mathematical Sciences, California Institute of Technology, USA

Introduction

This entry provides a detailed introductory description of Subset Simulation, an advanced stochastic simulation method for estimation of small probabilities of rare failure events. A simple and intuitive derivation of the method is given along with the discussion on its

implementation. The method is illustrated with several easy-to-understand examples. The reader is assumed to be familiar only with elementary probability theory and statistics.

Subset Simulation (SS) is an efficient and elegant method for simulating rare events and estimating the corresponding small tail probabilities. The method was originally developed by Siu-Kui Au and James Beck in the already classical paper (Au and Beck 2001a) for estimation of structural reliability of complex civil engineering systems such as tall buildings and bridges at risk from earthquakes. The method turned out to be so powerful and general that over the last decade, SS has been successfully applied to reliability problems in geotechnical, aerospace, fire, and nuclear engineering. Moreover, the idea of SS proved to be useful not only in reliability analysis but also in other problems associated with general engineering systems, such as sensitivity analysis, design optimization, and uncertainty quantification. As of October 2014, according to the Web of Science (ISI) database and Google Scholar, the original SS paper (Au and Beck 2001a) received 315 and 572 citations respectively, that indicates the high impact of the Subset Simulation method on the engineering research community.

Subset Simulation is essentially based on two different ideas: conceptual and technical. The conceptual idea is to decompose the rare event F into a sequence of progressively “less-rare” nested events,

$$F = F_m \subset F_{m-1} \subset \dots \subset F_1, \quad (1)$$

where F_1 is a relatively frequent event. For example, suppose that F represents the event of getting exactly m heads when flipping a fair coin m times. If m is large, then F is a rare event. To decompose F into a sequence (Eq. 1), let us define F_k to be the event of getting exactly k heads in the first k flips, where $k = 1, \dots, m$. The smaller the k , the less rare the corresponding event F_k , and F_1 – getting heads in the first flip – is relatively frequent.

Given a sequence of subsets (Eq. 1), the small probability $\mathbb{P}(F)$ of the rare event F can then be

represented as a product of larger probabilities as follows:

$$\begin{aligned} \mathbb{P}(F) &= \mathbb{P}(F_m) \\ &= \mathbb{P}(F_1) \frac{\mathbb{P}(F_2) \mathbb{P}(F_3)}{\mathbb{P}(F_1) \mathbb{P}(F_2)} \dots \frac{\mathbb{P}(F_{m-1}) \mathbb{P}(F_m)}{\mathbb{P}(F_{m-2}) \mathbb{P}(F_{m-1})} \\ &= \mathbb{P}(F_1) \cdot \mathbb{P}(F_2|F_1) \cdot \dots \cdot \mathbb{P}(F_m|F_{m-1}), \end{aligned} \quad (2)$$

where $\mathbb{P}(F_k|F_{k-1}) = \mathbb{P}(F_k)/\mathbb{P}(F_{k-1})$ denotes the conditional probability of event F_k given the occurrence of event F_{k-1} , for $k = 2, \dots, m$. In the coin example, $\mathbb{P}(F_1) = 1/2$, all conditional probabilities $\mathbb{P}(F_k|F_{k-1}) = 1/2$, and the probability of the rare event $\mathbb{P}(F) = 1/2^m$.

Unlike the coin example, in real applications, it is often not obvious how to decompose the rare event into a sequence in Eq. 1 and how to compute all conditional probabilities in Eq. 2. In Subset Simulation, the “sequencing” of the rare event is done adaptively as the algorithm proceeds. This is achieved by employing Markov chain Monte Carlo, an advanced simulation technique, which constitutes the second – technical – idea behind SS. Finally, all conditional probabilities are automatically obtained as a by-product of the adaptive sequencing.

The main goals of this entry are (a) to provide a detailed exposition of Subset Simulation at an introductory level, (b) to give a simple derivation of the method and discuss its implementation, and (c) to illustrate SS with intuitive examples. Although the scope of SS is much wider, in this entry the method is described in the context of engineering reliability estimation; the problem SS was originally developed for in Au and Beck (2001a).

The rest of the entry is organized as follows: section “[Engineering Reliability Problem](#)” describes the engineering reliability problem and explains why this problem is computationally challenging. Section “[The Direct Monte Carlo Method](#)” discusses how the Direct Monte Carlo method can be used for engineering reliability estimation and why it is often inefficient. In section “[Preprocessing: Transformation of Input Variables](#),” a necessary preprocessing step which is

often used by many reliability methods is briefly discussed. Section “[The Subset Simulation Method](#)” is the core of the entry, where the SS method is explained. Illustrative examples are considered in section “[Illustrative Examples](#).” For demonstration purposes, the MATLAB code for the considered examples is provided in section “[MATLAB code](#).” Section “[Summary](#)” concludes the entry with a brief summary.

Engineering Reliability Problem

One of the most important and computationally challenging problems in reliability engineering is to estimate the probability of failure for a system, that is, the probability of unacceptable system performance. The behavior of the system can be described by a *response variable* y , which may represent, for example, the roof displacement or the largest interstory drift. The response variable depends on *input variables* $x = (x_1, \dots, x_d)$, also called *basic variables*, which may represent geometry, material properties, and loads,

$$y = g(x_1, \dots, x_d), \quad (3)$$

where $g(x)$ is called the *performance function*. The performance of the system is measured by comparison of the response y with a specified critical value y^* : if $y \leq y^*$, then the system is safe; if $y > y^*$, then the system has failed. This failure criterion allows to define the *failure domain* F in the input x -space as follows:

$$F = \{x : g(x) > y^*\}. \quad (4)$$

In other words, the failure domain is a set of values of input variables that lead to unacceptable system performance, namely, to the exceedance of some prescribed critical threshold y^* , which may represent the maximum permissible roof displacement, maximum permissible interstory drift, etc.

Engineering systems are complex systems, where complexity, in particular, means that the information about the system (its geometric and material properties) and its environment (loads)

is never complete. Therefore, there are always uncertainties in the values of input variables x . To account for these uncertainties, the input variables are modeled as random variables whose marginal distributions are usually obtained from test data, from expert opinion, or from literature. Let $\pi(x)$ denote the joint probability density function (PDF) for x . The uncertainty in the input variables is propagated through Eq. 3 into the response variable y , which makes the *failure event* $\{x \in F\} = \{y > y^*\}$ also uncertain. The *engineering reliability problem* is then to compute the probability of failure p_F , given by the following expression:

$$p_F = \mathbb{P}(x \in F) = \int_F \pi(x) dx. \quad (5)$$

The behavior of complex systems, such as tall buildings and bridges, is represented by a complex model (3). In this context, complexity means that the performance function $g(x)$, which defines the integration region F in Eq. 5, is not explicitly known. The evaluation of $g(x)$ for any x is often time-consuming and usually done by the finite element method (FEM), one of the most important numerical tools for computation of the response of engineering systems. Thus, it is usually impossible to evaluate the integral in Eq. 5 analytically because the integration region, the failure domain F , is not known explicitly.

Moreover, traditional numerical integration is also generally not applicable. In this approach, the d -dimensional input x -space is partitioned into a union of disjoint hypercubes, $\square_1, \dots, \square_N$. For each hypercube $\square_i$, a “representative” point $x^{(i)}$ is chosen inside that hypercube, $x^{(i)} \in \square_i$. The integral in Eq. 5 is then approximated by the following sum:

$$p_F \approx \sum_{x^{(i)} \in F} \pi(x^{(i)}) \text{vol}(\square_i), \quad (6)$$

where $\text{vol}(\square_i)$ denotes the volume of $\square_i$ and summation is taken over all failure points $x^{(i)}$. Since it is not known in advance whether

a given point is a failure point or not (the failure domain F is not known explicitly), to compute the sum in Eq. 6, the failure criterion in Eq. 4 must be checked for all $x(i)$. Therefore, the approximation in Eq. 6 becomes

$$p_F \approx \sum_{i=1}^N I_F(x^{(i)}) \pi(x^{(i)}) \text{vol}(\square_i), \quad (7)$$

where $I_F(x)$ stands for the indicator function, i.e.,

$$I_F(x) = \begin{cases} 1, & \text{if } x \in F, \\ 0, & \text{if } x \notin F. \end{cases} \quad (8)$$

If n denotes the number of intervals each dimension of the input space is partitioned into, then the total number of terms in Eq. 7 is $N = n^d$. Therefore, the computational effort of numerical integration grows exponentially with the number of dimensions d . In engineering reliability problems, the dimension of the input space is typically very large (e.g., when the stochastic load time history is discretized in time). For example, $d \sim 10^3$ is not unusual in the reliability literature. This makes numerical integration computationally infeasible.

Over the past few decades, many different methods for solving the engineering reliability problem (5) have been developed. In general, the proposed reliability methods can be classified into three categories, namely:

- (a) *Analytic methods* are based on the Taylor-series expansion of the performance function, e.g., the first-order reliability method (FORM) and the second-order reliability method (SORM) (Ditlevsen and Madsen 1996; Madsen et al. 2006; Melchers 1999).
- (b) *Surrogate methods* are based on a functional surrogate of the performance function, e.g., the response surface method (RSM) (Faravelli 1989; Schuëller et al. 1989; Bucher 1990), Neural Networks (Papadrakakis et al. 1996), support vector machines (Hurtado and Alvarez 2003), and other methods (Hurtado 2004).

- (c) *Monte Carlo simulation methods*, among which are Importance Sampling (Engelund and Rackwitz 1993), Importance Sampling using Elementary Events (Au and Beck 2001b), Radial-based Importance Sampling (Grooteman 2008), Adaptive Linked Importance Sampling (Katafygiotis and Zuev 2007), Directional Simulation (Ditlevsen and Madsen 1996), Line Sampling (Koutsourelakis et al. 2004), Auxiliary Domain Method (Katafygiotis et al. 2007), Horseracing Simulation (Zuev and Katafygiotis 2011), and *Subset Simulation* (Au and Beck 2001a).

Subset Simulation is thus a reliability method which is based on (advanced) Monte Carlo simulation.

The Direct Monte Carlo Method

The Monte Carlo method, referred in this entry as *Direct Monte Carlo* (DMC), is a statistical sampling technique that has been originally developed by Stan Ulam, John von Neumann, Nick Metropolis (who actually suggested the name “Monte Carlo” (Metropolis 1987)), and their collaborators for solving the problem of neutron diffusion and other problems in mathematical physics (Metropolis and Ulam 1949). From a mathematical point of view, DMC allows to estimate the expected value of a quantity of interest. More specifically, suppose the goal is to evaluate $\mathbb{E}_\pi[h(x)]$, that is, an expectation of a function $h: \mathcal{X} \rightarrow \mathbb{R}$ with respect to the PDF $\pi(x)$,

$$\mathbb{E}_\pi[h(x)] = \int_{\mathcal{X}} h(x) \pi(x) dx. \quad (9)$$

The idea behind DMC is a straightforward application of the *law of large numbers* that states that if $x^{(1)}, x^{(2)}, \dots$ are i.i.d. (independent and identically distributed) from the PDF $\pi(x)$, then the empirical average $\frac{1}{N} \sum_{i=1}^N h(x^{(i)})$ converges to the true value $\mathbb{E}_\pi[h(x)]$ as N goes to $+\infty$. Therefore, if the number of samples N is large enough,

then $\mathbb{E}_\pi[h(x)]$ can be accurately estimated by the corresponding empirical average:

$$\mathbb{E}_\pi[h(x)] \approx \frac{1}{N} \sum_{i=1}^N h(x^{(i)}). \quad (10)$$

The relevance of DMC to the reliability problem (5) follows from a simple observation that the failure probability p_F can be written as an expectation of the indicator function (8), namely,

$$p_F = \int_F \pi(x) dx = \int_{\mathcal{X}} I_F(x) \pi(x) dx = \mathbb{E}_\pi[I_F(x)], \quad (11)$$

where $\mathcal{X}$ denotes the entire input x -space. Therefore, the failure probability can be estimated using the DMC method (10) as follows:

$$p_F \approx \hat{p}_F^{\text{DMC}} = \frac{1}{N} \sum_{i=1}^N I_F(x^{(i)}), \quad (12)$$

where $x^{(1)}, \dots, x^{(N)}$ are i.i.d. samples from $\pi(x)$.

The DMC estimate of p_F is thus just the ratio of the total number of *failure samples* $\sum_{i=1}^N I_F(x^{(i)})$, i.e., samples that produce system failure according to the system model, to the total number of samples, N . Note that $\hat{p}_F^{\text{DMC}}$ is an *unbiased* random estimate of the failure probability, that is, on average, $\hat{p}_F^{\text{DMC}}$ equals to p_F . Mathematically, this means that $\mathbb{E}[\hat{p}_F^{\text{DMC}}] = p_F$. Indeed, using the fact that $x^{(i)} \sim \pi(x)$ and in Eq. 11,

$$\begin{aligned} \mathbb{E}[\hat{p}_F^{\text{DMC}}] &= \mathbb{E}\left[\frac{1}{N} \sum_{i=1}^N I_F(x^{(i)})\right] \\ &= \frac{1}{N} \sum_{i=1}^N \mathbb{E}[I_F(x^{(i)})] \\ &= \frac{1}{N} \sum_{i=1}^N \mathbb{E}_\pi[I_F(x)] = p_F. \end{aligned} \quad (13)$$

The main advantage of DMC over numerical integration is that its accuracy does not depend on the dimension d of the input space. In reliability analysis, the standard measure of accuracy

of an unbiased estimate $\hat{p}_F$ of the failure probability is its *coefficient of variation* (c.o.v.) $\delta(\hat{p}_F)$, which is defined as the ratio of the standard deviation to the expected value of $\hat{p}_F$, i.e., $\delta(\hat{p}_F) = \sqrt{\mathbb{V}[\hat{p}_F] / \mathbb{E}[\hat{p}_F]}$, where $\mathbb{V}$ denotes the variance. The smaller the c.o.v. $\delta(\hat{p}_F)$, the more accurate the estimate $\hat{p}_F$ is. It is straightforward to calculate the variance of the DMC estimate:

$$\begin{aligned} \mathbb{V}[\hat{p}_F^{\text{DMC}}] &= \mathbb{V}\left[\frac{1}{N} \sum_{i=1}^N I_F(x^{(i)})\right] = \frac{1}{N^2} \sum_{i=1}^N \mathbb{V}[I_F(x^{(i)})] \\ &= \frac{1}{N^2} \sum_{i=1}^N \left(\mathbb{E}[I_F(x^{(i)})^2] - \mathbb{E}[I_F(x^{(i)})]^2 \right) \\ &= \frac{1}{N^2} \sum_{i=1}^N (p_F - p_F^2) = \frac{p_F(1 - p_F)}{N}. \end{aligned} \quad (14)$$

Here, the identity $I_F(x)^2 = I_F(x)$ was used. Using Eqs. 13 and 14, the c.o.v. of the DMC estimate can be calculated:

$$\delta(\hat{p}_F^{\text{DMC}}) = \frac{\sqrt{\mathbb{V}[\hat{p}_F^{\text{DMC}}]}}{\mathbb{E}[\hat{p}_F^{\text{DMC}}]} = \sqrt{\frac{1 - p_F}{N p_F}}. \quad (15)$$

This result shows that $\delta(\hat{p}_F^{\text{DMC}})$ depends only on the failure probability p_F and the total number of samples N and does not depend on the dimension d of the input space. Therefore, unlike numerical integration, the DMC method does not suffer from the “curse of dimensionality,” i.e., from an exponential increase in volume associated with adding extra dimensions, and is able to handle problems of high dimension.

Nevertheless, DMC has a serious drawback: it is inefficient in estimating small failure probabilities. For typical engineering reliability problems, the failure probability p_F is very small, $p_F \ll 1$. In other words, the system is usually assumed to be designed properly, so that its failure is a *rare event*. In the reliability literature, $p_F \sim 10^{-2} - 10^{-9}$ have been considered. If p_F is very small, then it follows from Eq. 15 that

$$\delta(\hat{p}_F^{\text{DMC}}) \approx \frac{1}{\sqrt{N p_F}}. \quad (16)$$

This means that the number of samples N needed to achieve an acceptable level of accuracy is inverse proportional to p_F , and therefore very large, $N \propto 1/p_F \gg 1$. For example, if $p_F = 10^{-4}$ and the c.o.v. of 10 % is desirable, then $N = 10^6$ samples are required. Note, however, that each evaluation of $I_F(x^{(i)})$, $i = 1, \dots, N$, in Eq. 12 requires a system analysis to be performed to check whether the sample $x^{(i)}$ is a failure sample. As it has been already mentioned in section “[Engineering Reliability Problem](#),” the computation effort for the system analysis, i.e., computation of the performance function $g(x)$, is significant (usually involves the FEM method). As a result, the DMC method becomes excessively costly and practically inapplicable for reliability analysis. This deficiency of DMC has motivated research to develop more advanced simulation algorithms for efficient estimation of small failure probabilities in high dimensions.

Remark 1 It is important to highlight, however, that even though DMC cannot be routinely used for reliability problems (too expensive), it is a very robust method, and it is often used as a check on other reliability methods.

Preprocessing: Transformation of Input Variables

Many reliability methods, including Subset Simulation, assume that the input variables x are independent. This assumption, however, is not a limitation, since in simulation one always starts from independent variables to generate the dependent input variables. Furthermore, for convenience, it is often assumed that x are i.i.d. Gaussian. If this is not the case, a “preprocessing” step that transforms x to i.i.d. Gaussian variables z must be undertaken. The transformation from x to z can be performed in several ways depending on the available information about the input variables. In the simplest case, when x are independent Gaussians, $x_k \sim \mathcal{N}(\cdot | \mu_k, \sigma_k^2)$, where μ_k and σ_k^2 are,

respectively, the mean and variance of x_k , the necessary transformation is standardization:

$$z_k = \frac{x_k - \mu_k}{\sigma_k}. \quad (17)$$

In other cases, more general techniques should be used, such as the Rosenblatt transformation (Rosenblatt 1952) and the Nataf transformation (Nataf 1962). To avoid introduction of additional notation, hereinafter, it is assumed without loss of generality that the vector x has been already transformed and it follows the standard multivariate Gaussian distribution,

$$\pi(x_1, \dots, x_d) = \prod_{k=1}^d \phi(x_k), \quad (18)$$

where $\phi(\cdot)$ denotes the standard Gaussian PDF,

$$\phi(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}x^2}. \quad (19)$$

The Subset Simulation Method

Unlike Direct Monte Carlo, where all computational resources are directly spent on sampling the input space $x^{(1)}, \dots, x^{(N)} \sim \pi(\cdot)$ and computing the values of the performance function $g(x^{(1)}), \dots, g(x^{(N)})$, Subset Simulation first “probes” the input space $\mathcal{X}$ by generating a relatively small number of i.i.d samples $x_0^{(1)}, \dots, x_0^{(n)} \sim \pi(x)$, $n < N$, and computing the corresponding system responses $y_0^{(1)} = g(x_0^{(1)}), \dots, y_0^{(n)} = g(x_0^{(n)})$. Here, the subscript 0 indicates the 0th stage of the algorithm. Since F is a rare event and n is relatively small, it is very likely that none of the samples $x_0^{(1)}, \dots, x_0^{(n)}$ belongs to F , that is, $y_0^{(i)} < y^*$ for all $i = 1, \dots, n$. Nevertheless, these Monte Carlo samples contain some useful information about the failure domain that can be utilized. To keep the notation simple, assume that $y_0^{(1)}, \dots, y_0^{(n)}$ are arranged in the decreasing order, i.e., $y_0^{(1)} \geq \dots \geq y_0^{(n)}$ (it is always possible to achieve this by renumbering $x_0^{(1)}, \dots, x_0^{(n)}$ if needed). Then, $x_0^{(1)}$ and $x_0^{(n)}$ are, respectively, the closest to failure and the safest samples among $x_0^{(1)}, \dots, x_0^{(n)}$, since $y_0^{(1)}$ and $y_0^{(n)}$ are the largest and the smallest responses. In general,

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 1 Monte Carlo samples $x_0^{(1)}, \dots, x_0^{(n)}$ and the failure domain F . $x_0^{(1)}$ and $x_0^{(n)}$ are, respectively, the closest to failure and the safest samples among $x_0^{(1)}, \dots, x_0^{(n)}$

the smaller the i , the closer to failure the sample $x_0^{(i)}$ is. This is shown schematically in Fig. 1.

Let $p \in (0, 1)$ be any number such that np is integer. By analogy with Eq. 4, define the *first intermediate failure domain* F_1 as follows:

$$F_1 = \{x : g(x) > y_1^*\}, \quad (20)$$

where

$$y_1^* = \frac{y_0^{(np)} + y_0^{(np+1)}}{2}. \quad (21)$$

In other words, F_1 is the set of inputs that lead to the exceedance of the *relaxed threshold* $y_1^* < y^*$. Note that by construction, samples $x_0^{(1)}, \dots, x_0^{(np)}$ belong to F_1 , while $x_0^{(np+1)}, \dots, x_0^{(n)}$ do not. As a consequence, the Direct Monte Carlo estimate for the probability of F_1 which is based on samples $x_0^{(1)}, \dots, x_0^{(n)}$ is automatically equal to p ,

$$\mathbb{P}(F_1) \approx \frac{1}{n} \sum_{i=1}^n I_{F_1}(x_0^{(i)}) = p. \quad (22)$$

The value $p = 0.1$ is often used in the literature, which makes F_1 a relatively frequent event. Figure 2 illustrates the definition of F_1 .

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 2 The first intermediate failure domain F_1 . In this schematic illustration, $n = 10$, $p = 0.2$, so that there are exactly $np = 2$ Monte Carlo samples in F_1 , $x_0^{(1)}, x_0^{(2)} \in F_1$

The first intermediate failure domain F_1 can be viewed as a (very rough) conservative approximation to the target failure domain F . Since $F \subset F_1$, the failure probability p_F can be written as a product:

$$p_F = \mathbb{P}(F_1)\mathbb{P}(F|F_1), \quad (23)$$

where $\mathbb{P}(F|F_1)$ is the conditional probability of F given F_1 . Therefore, in view of Eq. 22, the problem of estimating p_F is reduced to estimating the conditional probability $\mathbb{P}(F|F_1)$.

In the next stage, instead of generating samples in the whole input space (like in DMC), the SS algorithm aims to populate F_1 . Specifically, the goal is to generate samples $x_1^{(1)}, \dots, x_1^{(n)}$ from the conditional distribution

$$\pi(x|F_1) = \frac{\pi(x)I_{F_1}(x)}{\mathbb{P}(F_1)} = \frac{I_{F_1}(x)}{\mathbb{P}(F_1)} \prod_{k=1}^d \phi(x_k). \quad (24)$$

First of all, note that samples $x_0^{(1)}, \dots, x_0^{(np)}$ not only belong to F_1 but are also distributed according to $\pi(\cdot|F_1)$. To generate the remaining $(n - np)$ samples from $\pi(\cdot|F_1)$, which, in general, is not a trivial task, Subset Simulation uses the so-called Modified Metropolis algorithm (MMA). MMA belongs to the class of *Markov chain Monte Carlo* (MCMC) algorithms (Liu 2001;

Robert and Casella 2004), which are techniques for sampling from complex probability distributions that cannot be sampled directly, at least not efficiently. MMA is based on the original Metropolis algorithm (Metropolis et al. 1953) and specifically tailored for sampling from the conditional distributions of the form (24).

Modified Metropolis Algorithm

Let $x \sim \pi(\cdot|F_1)$ be a sample from the conditional distribution $\pi(\cdot|F_1)$. The Modified Metropolis algorithm generates another sample $\tilde{x}$ from $\pi(\cdot|F_1)$ as follows:

1. Generate a “candidate” sample ξ : For each coordinate $k = 1, \dots, d$,
 - (a) Sample $\eta_k \sim q_k(\cdot|x_k)$, where $q_k(\cdot|x_k)$, called the *proposal distribution*, is a univariate PDF for η_k centered at x_k with the symmetry property $q_k(\eta_k|x_k) = q_k(x_k|\eta_k)$. For example, the proposal distribution can be a Gaussian PDF with mean x_k and variance σ_k^2 ,

$$q_k(\eta_k|x_k) = \frac{1}{\sqrt{2\pi}\sigma_k} \exp\left(-\frac{(\eta_k - x_k)^2}{2\sigma_k^2}\right), \quad (25)$$

or it can be a uniform distribution over $[x_k - \alpha, x_k + \alpha]$, for some $\alpha \geq 0$.

- (b) Compute the acceptance ratio

$$r_k = \frac{\phi(\eta_k)}{\phi(x_k)}. \quad (26)$$

- (c) Define the k th coordinate of the candidate sample by accepting or rejecting η_k ,

$$\xi_k = \begin{cases} \eta_k, & \text{with probability } \min\{1, r_k\}, \\ x_k, & \text{with probability } 1 - \min\{1, r_k\}. \end{cases} \quad (27)$$

2. Accept or reject the candidate sample ξ by setting

$$\tilde{x} = \begin{cases} \xi, & \text{if } \xi \in F_1, \\ x, & \text{if } \xi \notin F_1. \end{cases} \quad (28)$$

The Modified Metropolis algorithm is schematically illustrated in Fig. 3.

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 3 Modified Metropolis algorithm

It can be shown that the sample $\tilde{x}$ generated by MMA is indeed distributed according to $\pi(\cdot|F_1)$. If the candidate sample ξ is rejected in Eq. 28, then $\tilde{x} = x \sim \pi(\cdot|F_1)$ and there is nothing to prove. Suppose now that ξ is accepted, $\tilde{x} = \xi$, so that the move from x to $\tilde{x}$ is a proper transition between two distinct points in F_1 . Let $f(\cdot)$ denote the PDF of $\tilde{x}$ (the goal is to show that $f(\tilde{x}) = \pi(\tilde{x}|F_1)$). Then

$$f(\tilde{x}) = \int_{F_1} \pi(x|F_1) t(\tilde{x}|x) dx, \quad (29)$$

where $t(\tilde{x}|x)$ is the transition PDF from x to $\tilde{x} \neq x$. According to the first step of MMA, coordinates of $\tilde{x} = \xi$ are generated independently, and therefore $t(\tilde{x}|x)$ can be expressed as a product,

$$t(\tilde{x}|x) = \prod_{k=1}^d t_k(\tilde{x}_k|x_k), \quad (30)$$

where $t_k(\tilde{x}_k|x_k)$ is the transition PDF for the k th coordinate $\tilde{x}_k$. Combining Eqs. 24, 29, and 30 gives

$$\begin{aligned}
 f(\tilde{x}) &= \int_{F_1} \frac{I_{F_1}(x)}{\mathbb{P}(F_1)} \prod_{k=1}^d \phi(x_k) \prod_{k=1}^d t_k(\tilde{x}_k|x_k) dx \\
 &= \frac{1}{\mathbb{P}(F_1)} \int_{F_1} \prod_{k=1}^d \phi(x_k) t_k(\tilde{x}_k|x_k) dx. \quad (31)
 \end{aligned}$$

The key to the proof of $f(\tilde{x}) = \pi(\tilde{x}|F_1)$ is to demonstrate that $\phi(x_k)$ and $t_k(\tilde{x}_k|x_k)$ satisfy the so-called detailed balance equation,

$$\phi(x_k) t_k(\tilde{x}_k|x_k) = \phi(\tilde{x}_k) t_k(x_k|\tilde{x}_k). \quad (32)$$

If $\tilde{x}_k = x_k$, then Eq. 32 is trivial. Suppose that $\tilde{x}_k \neq x_k$, that is, $\tilde{x}_k = \xi_k = \eta_k$ in Eq. 27. The actual transition PDF $t_k(\tilde{x}_k|x_k)$ from x_k to $\tilde{x}_k \neq x_k$ differs from the proposal PDF $q_k(\tilde{x}_k|x_k)$ because the acceptance-rejection step in Eq. 27 is involved. To actually make the move from x_k to $\tilde{x}_k$, one needs not only to generate $\tilde{x}_k \sim q_k(\cdot|x_k)$ but also to accept it with probability $\min\left\{1, \frac{\phi(\tilde{x}_k)}{\phi(x_k)}\right\}$. Therefore,

$$t_k(\tilde{x}_k|x_k) = q_k(\tilde{x}_k|x_k) \min\left\{1, \frac{\phi(\tilde{x}_k)}{\phi(x_k)}\right\}, \quad \tilde{x}_k \neq x_k. \quad (33)$$

Using Eq. 33, the symmetry property of the proposal PDF, $q_k(\tilde{x}_k|x_k) = q_k(x_k|\tilde{x}_k)$, and the identity $a \min\left\{1, \frac{b}{a}\right\} = b \min\left\{1, \frac{a}{b}\right\}$ for any $a, b > 0$,

$$\begin{aligned}
 \phi(x_k) t_k(\tilde{x}_k|x_k) &= q_k(\tilde{x}_k|x_k) \phi(x_k) \min\left\{1, \frac{\phi(\tilde{x}_k)}{\phi(x_k)}\right\} \\
 &= q_k(x_k|\tilde{x}_k) \phi(\tilde{x}_k) \min\left\{1, \frac{\phi(x_k)}{\phi(\tilde{x}_k)}\right\} \\
 &= \phi(\tilde{x}_k) t_k(x_k|\tilde{x}_k), \quad (34)
 \end{aligned}$$

and the detailed balance in Eq. 32 is thus established. The rest is a straightforward calculation:

$$\begin{aligned}
 f(\tilde{x}) &= \frac{1}{\mathbb{P}(F_1)} \int_{F_1} \prod_{k=1}^d \phi(\tilde{x}_k) t_k(x_k|\tilde{x}_k) dx \\
 &= \frac{1}{\mathbb{P}(F_1)} \prod_{k=1}^d \phi(\tilde{x}_k) \int_{F_1} t(x|\tilde{x}) dx \\
 &= \pi(\tilde{x}|F_1), \quad (35)
 \end{aligned}$$

since the transition PDF $t(x|\tilde{x})$ integrates to 1, and $I_{F_1}(\tilde{x}) = 1$.

Remark 2 A mathematically more rigorous proof of the Modified Metropolis algorithm is given in (Zuev et al. 2012).

Remark 3 It is worth mentioning that although the independence of input variables is crucial for the applicability of MMA, and thus for Subset Simulation, they need not be identically distributed. In other words, instead of Eq. 18, the joint PDF $\pi(\cdot)$ can have a more general form, $\pi(x) = \prod_{k=1}^d \pi_k(x_k)$, where $\pi^k(\cdot)$ is the marginal distributions of x_k which is not necessarily Gaussian. In this case, the expression for the acceptance ratio in Eq. 26 must be replaced by $r_k = \frac{\pi_k(\eta_k)}{\pi_k(x_k)}$.

Subset Simulation at Higher Conditional Levels

Given $x_0^{(1)}, \dots, x_0^{(np)} \sim \pi(\cdot|F_1)$, it is clear now how to generate the remaining $(n - np)$ samples from $\pi(\cdot|F_1)$. Namely, starting from each $x_0^{(i)}$, $i = 1, \dots, np$, the SS algorithm generates a sequence of $\left(\frac{1}{p} - 1\right)$ new MCMC samples $x_0^{(i)} = x_{0,0}^{(i)} \mapsto x_{0,1}^{(i)} \mapsto \dots \mapsto x_{0,\frac{1}{p}-1}^{(i)}$ using the Modified Metropolis transition rule described above. Note that when $x_{0,j}^{(i)}$ is generated, the previous sample $x_{0,j-1}^{(i)}$ is used as an input for the transition rule. The sequence $x_{0,0}^{(i)}, x_{0,1}^{(i)}, \dots, x_{0,\frac{1}{p}-1}^{(i)}$ is called a *Markov chain* with the *stationary distribution* $\pi(\cdot|F_1)$, and $x_{0,0}^{(i)} = x_0^{(i)}$ is often referred to as the “seed” of the Markov chain.

To simplify the notation, denote samples $\{x_{0,j}^{(i)}\}_{j=0, \dots, \frac{1}{p}-1}^{i=1, \dots, np}$ by $\{x_1^{(1)}, \dots, x_1^{(n)}\}$. The subscript 1 indicates that the MCMC samples $x_1^{(1)}, \dots, x_1^{(n)} \sim \pi(\cdot|F_1)$ are generated at the first conditional level of the SS algorithm. These conditional samples are schematically shown in Fig. 4. Also assume that the corresponding system responses $y_1^{(1)} = g(x_1^{(1)}), \dots, y_1^{(n)} = g(x_1^{(n)})$ are arranged in the decreasing order, i.e., $y_1^{(1)} \geq \dots \geq y_1^{(n)}$. If the failure event F is rare enough, that is, if p_F is sufficiently small, then it is very likely that none of the samples $x_1^{(1)}, \dots, x_1^{(n)}$ belongs to F , i.e., $y_1^{(i)} < y^*$ for all $i = 1, \dots, n$. Nevertheless, these MCMC samples can be used in the similar way the Monte Carlo samples $x_0^{(1)}, \dots, x_0^{(n)}$ were used.

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 4 MCMC samples generated by the Modified Metropolis algorithm at the first conditional level of Subset Simulation

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 5 The second intermediate failure domain F_2 . In this schematic illustration, $n = 10$, $p = 0.2$, so that there are exactly $np = 2$ MCMC samples in F_2 , $x_1^{(1)}, x_1^{(2)} \in F_2$

By analogy with Eq. 20, define the *second intermediate failure domain* F_2 as follows:

$$F_2 = \{x : g(x) > y_2^*\}, \quad (36)$$

where

$$y_2^* = \frac{y_1^{(np)} + y_1^{(np+1)}}{2}. \quad (37)$$

Note that $y_2^* > y_1^*$ since $y_1^{(i)} > y_1^*$ for all $i = 1, \dots, n$. This means that $F \subset F_2 \subset F_1$, and therefore, F_2 can be viewed as a conservative approximation to F which is still rough, yet more accurate than F_1 . Figure 5 illustrates the definition of F_2 . By construction, samples $x_1^{(1)}, \dots, x_1^{(np)}$ belong to F_2 , while $x_1^{(np+1)}, \dots, x_1^{(n)}$ do not. As a result, the estimate for the conditional probability of F_2 given F_1 which is based on samples $x_1^{(1)}, \dots, x_1^{(n)} \sim \pi(\cdot|F_1)$ is automatically equal to p ,

$$\mathbb{P}(F_2|F_1) \approx \frac{1}{n} \sum_{i=1}^n I_{F_2}(x_1^{(i)}) = p. \quad (38)$$

Since $F \subset F_2 \subset F_1$, the conditional probability $\mathbb{P}(F|F_1)$ that appears in Eq. 23 can be expressed as a product:

$$\mathbb{P}(F|F_1) = \mathbb{P}(F_2|F_1)\mathbb{P}(F|F_2). \quad (39)$$

Combining Eqs. 23 and 39 gives the following expression for the failure probability:

$$p_F = \mathbb{P}(F_1)\mathbb{P}(F_2|F_1)\mathbb{P}(F|F_2). \quad (40)$$

Thus, in view of Eqs. 22 and 38, the problem of estimating p_F is now reduced to estimating the conditional probability $\mathbb{P}(F|F_2)$.

In the next step, as one may have already guessed, the Subset Simulation algorithm populates F_2 by generating MCMC samples $x_2^{(1)}, \dots, x_2^{(n)}$ from $\pi(\cdot|F_2)$ using the Modified Metropolis algorithm, defines the third intermediate failure domain $F_3 \subset F_2$ such that $\mathbb{P}(F_3|F_2) \approx \frac{1}{n} \sum_{i=1}^n I_{F_3}(x_2^{(i)}) = p$, and reduces the original problem of estimating the failure probability p_F to estimating the conditional probability $\mathbb{P}(F|F_3)$ by representing $p_F = \mathbb{P}(F_1)\mathbb{P}(F_2|F_1)\mathbb{P}(F_3|F_2)\mathbb{P}(F|F_3)$. The algorithm proceeds in this way until the target failure domain F has been sufficiently sampled so that the conditional probability $\mathbb{P}(F|F_L)$ can be accurately estimated by $\frac{1}{n} \sum_{i=1}^n I_F(x_L^{(i)})$, where F_L is the L th intermediate failure domain and $x_L^{(1)}, \dots, x_L^{(n)} \sim \pi(\cdot|F_L)$ are the MCMC samples generated at the L th conditional level. Subset Simulation can thus be viewed as a method that decomposes the rare failure event F into a sequence of

progressively “less-rare” nested events, $F \subset F_L \subset \dots \subset F_1$, where all intermediate failure events $F_1, \dots, F_L$ are constructed adaptively by appropriately relaxing the value of the critical threshold $y_1^* < \dots < y_L^* < y^*$.

Stopping Criterion

In what follows, the stopping criterion for Subset Simulation is described in detail. Let $n_F(l)$ denote the number of failure samples at the l^{th} level, that is,

$$n_F(l) = \sum_{i=1}^n I_F(x_l^{(i)}), \quad (41)$$

where $x_l^{(1)}, \dots, x_l^{(n)} \sim \pi(\cdot|F_l)$. Since F is a rare event, it is very likely that $n_F(l) = 0$ for the first few conditional levels. As l gets larger, however, $n_F(l)$ starts increasing since F_l , which approximates F “from above,” shrinks closer to F . In general, $n_F(l) \geq n_F(l-1)$, since $F \subset F_l \subset F_{l-1}$ and the np closest to F samples among $x_{l-1}^{(1)}, \dots, x_{l-1}^{(n)}$ are present among $x_l^{(1)}, \dots, x_l^{(n)}$. At conditional level l , the failure probability p_F is expressed as a product,

$$p_F = \mathbb{P}(F_1)\mathbb{P}(F_2|F_1) \dots \mathbb{P}(F_l|F_{l-1})\mathbb{P}(F|F_l). \quad (42)$$

Furthermore, the adaptive choice of intermediate critical thresholds $y_1^*, \dots, y_l^*$ guarantees that the first l factors in Eq. 42 approximately equal to p , and, thus,

$$p_F \approx p^l \cdot \mathbb{P}(F|F_l). \quad (43)$$

Since there are exactly $n_F(l)$ failure samples at the l^{th} level, the estimate of the last conditional probability in Eq. 42 which is based on samples $x_l^{(1)}, \dots, x_l^{(n)} \sim \pi(\cdot|F_l)$ is given by

$$\mathbb{P}(F|F_l) \approx \frac{1}{n} \sum_{i=1}^n I_F(x_l^{(i)}) = \frac{n_F(l)}{n}. \quad (44)$$

If $n_F(l)$ is sufficiently large, i.e., the conditional event $(F|F_l)$ is not rare, then the estimate in Eq. 44 is fairly accurate. This leads to the following stopping criterion:

- If $\frac{n_F(l)}{n} \geq p$, i.e., there are at least np failure samples among $x_l^{(1)}, \dots, x_l^{(n)}$, then Subset Simulation stops: the current conditional level l becomes the last level, $L = l$, and the failure probability estimate derived from Eqs. 43 and 44 is

$$p_F \approx \hat{p}_F^{\text{SS}} = p^L \frac{n_F(L)}{n}. \quad (45)$$

- If $\frac{n_F(l)}{n} < p$, i.e., there are less than np failure samples among $x_l^{(1)}, \dots, x_l^{(n)}$, then the algorithm proceeds by defining the next intermediate failure domain $F_{l+1} = \{x : g(x) > y_{l+1}^*\}$, where $y_{l+1}^* = (y_l^{(np)} + y_l^{(np+1)})/2$, and expressing $\mathbb{P}(F|F_l)$ as a product $\mathbb{P}(F|F_l) = \mathbb{P}(F_{l+1}|F_l)\mathbb{P}(F|F_{l+1}) \approx p \cdot \mathbb{P}(F|F_{l+1})$.

The described stopping criterion guarantees that the estimated values of all factors in the factorization $p_F = \mathbb{P}(F_1)\mathbb{P}(F_2|F_1) \dots \mathbb{P}(F_L|F_{L-1})\mathbb{P}(F|F_L)$ are not smaller than p . If p is relatively large ($p = 0.1$ is often used in applications), then it is likely that the estimates $\mathbb{P}(F_1) \approx p$, $\mathbb{P}(F_2|F_1) \approx p, \dots, \mathbb{P}(F_L|F_{L-1}) \approx p$, and $\mathbb{P}(F|F_L) \approx \frac{n_F(L)}{n} (\leq p)$ are accurate even when the sample size n is relatively small. As a result, the SS estimate in Eq. 45 is also accurate in this case. This provides an intuitive explanation as to why Subset Simulation is efficient in estimating small probabilities of rare events. For a detailed discussion of error estimation for the SS method, the reader is referred to Au and Wang (2014).

Implementation Details

In the rest of this section, the implementation details of Subset Simulation are discussed. The SS algorithm has two essential components that affect its efficiency: the parameter p and the set of univariate proposal PDFs $\{q_k\}$, $k = 1, \dots, d$.

Level Probability

The parameter p , called the *level probability* in Au and Wang (2014) and the *conditional failure probability* in Zuev et al. (2012), governs how many intermediate failure domains F_l are needed

to reach the target failure domain F . As it follows from Eq. 45, a small value of p leads to a fewer total number of conditional levels L . But at the same time, it results in a large number of samples n needed at each conditional level l for accurate determination of F_l (i.e., determination of y_l^*) that satisfies $\frac{1}{n} \sum_{i=1}^n I_{F_l}(x_{l-1}^{(i)}) = p$. In the extreme case when $p \leq p_F$, no levels are needed, $L = 0$, and Subset Simulation reduces to the Direct Monte Carlo method. On the other hand, increasing the value of p will mean that fewer samples are needed at each conditional level, but it will increase the total number of levels L . The choice of the level probability p is thus a trade-off between the total number of level L and the number of samples n at each level. In the original paper (Au and Beck 2001a), it has been found that the value $p = 0.1$ yields good efficiency. The latter studies (Au and Wang 2014; Zuev et al. 2012), where the c.o.v. of the SS estimate $\hat{p}_F^{SS}$ has been analyzed, confirmed that $p = 0.1$ is a nearly optimal value of the level probability.

Proposal Distributions

The efficiency and accuracy of Subset Simulation also depends on the set of univariate proposal PDFs $\{q_k\}$, $k = 1, \dots, d$, that are used within the Modified Metropolis algorithm for sampling from the conditional distributions $\pi(\cdot|F_l)$. To see this, note that in contrast to the Monte Carlo samples $x_0^{(1)}, \dots, x_0^{(n)} \sim \pi(\cdot)$ which are i.i.d., the MCMC samples $x_l^{(1)}, \dots, x_l^{(n)} \sim \pi(\cdot|F_l)$ are *not independent* for $l \geq 1$, since the MMA transition rule uses $x_l^{(i)} \sim \pi(\cdot|F_l)$ to generate $x_l^{(i+1)} \sim \pi(\cdot|F_l)$. This means that although these MCMC samples can be used for statistical averaging as if they were i.i.d., the efficiency of the averaging is reduced if compared with the i.i.d. case (Doob 1953). Namely, the more correlated $x_l^{(1)}, \dots, x_l^{(n)}$ are, the slower is the convergence of the estimate $P(F_{l+1}|F_l) \approx \frac{1}{n} \sum_{i=1}^n I_{F_{l+1}}(x_l^{(i)})$, and, therefore, the less efficient it is. The correlation between samples $x_l^{(1)}, \dots, x_l^{(n)}$ is due to proposal PDFs $\{q_k\}$, which govern the generation of the next sample $x_l^{(i+1)}$ from the current one $x_l^{(i)}$. Hence, the choice of $\{q_k\}$ is very important.

It was observed in Au and Beck (2001a) that the efficiency of MMA is not sensitive to the type of the proposal PDFs (Gaussian, uniform, etc.); however, it strongly depends on their *spread* (variance). Both small and large spreads tend to increase the correlation between successive samples. Large spreads may reduce the acceptance rate in Eq. 28, increasing the number of repeated MCMC samples. Small spreads, on the contrary, may lead to a reasonably high acceptance rate, but still produce very correlated samples due to their close proximity. As a rule of thumb, the spread of q_k , $k = 1, \dots, d$, can be taken of the same order as the spread of the corresponding marginal PDF π_k (Au and Wang 2014). For example, if π is given by Eq. 18, so that all marginal PDFs are standard Gaussian, $\pi_k(x) = \phi(x)$, then all proposal PDFs can also be Gaussian with unit variance, $q_k(x/xk) = \phi(x - xk)$. This choice is found to give a balance between efficiency and robustness.

The spread of proposal PDFs can also be chosen adaptively. In Zuev et al. (2012), where the problem of optimal scaling for the Modified Metropolis algorithm was studied in more detail, the following nearly optimal scaling strategy was proposed: at each conditional level, select the spread such that the corresponding acceptance rate in Eq. 28 is between 30 % and 50 %. In general, finding the optimal spread of proposal distributions is problem specific and a highly nontrivial task not only for MMA but also for almost all MCMC algorithms.

Illustrative Examples

To illustrate Subset Simulation and to demonstrate its efficiency in estimating small probabilities of rare failure events, two examples are considered in this section. As it has been discussed in section “[Engineering Reliability Problem](#),” in reliability problems, the dimension d of the input space $\mathcal{X}$ is usually very large. In spite of this, for visualization and educational purposes, a linear reliability problem in two dimensions ($d = 2$) is first considered in section “[Subset Simulation in 2D](#).” A more realistic

high-dimensional example ($d = 10^3$) is considered in the subsequent section “[Subset Simulation in High Dimensions](#).”

Subset Simulation in 2D

Suppose that $d = 2$, i.e., the response variable y depends only on two input variables x_1 and x_2 . Consider a linear performance function

$$g(x_1, x_2) = x_1 + x_2, \quad (46)$$

where x_1 and x_2 are independent standard Gaussian, $x_i \sim N(0, 1)$, $i = 1, 2$. The failure domain F is then a half-plane defined by

$$F = \{(x_1, x_2) : x_1 + x_2 > y^*\}. \quad (47)$$

In this example, the failure probability p_F can be calculated analytically. Indeed, since $x_1 + x_2 \sim N(0, 2)$ and, therefore, $\frac{x_1 + x_2}{\sqrt{2}} \sim N(0, 1)$,

$$\begin{aligned} p_F &= \mathbb{P}(x_1 + x_2 > y^*) = \mathbb{P}\left(\frac{x_1 + x_2}{\sqrt{2}} > \frac{y^*}{\sqrt{2}}\right) \\ &= 1 - \Phi\left(\frac{y^*}{\sqrt{2}}\right), \end{aligned} \quad (48)$$

where Φ is the standard Gaussian CDF. This expression for the failure probability can be used as a check on the SS estimate. Moreover, expressing y^* in terms of p_F ,

$$y^* = \sqrt{2}\Phi^{-1}(1 - p_F), \quad (49)$$

allows to solve the inverse problem, namely, to formulate a linear reliability problem with a given value of the failure probability. Suppose that $p_F = 10^{-10}$ is the target value. Then the corresponding value of the critical threshold is $y^* \approx 9$.

Subset Simulation was used to estimate the failure probability of the rare event in Eq. 47 with $y^* = 9$. The parameters of the algorithm were chosen as follows: the level probability $p = 0.1$, the proposal PDFs $q_k(x/x_k) = \phi(x - x_k)$, and the sample size $n = 10^3$ per each level. This implementation of SS led to $L = 9$ conditional

levels, making the total number of generated samples $N = n + L(n - np) = 9.1 \times 10^3$. The obtained SS estimate is $\hat{p}_F^{SS} = 1.58 \times 10^{-10}$ which is quite close to the true value $p_F = 10^{-10}$. Note that, in this example, it is hopeless to obtain an accurate estimate by the Direct Monte Carlo method since the DMC estimate in Eq. 12 based on $N = 9.1 \times 10^3$ samples is effectively zero: the rare event F is too rare.

Figure 6 shows the samples generated by the SS method. The dashed lines represent the boundaries of intermediate failure domains F_l , $l = 1, \dots, L = 9$. The solid line is the boundary of the target failure domain F . This illustrates how Subset Simulation pushes Monte Carlo samples (red) toward the failure region.

Subset Simulation in High Dimensions

It is straightforward to generalize the low-dimensional example considered in the previous section to high dimensions. Consider a linear performance function

$$g(x) = \sum_{i=1}^d x_i, \quad (50)$$

where $x_1, \dots, x_d$ are i.i.d. standard Gaussian. The failure domain is then a half-space defined by

$$F = \left\{x : \sum_{i=1}^d x_i > y^*\right\}. \quad (51)$$

In this example, $d = 10^3$ is considered; hence the input space $\mathbf{x} = \mathbb{R}^d$ is indeed high dimensional. As before, the failure probability can be calculated analytically:

$$\begin{aligned} p_F &= \mathbb{P}\left(\sum_{i=1}^d x_i > y^*\right) = \mathbb{P}\left(\frac{\sum_{i=1}^d x_i}{\sqrt{d}} > \frac{y^*}{\sqrt{d}}\right) \\ &= 1 - \Phi\left(\frac{y^*}{\sqrt{d}}\right). \end{aligned} \quad (52)$$

This expression will be used as a check on the SS estimate.

First, consider the following range of values for the critical threshold, $y^* \in [0, 200]$.

**Subset Simulation
Method for Rare Event
Estimation:
An Introduction,**

Fig. 6 Samples generated by Subset Simulation: red samples are Monte Carlo samples generated at the 0th unconditional level, purple samples are MCMC sample generated at the 1st conditional level, etc. The dashed lines represent the boundaries of intermediate failure domains F_l , $l = 1, \dots, L = 9$. The solid line is the boundary of the target failure domain F [Example 6.1]

Figure 7 plots p_F versus y^* . The solid red curve corresponds to the sample mean of the SS estimates $\hat{p}_F^{SS}$ which is based on 100 independent runs of Subset Simulation. The two dashed red curves correspond to the sample mean $\pm$ one sample standard deviation. The SS parameters were set as follows: the level probability $p = 0.1$, the proposal PDFs $q_k(x/x_k) = \phi(x - x_k)$, and the sample size $n = 3 \times 10^3$ per each level. The solid blue curve (which almost coincides with the solid red curve) corresponds to the true values of p_F computed from Eq. 52. The dark green curves correspond to Direct Monte Carlo: the solid curve is the sample mean (based on 100 independent runs) of the DMC estimates $\hat{p}_F^{DMC}$ in Eq. 12, and the two dashed curves are the sample mean $\pm$ one sample standard deviation. The total number of samples N used in DMC equals to the average (based on 100 runs) total number of samples used in SS. Finally, the dashed light green curves show the theoretical performance of Direct Monte Carlo, namely, they correspond to the true value of p_F (52) $\pm$ one theoretical standard deviation obtained from Eq. 14. The bottom panel of Fig. 7

shows the zoomed-in region that corresponds to the values $y^* \in [100, 160]$ of the critical threshold. Note that for relatively large values of the failure probability, $p_F < 10^{-3}$, both DMC and SS produce accurate estimates of p_F . For smaller values however, $p_F < 10^{-5}$, the DMC estimate starts to degenerate, while SS still accurately estimates p_F . This can be seen especially well in the bottom panel of the figure.

The performances of Subset Simulation and Direct Monte Carlo can be also compared in terms of the coefficient of variation of the estimates $\hat{p}_F^{SS}$ and $\hat{p}_F^{DMC}$. This comparison is shown in Fig. 8. The red and dark green curves represent the sample c.o.v. for SS and DMC, respectively. The light green curve is the theoretical c.o.v. of $\hat{p}_F^{DMC}$ given by Eq. 15. When the critical threshold is relatively small $y^* < 60$, the performances of SS and DMC are comparable. As y^* gets large, the c.o.v. of $\hat{p}_F^{DMC}$ starts to grow much faster than that of $\hat{p}_F^{SS}$. In other words, SS starts to outperform DMC, and the larger the y^* , i.e., the more rare the failure event, the more significant the outperformance is.

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 7 Failure probability p_F versus the critical threshold y^* [Example 6.2]

The average total number of samples used in Subset Simulation versus the corresponding values of failure probability is shown in the top panel of Fig. 9. The staircase nature of the plot is due to the fact that every time p_F crosses the value p^k by decreasing from $p^k + \epsilon$ to $p^k - \epsilon$, an additional conditional level is required. In this example, $p = 0.1$ is used, that is why the jumps occur at $p_F = 10^{-k}$, $k = 1, 2, \dots$. The jumps are more pronounced for larger values of p_F , where the SS estimate is more accurate. For smaller values of p_F , where the SS estimate is less accurate, the jumps are more smoothed out by averaging over independent runs.

In Fig. 8, where the c.o.v.'s of SS and DMC are compared, the total numbers of samples (computational efforts) used in the two methods are the same. The natural question is then the following: by how much should the total number of samples N used in DMC be increased to achieve the same c.o.v as in SS (so that the green curve in Fig. 8 coincides with the red curve)? The answer is given in the bottom panel of Fig. 9. For example, if $p_F = 10^{-10}$, then $N = 1010$, while the computational effort of SS is less than 105 samples.

Simulation results presented in Figs. 7, 8, and 9 clearly indicate that (a) Subset Simulation

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 8 C.o.v versus the critical threshold [Example 6.2]

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 9 Total number of samples versus the failure probability [Example 6.2]

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 10 Performance of Subset Simulation for 100 independent runs. The critical threshold is $y^* = 200$, and the corresponding true value of the failure probability is $p_F = 1.27 \times 10^{-10}$ [Example 6.2]

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 11 System responses $y_1^{(1)} \geq \dots \geq y_1^{(n)}$, $n = 3 \times 10^3$, for all levels, $l = 0, \dots, L = 9$, for a fixed simulation run [Example 6.2]

Subset Simulation Method for Rare Event Estimation: An Introduction, Fig. 12 Intermediate critical thresholds $y_1^*, \dots, y_L^*$, $L = 9$, at different conditional levels in a fixed simulation run [Example 6.2]

produces a relatively accurate estimate of the failure probability and (b) Subset Simulation drastically outperforms Direct Monte Carlo when estimating probabilities of rare events.

Let us now focus on a specific value of the critical threshold, $y^* = 200$, which corresponds to a very rare failure event in Eq. 51 with probability $p_F = 1.27 \times 10^{-10}$. Figure 10 demonstrates the performance of Subset Simulation for 100 independent runs. The top panel shows the obtained SS estimate $\hat{p}_F^{SS}$ for each run. Although $\hat{p}_F^{SS}$ varies significantly (its c.o.v. is $\delta(\hat{p}_F^{SS}) = 0.74$), its mean value $\overline{\hat{p}_F^{SS}} = 1.18 \times 10^{-10}$ (dashed red line) is close to the true value of the failure probability (dashed blue line). The bottom panel shows the total number of samples used in SS in each run. It is needless to say that the DMC estimate based on $N \sim 3 \times 10^4$ samples would almost certainly be zero.

Figure 11 shows the system responses $y_l^{(1)} \geq \dots \geq y_l^{(n)}$, $n = 3 \times 10^{-10}$ for all levels, $l = 0, \dots, L = 9$, for a fixed simulation run. As expected, for the first few levels (six levels in this case), the number of failure samples $n_F(l)$, i.e., samples $x_l^{(i)}$ with $y_l^{(i)} = g(x_l^{(i)}) > y^*$, is zero. As Subset Simulation starts pushing the samples toward the failure domain, $n_F(l)$ starts increasing

with $n_F(6) = 3$, $n_F(7) = 6$, $n_F(8) = 59$, and, finally, $n_F(9) = 582$, after which the algorithm stopped since $n_F(9)/n = 0.194$ which is large than $p = 0.1$. Finally, Fig. 12 plots the intermediate (relaxed) critical thresholds $y_1^*, \dots, y_L^*$ at different levels obtained in a fixed simulation run.

MATLAB Code

This section contains the MATLAB code for the examples considered in section “[Illustrative Examples](#).” For educational purposes, the code was written as readable as possible with numerous comments. As a result of this approach, the efficiency of the code was unavoidably scarified.

Summary

In this entry, a detailed exposition of Subset Simulation, an advanced stochastic simulation method for estimation of small probabilities of rare events, is provided at an introductory level. A simple step-by-step derivation of Subset Simulation is given, and important implementation details are discussed. The method is illustrated with a few intuitive examples.

After the original paper (Au and Beck 2001a) was published, various modifications of SS were proposed: SS with splitting (Ching et al. 2005a), hybrid SS (Ching et al. 2005b), and two-stage SS (Katafygiotis and Cheung 2005), to name but

a few. It is important to highlight, however, that none of these modifications offers a drastic improvement over the original algorithm. A Bayesian analog of SS was developed in Zuev et al. (2012). For further reading on Subset Simulation and its applications, a fundamental and very accessible monograph (Au and Wang 2014) is strongly recommended, where the method is presented from the CCDF (complementary cumulative distribution function) perspective and where the error estimation is discussed in detail.

Also, it is important to emphasize that Subset Simulation provides an efficient solution for general reliability problems without using any specific information about the dynamic system other than an input–output model. This independence of a system’s inherent properties makes Subset Simulation potentially useful for applications in different areas of science and engineering.

As a final remark, it is a pleasure to thank Professor Siu-Kui Au whose comments on the first draft of the entry were very helpful; Professor James Beck, who generously shared his knowledge of and experience with Subset Simulation and made important comments on the pre-final draft of the entry; and Professor Francis Bonahon for his general support and for creating a nice atmosphere at the Department of Mathematics of the University of Southern California, where the author started this work.

Introduction

The motivations for employing substructuring in finite element modeling vary from reduction of computational time, modal synthesis using substructure modes, combining experimental and numerical modeling approaches, equitable sharing of resources in parallel computing environment, and treatment of global/local nonlinearities. The details of methods and tools accordingly also vary. An overview of related issues is presented in this entry.

Problems of computational structural mechanics of realistic systems involve inversion and eigenanalysis of large-size matrices and solutions of a large number of coupled ordinary differential equations or algebraic equations. These are computationally demanding tasks, and development of methods to reduce the computational efforts remains relevant notwithstanding advances in computational hardware. This is particularly true in problems of uncertainty quantification, reliability analysis, structural optimization, modeling of actively controlled systems, local/global sensitivity analysis, and problems of damage detection. Substructuring methods primarily serve to achieve reduction in computational effort in these types of problems. Here, the given structure is divided into a set of subsystems, each component is modeled separately, and the behavior of the built-up structure is inferred by synthesis of component behavior. The decomposition and synthesis steps are designed to achieve reduction in sizes of matrices to be handled and (or) reduction in time required to integrate equations of motion. In the context of computing using distributed memory multiprocessor computers, substructuring is used to distribute workload equally among all the processors. On a different note, the idea of substructuring is also attractive in experimental studies. Here again, the structure to be studied is divided into a set of subsystems, and one, more, or all of the subsystems can be studied experimentally in their uncoupled states, and a model for behavior of built-up structure is synthesized therefrom. In such studies, where both

computational and experimental studies are combined, the substructuring methods are termed as hybrid simulation methods. Furthermore, in treatment of transient dynamical problems, if the coupling between numerical substructures and experimental substructures is achieved in real time, then one gets real-time substructuring methods. Apart from computational advantages, the substructuring methods afford other benefits too: (a) structures made up of technologically diverse components having notably different dynamical characteristics can be separately studied and developed by different teams, (b) better insights can be gained on global behavior of built-up structures in terms of local behavior of components, and (c) a combination of computational and experimental tools can be brought to bear on study of large complex systems. The literature on substructuring in structural mechanics is vast, and comprehensive overviews can be found in the works of Hurty (1965), Craig (1995), Maia and de Silva (1997), Ewins (2000), Williams and Blakeborough (2001), de Klerk et al. (2008), Bursi and Wagg (2008), and Saouma and Sivaselvan (2008). This entry details a few select set of tools for substructuring and briefly touches upon a few other issues.

Problem Statement

The motivations for substructuring in finite element modeling vary and so do the details of the methods and criteria for assessing their success. The following is a list of questions which may be conceived in this context:

- (a) Given modal characteristics (natural frequencies, mode shapes, damping ratios, and participation factors), set of frequency response functions, or structural matrices and forcing vectors, for a set of N_S substructures in their uncoupled state, how to synthesize the dynamical characteristics and response of the built-up system? How to deal with incompleteness in spatial, modal, and frequency domains? How to best configure the substructures?
- (b) How to deal with presence of nonlinearities in one or more of the subsystems?
- (c) Given an N degree of freedom dynamical system, how to partition the degrees of freedom into N_S subsets so that efficient schemes can be evolved to integrate the equation of motion of the built-up system?
- (d) If some of the subsystems (linear or nonlinear) are studied experimentally and the remaining numerically, how to interface the subsystem responses? How to carry out this in real time for transient dynamic response analysis?
- (e) Given the response of a built-up system, how to infer behavior of component subsystems? (This is known as the problem of inverse substructuring.)
- (f) Given a computer with multiple processors (generally distributed memory), how to solve the governing equation by decomposing the domain followed by distributing the workload among the processors so that the execution cost reduces significantly? How to best maximize the usage of computational resources and use simultaneously all available processors equally well?
- (g) How to divide a large structure into N_S subsets without a corresponding increase in the number of interface coordinates involved in the component mode synthesis step?

In the same vein, one could pose several other questions pertaining to uncertainty propagation, system identification, vibration energy flow modeling, and treatment of multiphysics problems (such as fluid–structure interactions, soil–structure interactions, primary–secondary structure interactions, etc.). The discussion in the following sections will focus on a few of these issues.

Fixed-Interface Modal Synthesis

The method is illustrated by considering the system shown in Fig. 1a (Maia and de Silva 1997). The given system is divided into two substructures labeled as A and B, and the two

Substructuring Methods for Finite Element Analysis, Fig. 1

(a) Built-up system with two substructures; (b) two substructures in uncoupled states

substructures in their uncoupled state are considered (Fig. 1b). The substructure degrees of freedom (dofs) are partitioned as shown into interior dofs (subscript i) and coupling dofs (subscript c). The equation for substructure A is written in the partitioned form as

$$\begin{bmatrix} M_{ii}^A & M_{ic}^A \\ M_{ci}^A & M_{cc}^A \end{bmatrix} \begin{Bmatrix} \ddot{u}_i^A \\ \ddot{u}_c^A \end{Bmatrix} + \begin{bmatrix} K_{ii}^A & K_{ic}^A \\ K_{ci}^A & K_{cc}^A \end{bmatrix} \begin{Bmatrix} u_i^A \\ u_c^A \end{Bmatrix} = \begin{Bmatrix} 0_i^A \\ f_c^A \end{Bmatrix} \quad (1)$$

Here $f_c^A(t)$ is the vector of interaction forces between A and B. Two separate analyses on this system are performed: first by assuming $u_c^A(t) = 0$ (fixed interface) and the second by taking $u_c^A(t) \neq 0$. In the first case, the governing equation is obtained as $M_{ii}^A \ddot{u}_i^A + K_{ii}^A u_i^A = 0_i^A$, and this equation is analyzed to determine the natural frequencies ω_r^A and modal vectors $\phi_r^A, r = 1, 2, \dots, n_i^A$. The system response is

further represented using a k -term modal expansion as $u_{i(\text{Fix})}^A(t) = [\Phi_{ik_A}^A] \{p_{k_A}^A(t)\}$; the subscript k_A is used here to denote that the expansion has been truncated at k_A modes. In the second analysis, it is assumed that the interior and coupling dofs are related through conditions valid only under static conditions. This leads to the solution $u_{i(\text{Free})}^A(t) = -[K_{ii}^A]^{-1} K_{ic}^A u_c^A(t)$. The solution vector in Eq. 1 is now represented as

$$\begin{Bmatrix} u_i^A \\ u_c^A \end{Bmatrix} = \begin{bmatrix} \Phi_{ik}^A & -[K_{ii}^A]^{-1} K_{ic}^A \\ 0 & I \end{bmatrix} \begin{Bmatrix} p_{k_A}^A(t) \\ u_c^A(t) \end{Bmatrix} = \Psi_k^A \begin{Bmatrix} p_{k_A}^A(t) \\ u_c^A(t) \end{Bmatrix} \quad (2)$$

Here I is the identity matrix. Substituting this in Eq. 1, premultiplying by $[\Psi_{k_A}^A]^T$, and simplifying, one gets equation of the form

$$\begin{aligned}
& \begin{bmatrix} \tilde{M}_{kk}^A & \tilde{M}_{kc}^A \\ \tilde{M}_{ck}^A & \tilde{M}_{cc}^A \end{bmatrix} \begin{Bmatrix} \ddot{p}_{k_A}^A(t) \\ \ddot{u}_c^A(t) \end{Bmatrix} + \begin{bmatrix} \tilde{K}_{kk}^A & \tilde{K}_{kc}^A \\ \tilde{K}_{ck}^A & \tilde{K}_{cc}^A \end{bmatrix} \begin{Bmatrix} p_{k_A}^A(t) \\ u_c^A(t) \end{Bmatrix} = [\Psi_{k_A}^A]^t \begin{Bmatrix} 0_i^A \\ f_c^A \end{Bmatrix} \\
& \text{with} \\
& \begin{bmatrix} \tilde{M}_{kk}^A & \tilde{M}_{kc}^A \\ \tilde{M}_{ck}^A & \tilde{M}_{cc}^A \end{bmatrix} = \begin{bmatrix} I & (\Phi_{ik}^A)^t (M_{ii}^A \alpha^A + M_{ic}^A) \\ (\alpha^A)^t M_{ii}^A \Phi_{ik}^A & (\alpha^A)^t (M_{ii}^A \alpha^A + M_{ic}^A) + (M_{ci}^A \alpha^A + M_{cc}^A) \end{bmatrix} \\
& \begin{bmatrix} \tilde{K}_{kk}^A & \tilde{K}_{kc}^A \\ \tilde{K}_{ck}^A & \tilde{K}_{cc}^A \end{bmatrix} = \begin{bmatrix} \Lambda^A & (\Phi_{ik}^A)^t (K_{ii}^A \alpha^A + K_{ic}^A) \\ (\alpha^A)^t K_{ii}^A \Phi_{ik}^A & (\alpha^A)^t (K_{ii}^A \alpha^A + K_{ic}^A) + (K_{ci}^A \alpha^A + K_{cc}^A) \end{bmatrix} \\
& \Lambda^A = \text{Diag}[(\omega_r^A)^2]; \alpha^A = -[K_{ii}^A]^{-1} K_{ic}^A
\end{aligned} \tag{3}$$

A similar analysis on substructure B leads to the equation

$$\begin{aligned}
& \begin{bmatrix} \tilde{M}_{kk}^B & \tilde{M}_{kc}^B \\ \tilde{M}_{ck}^B & \tilde{M}_{cc}^B \end{bmatrix} \begin{Bmatrix} \ddot{p}_{k_B}^B(t) \\ \ddot{u}_c^B(t) \end{Bmatrix} + \begin{bmatrix} \tilde{K}_{kk}^B & \tilde{K}_{kc}^B \\ \tilde{K}_{ck}^B & \tilde{K}_{cc}^B \end{bmatrix} \begin{Bmatrix} p_{k_B}^B(t) \\ u_c^B(t) \end{Bmatrix} \\
& = [\Psi_{k_B}^B]^t \begin{Bmatrix} 0_i^B \\ f_c^B \end{Bmatrix}
\end{aligned} \tag{4}$$

Returning to the built-up system in Fig. 1a and by imposing the conditions $u_c^A = u_c^B$ and $f_c^A + f_c^B = 0$ at the interfaces, one gets the governing equations for the built-up system as

$$\begin{aligned}
& \begin{bmatrix} I_{kk}^A & 0 & \tilde{M}_{kc}^A \\ 0 & I_{kk}^B & \tilde{M}_{kc}^B \\ \tilde{M}_{ck}^A & \tilde{M}_{ck}^B & \tilde{M}_{cc}^A + \tilde{M}_{cc}^B \end{bmatrix} \begin{Bmatrix} \ddot{p}_k^A(t) \\ \ddot{p}_k^B(t) \\ \ddot{u}_c(t) \end{Bmatrix} \\
& + \begin{bmatrix} (\omega_r^A)^2 & 0 & 0 \\ 0 & (\omega_r^B)^2 & 0 \\ 0 & 0 & \tilde{K}_{cc}^A + \tilde{K}_{cc}^B \end{bmatrix} \begin{Bmatrix} p_k^A(t) \\ p_k^B(t) \\ u_c(t) \end{Bmatrix} = 0
\end{aligned} \tag{5}$$

The dynamic characteristics for the built-up system can now be determined using this model. The total number of dofs here is equal to the total number of substructure modes included in representing the fixed-interface responses for

systems A and B plus the number of interface dofs. This number is expected to be substantially less than the dof that one would get if the built-up system were to be analyzed without substructuring. This method of substructuring is also known as component mode synthesis and is a widely studied method in the existing literature. Various generalizations to include more than two substructures, presence of damping, substructure coupling through flexible elements, and response to external excitations have been explored.

Free-Interface Modal Synthesis

The fixed-interface method discussed in the preceding section requires the knowledge of subsystem structural matrices, and for this reason, they are not suited if one or more of the subsystems are studied experimentally (Maia and de Silva 1997). Also, creating fixed interfaces for substructures in experimental work is generally not feasible. An alternative formulation to overcome these difficulties is as follows. Consider the substructure Eq. 1 and determine the natural frequencies and mode shapes by solving the eigenvalue problem $K^A \phi^A = \omega_A^2 M^A \phi^A$. This leads to the $N_A \times N_A$ matrices: $\Lambda^A = \text{diag}[\omega_{Ai}^2]$ and Φ^A such that $[\Phi^A]^t M^A \Phi^A = I$ and $[\Phi^A]^t K^A \Phi^A = \Lambda^A$. Now u^A is represented by a k_A term expansion $u^A(t) = \Phi_{k_A}^A p_{k_A}(t)$. The modal

matrix is further partitioned as $\Phi_{k_A}^A = [\Phi_{k_A i}^A \quad \Phi_{k_A c}^A]^t$, and using Eq. 1, one gets

$$I\ddot{p}_{k_A}(t) + \Lambda_{k_A}^A p_{k_A}(t) = [\Phi_{k_A c}^A]^t f_c^A(t) \quad (6)$$

A similar equation can also be obtained for subsystem B, and by combining these equations, one gets

$$\begin{aligned} [I] \begin{Bmatrix} \ddot{p}_{k_A}(t) \\ \ddot{p}_{k_B}(t) \end{Bmatrix} + \begin{bmatrix} \Lambda_{k_A}^A & 0 \\ 0 & \Lambda_{k_B}^B \end{bmatrix} \begin{Bmatrix} p_{k_A}(t) \\ p_{k_B}(t) \end{Bmatrix} \\ = \begin{bmatrix} [\Phi_{k_A c}^A]^t & 0 \\ 0 & [\Phi_{k_B c}^B]^t \end{bmatrix} \begin{Bmatrix} f_c^A(t) \\ f_c^B(t) \end{Bmatrix} \end{aligned} \quad (7)$$

The condition $u_c^A(t) = u_c^B(t)$ at the interface is expressed as $\Phi_{k_A c}^A p_{k_A}(t) = \Phi_{k_B c}^B p_{k_B}(t)$. This equation is rewritten as

$$\begin{aligned} [\Phi_{k_A c}^A \quad -\Phi_{k_B c}^B] \begin{Bmatrix} p_{k_A}(t) \\ p_{k_B}(t) \end{Bmatrix} = 0 \Rightarrow \\ Sp = 0 \text{ with } S = [\Phi_{k_A c}^A \quad -\Phi_{k_B c}^B] \end{aligned} \quad (8)$$

Now, the matrix S is partitioned as $S = [S_d \quad S_i]$ where S_d is a nonsingular square matrix and remaining part is S_i . This leads to

$$\begin{aligned} [S_d \quad S_i] \begin{Bmatrix} p_d \\ p_i \end{Bmatrix} = 0 \Rightarrow p_d = -S_d^{-1} S_i p_i \text{ and} \\ \begin{Bmatrix} p_{k_A}(t) \\ p_{k_B}(t) \end{Bmatrix} = \begin{Bmatrix} p_d \\ p_i \end{Bmatrix} = \begin{bmatrix} -S_d^{-1} S_i \\ I \end{bmatrix} p_i = \Psi \{p_i\} \end{aligned} \quad (9)$$

Furthermore, by noting that $f_c^A(t) + f_c^B(t) = 0$, one gets

$$I \begin{Bmatrix} \ddot{p}_{k_A}(t) \\ \ddot{p}_{k_B}(t) \end{Bmatrix} + \begin{bmatrix} \Lambda_{k_A}^A & 0 \\ 0 & \Lambda_{k_B}^B \end{bmatrix} \begin{Bmatrix} p_{k_A}(t) \\ p_{k_B}(t) \end{Bmatrix} = 0 \quad (10)$$

By using Eq. 9 in the above equation and premultiplying by Ψ^t , one gets

$$M\ddot{q} + Kq = 0 \text{ with } M = \Psi^t \Psi; K = \Psi^t \begin{bmatrix} \Lambda_{k_A}^A & 0 \\ 0 & \Lambda_{k_B}^B \end{bmatrix} \Psi \quad (11)$$

This equation can now be analyzed to deduce the built-up system natural frequencies and mode shapes. It is emphasized that the mass and stiffness matrices for the built-up system here are constructed in terms of the natural frequencies, and mode shapes of the subsystem in the uncoupled states and knowledge of substructure structural matrices are not needed in this formulation. This enables the introduction of experimentally studied substructures to be embedded into the modal synthesis of the built-up system.

Multilevel Substructuring

Consider an N -dof system being split into N_S substructures, such that dof of the largest substructure n satisfies the requirement $n \ll N$. If the value of N is large, the value of N_S also needs to be large in order to satisfy this requirement. This results in a large number of interface dofs appearing in the model thereby increasing the size of the synthesized system equation and consequent demands on computational efforts. The multilevel substructuring method addresses this issue by allowing for small substructures to be used without having to include a large number of interface dofs in the modal synthesis step.

The first step in multilevel substructuring is splitting the structure into multiple substructures, which form the first level of substructures. Then, each of these substructures is subdivided into multiple substructures, which form the second level. This process is continued until the substructures are as small as necessary. The substructures follow a tree topology, with the system to be analyzed at the top. At each level, each substructure has one parent one level above it and multiple-child substructures one level below. The equation of motion for each substructure (up to the penultimate level) can be

synthesized using its child substructures using component mode synthesis, and the interface elements belonging to those substructures alone appear in the synthesized system equation. Modal reduction is achieved in each of the substructures, and the interface dofs are retained. After the equations of motion of all substructures at a level are synthesized, the algorithm proceeds to the level above it. A fraction of the interface dofs at any level appears as interface dofs at the level above it, the rest turning into interior dofs, which can now be eliminated using modal reduction. Therefore, for the structure, the equation of motion can have, in the extreme case, only the interface dofs at the first level. This means that the method can be used to achieve a high degree of modal reduction. Additionally, at each level, the substructures can be analyzed in parallel, as in the case of single-level substructuring. At the higher levels, the number of substructures, and parallelizability, increases (see section “[Domain Decomposition Techniques and Their Parallel Implementation](#)” for issues related to parallelization).

The multilevel substructuring method has been used for linear and nonlinear structures with a large number of dofs (Papalukopoulos and Natsiavas 2007). Bennighof and Kaplan (1998) describe an adaptive multilevel substructuring procedure, where the contribution of each mode to the strain energy is used to decide whether or not to include the mode in the substructure analysis. This allows for a control on error due to modal reduction.

Nonlinear Substructures

Treatment of structural nonlinearities within the framework of ideas presented in the preceding sections offers several conceptual challenges. For problems involving linear substructures coupled through nonlinear elements, the fixed- and free-interface methods can be extended in a relatively easy manner. However, for problems involving globally distributed nonlinearities, the extensions

are not straightforward. An approach that employs fixed-interface component mode synthesis based on the idea of nonlinear normal modes has been developed by Apiwattanalungarn et al. (2005). In a conservative structure vibrating in its nonlinear normal mode, the motion would be periodic and all points on the structure reach their respective extrema simultaneously and pass through zeros simultaneously (see Kerschen et al. 2009 for a detailed introduction). A few details of this approach are presented here.

Consider a nonlinear system divided into two nonlinear substructures A and B , as shown in Fig. 1a. The equation for substructure A is written in partitioned form as

$$\begin{bmatrix} M_{ii}^A & M_{ic}^A \\ M_{ci}^A & M_{cc}^A \end{bmatrix} \begin{Bmatrix} \ddot{u}_i^A \\ \ddot{u}_c^A \end{Bmatrix} + \begin{bmatrix} K_{ii}^A & K_{ic}^A \\ K_{ci}^A & K_{cc}^A \end{bmatrix} \begin{Bmatrix} u_i^A \\ u_c^A \end{Bmatrix} + \begin{Bmatrix} G_i^A(u_i^A, u_c^A) \\ G_c^A(u_i^A, u_c^A) \end{Bmatrix} = \begin{Bmatrix} 0_i^A \\ f_c^A \end{Bmatrix} \quad (12)$$

Here, $G_i^A(u_i^A, u_c^A)$ and $G_c^A(u_i^A, u_c^A)$ are the nonlinear forces associated with the interior and coupling dofs, respectively, and $f_c^A(t)$ is the vector of interaction forces between A and B . The procedure followed here has much in common with the fixed-interface method described earlier for linear substructures (section “[Fixed-Interface Modal Synthesis](#)”). In order to relate u_c^A to u_i^A , two separate analyses are done. First, fixed-interface linear modes are computed for A by assuming $u_c^A = 0$ and ignoring the nonlinear terms in Eq. 11. The governing equation is obtained as $M_{ii}^A \ddot{u}_{i(Fix)}^A + K_{ii}^A u_{i(Fix)}^A = 0$, which has natural frequencies ω_r^A and modal vectors $\phi_k^A, r = 1, 2, \dots, n_i^A$. The system response represented by a modal expansion (truncated to k_A modes) is $u_{i(Fix)}^A = [\Phi_{i_{k_A}}^A] \{p_{k_A}^A(t)\}$. Next, a relationship is obtained between u_c^A and u_i^A under static conditions, again ignoring nonlinear terms in Eq. 11. This leads to the relation $u_{i(Free)}^A(t) = -[K_{ii}^A]^{-1} K_{ic}^A u_c^A(t)$. The solution vector in Eq. 11 is represented as

$$\begin{Bmatrix} u_i^A \\ u_c^A \end{Bmatrix} = \begin{bmatrix} \Phi_{ik_A}^A & -[K_{ii}^A]^{-1} K_{ic}^A \\ 0 & I \end{bmatrix} \begin{Bmatrix} p_{k_A}^A(t) \\ u_c^A(t) \end{Bmatrix} \quad (13)$$

Substituting Eq. 12 in Eq. 11 leads to

$$\begin{bmatrix} I & \tilde{M}_{ic}^A \\ \tilde{M}_{ci}^A & \tilde{M}_{cc}^A \end{bmatrix} \begin{Bmatrix} \ddot{p}_{k_A}^A \\ \ddot{u}_c^A \end{Bmatrix} + \begin{bmatrix} \Lambda^A & 0 \\ \tilde{K}_{ci}^A & \tilde{K}_{cc}^A \end{bmatrix} \begin{Bmatrix} p_{k_A}^A \\ u_c^A \end{Bmatrix} + \begin{Bmatrix} \tilde{G}_i^A(p_{k_A}^A, u_c^A) \\ \tilde{G}_c^A(p_{k_A}^A, u_c^A) \end{Bmatrix} = \begin{Bmatrix} 0_i^A \\ f_c^A \end{Bmatrix} \quad (14)$$

Here, $\tilde{M}_{ic}^A$, Λ^A , $\tilde{M}_{ci}^A$, $\tilde{M}_{cc}^A$, $\tilde{K}_{ci}^A$, and $\tilde{K}_{cc}^A$ are given in Eq. 3, $\tilde{G}_i^A(p_{k_A}^A, u_c^A) = (\Phi_{ik_A}^A)^T G_i^A(\Phi_{ik_A}^A p_{k_A}^A, u_c^A)$, and $\tilde{G}_c^A(p_{k_A}^A, u_c^A) = G_c^A(\Phi_{ik_A}^A p_{k_A}^A, u_c^A)$.

In Eq. 13, setting $u_c^A = 0$, one gets $\ddot{p}_{k_A}^A + \Lambda^A p_{k_A}^A + \tilde{G}_i^A(p_{k_A}^A, u_c^A) = 0_i^A$. Now, a nonlinear normal mode is constructed for this equation. The M^{th} coordinate of $p_{k_A}^A$, $p_{k_A,M}^A$, is taken as the master node, and all other dofs are related to it by the following constraints

$$p_{k_A,i}^A = X_i(p_{k_A,M}^A, p_{k_A,M}^A), i = 1, 2, \dots, k_A, i \neq M \quad (15)$$

$$\dot{p}_{k_A,i}^A = Y_i(p_{k_A,M}^A, \dot{p}_{k_A,M}^A), i = 1, 2, \dots, k_A, i \neq M \quad (16)$$

These constraint relations are used to reduce A to a $N_C + 1$ degree of freedom system with the equation of motion

$$\begin{bmatrix} \hat{M}_{ii}^A & \hat{M}_{ic}^A \\ \hat{M}_{ci}^A & \hat{M}_{cc}^A \end{bmatrix} \begin{Bmatrix} \ddot{p}_{k_A,M}^A \\ \ddot{u}_c^A \end{Bmatrix} + \begin{bmatrix} \hat{K}_{ii}^A & \hat{K}_{ic}^A \\ \hat{K}_{ci}^A & \hat{K}_{cc}^A \end{bmatrix} \begin{Bmatrix} p_{k_A,M}^A \\ u_c^A \end{Bmatrix} + \begin{Bmatrix} \hat{G}_i^A(p_{k_A,M}^A, \dot{p}_{k_A,M}^A, u_c^A) \\ \hat{G}_c^A(p_{k_A,M}^A, \dot{p}_{k_A,M}^A, u_c^A) \end{Bmatrix} = \begin{Bmatrix} 0 \\ f_c^A \end{Bmatrix} \quad (17)$$

Here, the terms $\hat{M}_{ii}^A$, $\hat{M}_{ic}^A$, $\hat{M}_{ci}^A$, $\hat{M}_{cc}^A$, $\hat{K}_{ii}^A$, $\hat{K}_{ic}^A$, $\hat{K}_{ci}^A$, $\hat{K}_{cc}^A$, $\hat{G}_i^A(p_{k_A,M}^A, \dot{p}_{k_A,M}^A, u_c^A)$, and $\hat{G}_c^A(p_{k_A,M}^A, \dot{p}_{k_A,M}^A, u_c^A)$ are obtained by substituting the constraints Eqs. 14 and 15 in Eq. 13. A similar procedure is followed for substructure B , and the equation of motion is obtained as

$$\begin{bmatrix} \hat{M}_{ii}^B & \hat{M}_{ic}^B \\ \hat{M}_{ci}^B & \hat{M}_{cc}^B \end{bmatrix} \begin{Bmatrix} \ddot{p}_{k_B,M}^B \\ \ddot{u}_c^B \end{Bmatrix} + \begin{bmatrix} \hat{K}_{ii}^B & \hat{K}_{ic}^B \\ \hat{K}_{ci}^B & \hat{K}_{cc}^B \end{bmatrix} \begin{Bmatrix} p_{k_B,M}^B \\ u_c^B \end{Bmatrix} + \begin{Bmatrix} \hat{G}_i^B(p_{k_B,M}^B, \dot{p}_{k_B,M}^B, u_c^B) \\ \hat{G}_c^B(p_{k_B,M}^B, \dot{p}_{k_B,M}^B, u_c^B) \end{Bmatrix} = \begin{Bmatrix} 0 \\ f_c^B \end{Bmatrix} \quad (18)$$

Applying the constraints $u_c^A = u_c^B = u_c$ and $f_c^A + f_c^B = 0$, Eqs. 16 and 17 combine to form the following equation of motion for the built-up system:

$$\begin{bmatrix} \hat{M}_{ii}^A & 0 & \hat{M}_{ic}^A \\ 0 & \hat{M}_{ii}^B & \hat{M}_{ic}^B \\ \hat{M}_{ci}^A & \hat{M}_{ci}^B & \hat{M}_{cc}^A + \hat{M}_{cc}^B \end{bmatrix} \begin{Bmatrix} \ddot{p}_{k_A,M}^A(t) \\ \ddot{p}_{k_B,M}^B(t) \\ \ddot{u}_c(t) \end{Bmatrix} + \begin{bmatrix} \hat{K}_{ii}^A & 0 & \hat{K}_{ic}^A \\ 0 & \hat{K}_{ii}^B & \hat{K}_{ic}^B \\ \hat{K}_{ci}^A & \hat{K}_{ci}^B & \hat{K}_{cc}^A + \hat{K}_{cc}^B \end{bmatrix} \begin{Bmatrix} p_{k_A,M}^A(t) \\ p_{k_B,M}^B(t) \\ u_c(t) \end{Bmatrix} + \begin{Bmatrix} \hat{G}_i^A(p_{k_A,M}^A, \dot{p}_{k_A,M}^A, u_c^A) \\ \hat{G}_i^B(p_{k_B,M}^B, \dot{p}_{k_B,M}^B, u_c^B) \\ \hat{G}_c^A(p_{k_A,M}^A, \dot{p}_{k_A,M}^A, u_c^A) + \hat{G}_c^B(p_{k_B,M}^B, \dot{p}_{k_B,M}^B, u_c^B) \end{Bmatrix} = 0 \quad (19)$$

The reduced system has $N_C + 2$ dofs. This procedure can be extended straightforwardly to more than two substructures.

Mesh Partitioning and Implicit–Explicit Schemes

Here time integration of equations of motion of nonlinear dynamical systems is considered. Methods to obtain numerical solutions can be either explicit or implicit in nature. In the context of linear dynamical systems, implicit methods of integration are preferred since they are unconditionally stable and permit the analyst to choose step size based on engineering judgment. On the other hand, explicit schemes for such systems are conditionally stable, and the step size is often controlled by the stability requirements. For nonlinear dynamical systems, implicit methods typically involve solution of nonlinear algebraic/transcendental equations at every time step. On the other hand, explicit schemes are non-iterative, and the computational effort needed at each time step is less than that for implicit schemes. Given this, in structural dynamic problems involving spatially localized nonlinearities, it becomes advantageous to bifurcate the degrees of freedom into those associated with linear and those with nonlinear parts of the system. Such a strategy has earlier been proposed by Hughes et al. (1979) and in more recent years has gained attention in the context of substructuring involving hybrid simulation (see section “Hybrid Simulations”).

The essence of this strategy can be explained by considering an N degree of freedom dynamical system governed by the equation $M\ddot{U} + F(U, \dot{U}) = G(t)$, $U(0) = U_0$, $\dot{U}(0) = \dot{U}_0$. The elements are bifurcated into an implicit and an explicit set, and the corresponding internal force vectors are $F^I(U, \dot{U})$ and $F^E(U, \dot{U})$, respectively. The equation of motion becomes $M\ddot{U} + F^I(U, \dot{U}) + F^E(U, \dot{U}) = G(t)$, $U(0) = U_0$, $\dot{U}(0) = \dot{U}_0$. This equation is solved using a predictor–corrector scheme. The prediction step provides the initial estimates of the values of

displacement and velocity vectors at the $(n + 1)^{th}$ time step, $n = 1, 2, \dots$, as $\tilde{U}_{n+1}$ and $\dot{\tilde{U}}_{n+1}$, respectively. An implicit scheme is then used for the corrector step to obtain U_{n+1} and $\dot{U}_{n+1}$. The value of the explicit force vector used in the corrector step is $F^E(\tilde{U}_{n+1}, \dot{\tilde{U}}_{n+1})$. If the implicit partition of the mesh is linear, $F^I(U, \dot{U})$ is of the form $C^I\dot{U} + K^IU$, where C^I and K^I are the implicit damping and mass matrices. The equation in the corrector step, $M\ddot{U}_{n+1} + C^I\dot{U}_{n+1} + K^IU_{n+1} = G(t_{n+1}) - F^E(\tilde{U}_{n+1}, \dot{\tilde{U}}_{n+1})$, is also linear. Hence, a non-iterative implicit scheme can be used to obtain U_{n+1} and $\dot{U}_{n+1}$. In this procedure, although mesh partitioning is done, the implicit and explicit dofs are evaluated together. On the other hand, in problems of fluid–structure interaction, although the flow equation and the equation of motion of the structure are coupled, they are usually solved separately. In the strong coupling method (Ahn and Kallinderis 2006) based on predictor–corrector steps, an explicit scheme is used for the predictor step. The flow equation is then solved in order to provide the input for solving the equation of the structure. The corrector step involves solving the structure and flow equations in that sequence iteratively. Here, the time step used in the equations for the fluid and the structure has to be equal. If the structure is linear, implicit schemes can be used with a large time step. Both implicit and explicit schemes can be applied in solving the flow equations, with implicit schemes allowing for larger time steps, but requiring an iterative solution.

Domain Decomposition Techniques and Their Parallel Implementation

Present-day computer processors possess multicore architecture, and the usual sequential solvers are unable to use all the cores simultaneously. Therefore, the resource remains underutilized. Furthermore, with the advent of computer technology, parallel computers (often referred to as clusters) can be easily and economically built from off-the-shelf components.

Therefore, to take advantage of these inexpensive technologies, the solvers need to be parallelized.

As the name domain decomposition (DD) suggests, in these techniques the computational domain is decomposed into a set of subdomains, and a divide-and-conquer strategy is developed that permits using multiple processors more efficiently than the traditional single-domain approaches. For parallelizing a time-dependent (deterministic) problem, two options can be explored: (i) parallelizing in space and (ii) parallelizing in time. While there have been attempts on parallelizing in time for a few applications, it is generally very difficult due to the inherent sequential nature in the temporal domain. Whereas the spatial dependence is not sequential, although the subdomains are coupled. Therefore, to achieve parallelization in space, in a typical (iterative) DD method, (a) the spatial domain is divided into a number of subdomains, (b) each of the processors independently performs the computation related to one or more subdomains, and (c) at the end of each iteration, the processors communicate relevant information among them. As the iteration grows, the method converges toward achieving the global (considering the entire spatial domain) equilibrium and compatibility. A few dominant methods are component mode synthesis (CMS), finite element tearing and interconnecting (FETI) and its variants, and Schur complement (this is a direct method). One major use of DD methods is development of preconditioners for linear systems. When the condition number of the coefficient matrix A in a linear system $Ax = b$ becomes high, iterative techniques such as conjugate gradient becomes very slow. In this situation, a preconditioner matrix P is often used where PA has a low condition number, and finally $PAx = Pb$ is solved. DD is often used in developing P (Ghosh et al. 2009).

FETI methods are iterative methods where the subdomains communicate with each other through a set of Lagrange multipliers defined at subdomain boundaries. In a static problem, the equilibrium of each subdomain is satisfied at each iteration whereas the continuity of the displacement field is achieved at convergence.

The estimates from a DD method must be in good agreement with the exact result, that is, the results from a direct solver using a single domain. The success of a DD method is measured by its convergence rate toward the exact solution and by its scalability. In terms of scalability of an iterative method when the iteration count does not depend strongly on the problem size, then it is called numerical scalability. On the other hand, when an m -times bigger problem can be solved using m -times bigger computer (in terms of number of processors) in similar time, it is called parallel scalability. The efficiency of a DD method is often measured in terms of the ratio H/h where H denotes a characteristic size of a subdomain and h denotes element size.

A linear structural dynamics problem can be solved in two ways, either using a modal reduction or using a direct integration. For the modal approach, the domain decomposition can be used in the eigenvalue computation level, as described earlier in this entry (section “[Fixed-Interface Modal Synthesis](#)”). For direct integration, two separate approaches can be taken. First, casting the vibration problem in a single domain and adopting an implicit time integration scheme and then using the domain decomposition in the linear system solving level. To this end, the methods developed for solving elliptic equations can be directly used. For instance, when the Newmark-beta time integration is used, the system of linear algebraic equations can be solved using DD at every time step. The second option in the direct integration is to cast the structural dynamics problem in multiple domains itself and develop a time integrator. For this purpose, the compatibility and equilibrium among the subdomains must be ensured for all time instants or a selected set of time instants when different time steps are considered at different subdomains. In a FETI-type scheme, a Lagrange multiplier is used. Both these approaches are outlined below.

To explain the first option, consider a linear static problem (which essentially should be viewed as a system of linear algebraic equations)

$$Ku = f \quad (20)$$

Now let the computational domain D be divided into N_s subdomains with the s -th subdomain denoted as $D^{(s)}$ and the boundary as $\partial D^{(s)}$. In the original formulation of FETI, these domains are completely unconnected; however, in a later development (FETI-DP), the corners of the subdomains are assumed to be connected. Following the FETI-DP formulation (Farhat et al. 2000), within the subdomain $D^{(s)}$, partition the displacement field $u^{(s)}$ as

$$u^{(s)} = \begin{bmatrix} u_{int}^{(s)} \\ u_{b_r}^{(s)} \\ u_{b_c}^{(s)} \end{bmatrix} = \begin{bmatrix} u_r^{(s)} \\ u_{b_c}^{(s)} \end{bmatrix} \text{ with } u_r^{(s)} = \begin{bmatrix} u_{int}^{(s)} \\ u_{b_r}^{(s)} \end{bmatrix} \quad (21)$$

where the subscript *int* means interior, b_c denotes the nodes at the corner, b_s denotes the nodes at the boundary but not on the corner, and r means the collection of *int* and b_r , that is, all the nodes except the corners – often referred to as *residual*. Accordingly, let the stiffness matrix and forcing vector be partitioned as

$$K^{(s)} = \begin{bmatrix} K_{rr}^{(s)} & K_{rc}^{(s)} \\ K_{cr}^{(s)} & K_{cc}^{(s)} \end{bmatrix}, f^{(s)} = \begin{bmatrix} f_r^{(s)} \\ f_{b_c}^{(s)} \end{bmatrix} \quad (22)$$

Let λ denote a vector-valued Lagrange multiplier defined globally over the subdomain interface dofs except the corner points, that is, on the dof denoted by b_r . Following these notations, the equilibrium for the interior and boundary (except the corner nodes) is written as

$$K_{rr}^{(s)} u_r^{(s)} + K_{rc}^{(s)} B_c^{(s)} u_c + B_r^{(s)T} \lambda = f_r^{(s)}; s = 1, 2, \dots, N_s \quad (23)$$

and the equilibrium for the corner dofs is written as

$$\begin{aligned} \sum_{s=1}^{N_s} B_c^{(s)T} K_{rc}^{(s)T} u_r^{(s)} + \sum_{s=1}^{N_s} B_c^{(s)T} K_{cc}^{(s)T} B_c^{(s)} u_c \\ = \sum_{s=1}^{N_s} B_c^{(s)T} f_{b_c}^{(s)} \end{aligned} \quad (24)$$

where $B_c^{(s)}$ denotes a Boolean matrix mapping the global vector u_c containing all corner DOF to $u_{b_c}^{(s)}$ and $B_r^{(s)}$ denotes another Boolean matrix mapping the residual dof to $u_{b_r}^{(s)}$. The Boolean matrices are (usually rectangular) matrices with the entries as zeros or one. They are used to describe the binary relationship among the elements of two vectors. For instance, consider the Boolean relationship $B_c^{(s)} u_c = u_{b_c}^{(s)}$

where the Boolean matrix $B_c^{(s)}$ operates on the vector u_c enlisting all the corner DOFs and produces a vector $u_{b_c}^{(s)}$ of lower dimension that enlists only the corner DOFs in the subdomain $\mathcal{D}^{(s)}$. To explain it further, consider the i^{th} row of the matrix $B_c^{(s)}$. The j^{th} column in this row will be 1 if the j^{th} element in the vector u_c corresponds to the i^{th} element in the vector $u_{b_c}^{(s)}$, with all other entries being zero. The compatibility condition at the subdomain interface is stated as

$$u_{b_c}^{(s)} - u_{b_c}^{(q)} = 0 \text{ on } \partial D^{(s)} \cap \partial D^{(q)} \quad (25)$$

Upon a few algebraic operations, Eqs. 22, 23, and 24 are combined to a single system of linear algebraic equations with λ as the unknown vector. This resulting system is solved using a preconditioned conjugate gradient (PCG) method. The parallelization is achieved by distributing the subdomains among the processors and thereby distributing the operations involved in (Eqs. 22, 23, and 24).

To apply this method in a direct integration scheme, consider an implicit scheme such as Newmark-beta. Here the linear system of equations is needed to be solved at every time step

$$\hat{K} u_{t+\Delta t} = \hat{f}_{t+\Delta t} \quad (26)$$

where the coefficient matrix $\hat{K}$ and the vector $\hat{f}_{t+\Delta t}$ depend upon stiffness, mass and damping matrices, the parameters of the integration scheme, and the time step. In this case, the aforementioned DD solver can be used at every time step. Instead of an iterative method such as FETI, direct methods such as Schur complement can also be used which can be parallelized.

For explaining the Schur complement, consider the structure with two subdomains in Fig. 1a. Accordingly, the stiffness matrix, displacement vector, and the force vector are partitioned, and the static equilibrium condition is written as

$$\begin{bmatrix} K_{ii}^A & 0 & K_{ic}^A \\ 0 & K_{ii}^B & K_{ic}^B \\ K_{ci}^A & K_{ci}^B & K_{cc}^A + K_{cc}^B \end{bmatrix} \begin{Bmatrix} u_i^A \\ u_i^B \\ u_c \end{Bmatrix} = \begin{Bmatrix} f_i^A \\ f_i^B \\ f_c \end{Bmatrix} \quad (27)$$

To solve this equation, first the displacement at the boundary, u_c , is computed by solving

$$\begin{aligned} \sum_{s=A,B} \left(K_{cc}^s - K_{ci}^s (K_{ii}^s)^{-1} K_{ic}^s \right) u_c \\ = \sum_{s=A,B} \left(f_c^s - K_{ci}^s (K_{ii}^s)^{-1} f_i^s \right) \end{aligned} \quad (28)$$

where the coefficient matrix is known as the Schur complement. Then the displacement at internal degrees of freedom is computed by solving

$$K_{ii}^s u_i^s = f_i^s - K_{ic}^s u_c; s = A, B \quad (29)$$

The computation in Eqs. 27 and 28 can be parallelized by performing the computation related to subdomains A and B in two different processors.

In the second approach (Prakash and Hjelmstad 2004), consider the equation of motion of a forced undamped motion as

$$M\ddot{u}(t) + ku(t) = f(t) \quad (30)$$

Now let the domain D be divided into N_s subdomains without the connectivity at the corner. Then the equation of motion for each subdomain can be written as

$$M^{(s)} \ddot{u}^{(s)}(t) + K^{(s)} u^{(s)}(t) + B^{(s)T} \lambda = f^{(s)}(t) \quad (31)$$

where $B^{(s)}$ denotes a Boolean matrix mapping from the subdomain s to a global vector

containing the dofs at all the inter-subdomain boundaries (interfaces) and λ is a Lagrange multiplier, this time with the units of velocity. Inter-subdomain compatibility is imposed in terms of velocity as

$$\sum_{s=1}^{N_s} B^{(s)} \dot{u}^{(s)}(t) = 0 \quad (32)$$

Once again, using a Newmark-beta scheme, the discretized equation

$$\begin{aligned} \mathcal{M}^{(s)} \ddot{\mathbf{u}}_{i+1}^{(s)}(t) + \mathcal{B}^{(s)} \lambda_{i+1} \\ = \mathbf{f}_{i+1}^{(s)}(t) - \mathcal{N}^{(s)} \mathbf{u}_i^{(s)}; s = 1, 2, \dots, N_s \end{aligned} \quad (33)$$

where the index i denotes the time step,

$$\mathbf{u}_i^{(s)} = \begin{Bmatrix} \ddot{u}_i^{(s)} \\ \dot{u}_i^{(s)} \\ u_i^{(s)} \end{Bmatrix}, \mathbf{f}_i^{(s)} = \begin{Bmatrix} f_i^{(s)} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix}, \mathcal{B}^{(s)} = \begin{Bmatrix} B^{(s)T} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix}, \quad (34)$$

and the matrices $\mathcal{M}^{(s)}$ and $\mathcal{N}^{(s)}$ follow from the Newmark-beta scheme. Equations 32 and 31 are then solved to find the time history of response. Parallelization follows from the data independence of the subdomains in Eq. 32 by distributing the subdomains among the processors. Note that this method can be further refined to accommodate different time steps in different subdomains. In that case, the compatibility condition Eq. 32 is not enforced at every time step, but after a few time steps.

In all the DD methods described in this section, no reduction in the total number of degrees of freedom is made. Therefore, the error associated with static condensation of component mode synthesis where a set of degrees of freedom is eliminated from the calculation does not appear here. However, approximations arise from usage of iterative solvers. The main goal here is to reduce the total computational cost by distributing the total computational burden among a

number of processors. To this end, two important criteria must be followed for computational efficiency. First, the computational load must be equally distributed among the processors; this is called load balancing. Second, the inter-processor communication should be minimal, as communication is slower than computation within a processor. In a distributed memory system, the Message Passing Interface (MPI) is used for parallelization. Once a parallel algorithm is developed, often the data structure needs to be reworked. Then the computer program (written in, for instance, Fortran/C/C++) is augmented by a set of MPI commands to distribute and manage the computation among the processors (Karniadakis and Kirby 2003). The parallel computing would help not only in solving very large and complicated problems, but also in the context of reliability analysis where numerous repeated analyses are required.

Hybrid Simulations

The idea of substructuring also has applications in laboratory testing-based performance assessment of engineering systems for dynamic loads such as those included due to earthquakes. The test hardware here consists of computer-controlled servo-hydraulic actuators driving either a shake table or serving as loading devices in reaction-wall-based systems. In conventional test methods, these actuators are either in displacement or a force control and aim to apply prescribed time variations of dynamic loads on the test structure. This strategy however suffers from two drawbacks, namely, the need to geometrically scale and structure the study (dictated by limitations on payload capacity of the shake table and actuator force ratings) and the neglect of possible dynamic interaction between structural subsystems being tested (e.g., heavy machinery like turbines, rotors, and pumps) and the structure in which these systems are housed. Newer testing protocols aimed at overcoming these limitations which employ substructuring

schemes have been developed in recent years (Saouma and Sivaselvan 2008; Bursi and Wagg 2008; Williams and Blakeborough 2001). Two such strategies, namely, pseudodynamic testing and real-time substructuring, are discussed in the following:

The pseudodynamic test is carried out on a reaction-wall-based system using servo-hydraulic actuators under displacement control. The test structure under study is modeled as

$$M\ddot{X} + C\dot{X} + R[X(\tau), 0 \leq \tau \leq t] \\ = -M\Gamma\ddot{x}_g(t), X(0) = X_0, \dot{X}(0) = \dot{X}_0 \quad (35)$$

Here, the term R represents nonlinearities due to inelastic behavior of the structure, Γ is the influence matrix, and $\ddot{x}_g(t)$ is the earthquake-induced ground acceleration. The basic premise of this approach is that the inertial, viscous damping and external force characteristics can be numerically modeled while the inelastic nonlinear term R is obtained experimentally. This would mean that the terms $M\ddot{X}$, $C\dot{X}$, and $-M\Gamma\ddot{x}_g(t)$ constitute the numerical component of the test while R represents the experimental component. Furthermore, the time variable t is scaled to slow down such that the test involves the application of only static actions. A partial finite element model of the structure which characterizes the terms $M\ddot{X}$, $C\dot{X}$, and $-M\Gamma\ddot{x}_g(t)$ is first formulated, and it is embedded into the software that commands the servo-hydraulic actuators. The actuators are kept under displacement control. Beginning with an initial guess on stiffness characteristics, the finite element equations of motion are integrated to determine displacement vector $X(t)$ at $t = \Delta t$. These displacements are further applied on the test structure experimentally, and the reactions transferred to the walls are measured through load cells. These measured reactions serve to establish the term R in the governing equation of motion, which in turn is used to advance the integration steps. Thus the integration of equation of motion and measurement of nonlinear stiffness characteristics of

the structure go hand in hand leading to determination of structural response to a specified $\ddot{x}_g(t)$. The works of Takanashi and Nakashima (1987), Severn et al. (1989), Nakashima (2001), and Williams and Blakeborough (2001) provide comprehensive overviews on related topics. It is important to note that the earthquake-induced structural displacements are evaluated computationally and applied to the structure in a static manner. This test clearly does not permit experimental evaluation of time dependant nonlinear behavior, rate dependant stress–strain laws, and behavior of active elements, if any.

The real-time substructure test does not scale the time as is done in pseudodynamic testing. The test structure here is spatially divided into two parts: one which permits reliable numerical modeling and the other that requires experimental testing. The finite element model for the numerical substructure is embedded into the control software that controls the actuators, and the experimental substructure is placed on the test rig. Clearly the numerical and experimental models are coupled, and the integration of governing equations for the numerical model and the testing of experimental substructure take place hand in hand in real time. This requires online exchange of interfacial forces/displacements between the two substructures which in turn places demands on accurate sensing, fast data acquisition, and efficient numerical integration. Several issues related to time delays, measurement noise, and choice of integration schemes become critical in this context. Examples of recent studies include those by Sajeeb et al. (2009), Chen and Ricles (2010, 2012), and Gao et al. (2013).

Summary

A wide range of contexts in which substructuring is used in finite element modeling is reviewed. The motivations for substructuring include desire to reduce the model size, desire to combine experimental and numerical modeling

approaches in an online or offline manner for steady-state/transient dynamics, and desire to equitably employ computational resources in a parallel computing environment. The challenges here pertain to choice of substructures, incompleteness in modal, spatial, and (or) frequency domains, dissipative mechanisms, local/global nonlinearities, and non-idealities in experimental work (such as measurement noise and time delays) and their role in selection of algorithmic parameters. The overview presented in this entry has endeavored to bring out currently available techniques and tools in the area of modeling.

Introduction

When earthquakes occur, affected societies and their members suddenly find themselves having to deal with demands that differ considerably from anything they would encounter under normal conditions and in circumstances in which normal societal functions and resources are marked by their absence. The aftershock sequence that can accompany seismic events can prolong the period over which people have to deal with disruption. However, the degree of disruption and loss that people, communities, and societies experience is a function of the degree to which they have developed the knowledge, skills, and relationships required to anticipate, cope with, adapt to, and recover from earthquake consequences during both the initial event and the consequences they can encounter as they cycle through response and recovery processes with successive aftershocks. Furthermore, the fact that earthquakes occur without warning makes it imperative that people prepare prior to any event. Because it is impossible to predict when the next

earthquake will occur (it could be years or decades or longer into the future), preparedness strategies must ensure that once developed, preparedness is sustained by people and communities. The task of facilitating sustained preparedness occurs as part of a comprehensive risk management strategy.

Risk management offers ways in which societies and their members (individually and collectively) can make choices about mitigating risk and facilitating their preparedness to respond to seismic hazard events using a mix of mitigation and preparedness strategies. Mitigation and preparedness strategies play complementary roles in risk management.

Mitigation strategies describe ways societies can prepare themselves in advance of earthquakes occurring by undertaking activities designed to prevent or minimize the risk earthquakes pose to a society and its members. Mitigation encompasses, for example, land-use planning (e.g., precluding building in areas susceptible to liquefaction) and developing and implementing building codes and standards (e.g., specifying building codes to include, for instance, base isolation to increase building capacity to withstand ground shaking) and retrofitting existing buildings to facilitate their capacity to withstand the action of seismic hazards (at least up to a point). Building codes can reduce the adverse impacts of hazards and increase the likelihood of a building remaining available for people's use after the event. However, additional strategies may be required if it is possible to anticipate future earthquake events whose intensity or duration would exceed design parameters and retrofitting capability.

For example, a mitigation measure may function effectively when impacted by a 100-year event yet fail catastrophically if a 500-year (typically more intense) event is experienced. Thus, people could experience problems from events at the higher end of the spectrum of seismic intensities, magnitudes, and durations (e.g., continuing damage resulting from prolonged aftershocks such as what occurred in Christchurch) that could exceed the parameters of structural measures designed in part on

cost-benefit and political criteria (which reflect the level of risk mitigation a society is willing to pay for). This introduces into the risk management process a need for strategies designed to reduce the degree of loss and disruption experienced through encouraging personal and community preparedness.

The goal of preparedness strategies is to increase the likelihood of people and communities being in a position to be able to *respond* in planned and functional (resilient and adaptive) ways to the complex, challenging, and emergent challenges and demands that earthquakes create rather than having to *react* to them in ad hoc ways. For example, ensuring the physical integrity of the house and storing water and food helps people deal with the effects of ground shaking on their home and on the loss of utilities. Taking steps to ensure the structural integrity of the home not only reduces the risk of injury and death to its inhabitants, but it also increases the likelihood of people having shelter during their recovery, reduces demands on societal resources for temporary accommodation, and increases the probability that people will remain in an area and be able to participate in social (mutual aid, social support), economic, and environmental recovery activities. The effectiveness of the mutual aid and social support people within communities can provide for each other and the quality of the working relationship between community members and civic agencies during and after earthquake events is a function of the degree to which community members have developed the knowledge, skills, and relationships with neighbors, community members, and civic agencies necessary to expedite local response and recovery initiatives before earthquakes occur (Paton and McClure 2013).

Preparedness programs aim to facilitate the proactive development of household, community, and societal capabilities (e.g., develop emergency plans and resources, capacity for self-reliance, ability to work with others to confront local problems, etc.) in ways that increase people's ability to anticipate what they may have to contend with and develop their capacity to cope with, adapt to, and recover from the physical, personal, and social consequences that

earthquakes create (Paton and McClure 2013). Achieving this goal falls within the remit of comprehensive risk management (i.e., where responsibility is shared between community members and agencies in ways that increase the likelihood of their respective activities playing complementary roles) in ways that devolve (partial) responsibility for personal and local risk management to individuals and communities. Involving people in risk management is pursued using risk communication and community outreach strategies.

In order to design and implement risk communication and community outreach strategies, it is important to know what to communicate and engage people about. The content of risk communication tends to reflect the fact that, fundamentally, risk is a product of the likelihood of earthquakes occurring and the consequences that arise when they do occur. Communicating about both, and particularly about consequences, is essential. Communicating information about the earthquake likelihood is not a good predictor of preparedness (McClure et al. 1999; Mileti and Darlington 1995). Preparedness is more likely when people believe they are likely to suffer negative consequences from an earthquake if they do not prepare (Palm et al. 1990). This suggests that risk communication strategies profit from including information about earthquake consequences and encourage citizens to personalize this risk in ways that focus on how they can prepare in ways that can prevent or minimize adverse earthquake consequences (Paton and McClure 2013). To do so requires several pieces of information.

The first concerns identifying what people need to know and be able to do (individually and collectively) to cope with and adapt to the earthquake hazard consequences that emerge and evolve over the course of the response, recovery, and rebuilding phases of earthquake disasters. That is, identifying earthquake consequences and the physical and social demands they create for people and identifying the strategies required to prepare for these consequences and demands (i.e., what being comprehensively prepared looks like). It is also important to identify why some people prepare and others less so or not at all.

Knowledge of the latter informs how risk communication and community outreach strategies can be developed to facilitate sustained, comprehensive preparedness. Finally, because earthquakes occur in culturally diverse locations, a third issue is ascertaining whether or not preparedness theories and practices are applicable across cultures. The first issue to be tackled is identifying what comprehensive preparedness is.

Comprehensive Earthquake Preparedness

The goal of preparedness strategies is to facilitate people's ability to deal with the full spectrum of demands that unfold over prolonged periods of response and recovery. People need to be able to deal with direct (e.g., impact of ground shaking, liquefaction, and aftershocks on buildings and infrastructure) and secondary (e.g., loss of lifelines like water, power, and sewerage services and the consequent need for people to be self-reliant and able to continue to function as well as possible in the absence of normal services) hazard consequences. As physical and social rebuilding occurs, people also need to be prepared to contend with challenges emanating from recovery processes (e.g., dealing with government agencies, insurance companies, builders, etc.) that may persist for weeks, months, or years. Furthermore, they may, as was evident in Christchurch, New Zealand, following the 2011 earthquake, have to cycle through response and recovery several times as they deal with the implications of aftershock sequences that prolonged people's experience of the physical and social consequences of earthquake activity (Paton et al. 2014). Recognition of the diverse issues people could encounter led to the development of functional typologies of earthquake preparedness that maps the content of preparedness programs onto the demands and challenges people have to contend with over time.

Functional Typologies

Russell et al. (1995) developed a preparedness typology that comprised three factors: structural,

survival, and planning preparedness. Structural actions encompass activities that secure the house (e.g., secure house to foundations) and its contents (e.g., securing water heaters and tall furniture) to prevent contents from injuring inhabitants (e.g., from ground shaking). Survival actions facilitate people's capacity for self-reliance during periods of disruption (e.g., ensuring a supply of water/dehydrated or canned food for several days, having a radio with spare batteries, etc.). Finally, planning includes, for example, developing household hazard plans and attending meetings to learn about earthquakes and how to deal with their consequences. The latter introduces a social dimension into how preparedness is conceptualized. A subsequent factor analytic study (Lindell et al. 2009) proposed that preparedness comprise direct action (e.g., learn how to shut off utilities, have a 4-day supply of canned food, strap heavy objects, etc.) and capacity building (e.g., join an earthquake-related organization, attend meetings about earthquake hazards) factors. These studies identify a need for preparedness strategies to facilitate the development of structural, survival, planning, and capacity building (social) activities. The importance of including all these aspects within a typology of comprehensive earthquake preparedness has been reinforced by studies of what people affected by earthquakes identified as being required to increase their ability to deal with the consequences of earthquakes.

For example, in Christchurch, NZ, residents affected by the 2011 earthquake reinforced the importance of developing (pre-event) structural and survival preparedness and household emergency planning (Paton et al. 2014). Christchurch respondents reported how their lack of survival and planning preparedness made coping with the loss of essential societal utilities (e.g., loss of water, power, and sewerage services) more challenging than it would have been had they prepared before the earthquake struck. Respondents also called for preparedness programs to address dealing with loss of or disruption to people's livelihoods (both directly from damage to place of work and indirectly from being relocated or injured), developing psychological preparedness,

adapting to changes in living conditions and loss of and disruption to family and social relationships, and accommodating the fact that the period of loss and disruption people have to confront extends to months and years. A need for effort to be directed to developing social relationships and social competencies within a preparedness strategy was identified by those affected by the 2011 earthquake.

Respondents suggested that preparedness programs should develop the ability of neighborhood and community group members to collaborate in ways that facilitate their ability to effectively confront local physical and social demands (e.g., removing rubble, providing mutual support, setting up community meeting places, taking care of those with special needs, organizing local efforts to repair homes, identifying and meeting local needs) when responding under conditions in which normal societal resources and functions are absent. Respondents also called for effort to be directed to preparedness programs including content to develop, for example, community leadership, social inclusion, prioritizing problems, problem-solving and decision-making skills. The latter, in conjunction with developing community capacity to represent diverse community and local needs to agencies and government will facilitate the ability of communities to proactively secure the resources they need to take responsibility for their own recovery (Paton et al. 2014).

Taken together, this discussion highlights a need for preparedness to encompass structural, survival, planning, and community capacity capabilities. The Christchurch work introduced a need to complement these functional categories with those addressing livelihood and psychological and community-societal relationship (e.g., between communities and governments, NGOs, business, etc.) preparedness. These are summarized in Fig. 1 (right-hand column). While the Christchurch research discussed what people realized they needed during a disaster, the focus of preparedness research is on developing these capacities and relationships prior to the occurrence of a hazard event. A need to research the latter reflects the finding that comprehensive preparedness is the exception rather than the rule.

Sustained Earthquake Preparedness: Functional, Social, and Cultural Issues, Fig. 1 Summary of the relationship between protective action decision-making;

personal-, social-, and agency-level predictors; and the functional categories of earthquake preparedness

Despite the considerable time, effort, and expenditure invested in earthquake public education programs, levels of preparedness for earthquakes typically remain low (Lechlitter and Willis 1996; Lindell et al. 2009; Paton et al. 2014; Paton and McClure 2013). Finding considerable diversity in existing levels of preparedness introduces the second issue discussed in this chapter; the need to account for why some people prepare comprehensively, some much less so, and others not at all.

Accounting for Differences in Preparedness

When making decisions about uncertain, threatening events, several dispositional or individual-level predictors of preparedness have been identified. Some, such as fatalism, reduce the likelihood of preparing. Others influence how people

make judgments about who is responsible for their preparedness. Some increase the likelihood of people preparing.

People who are fatalistic about hazard activity are unlikely to prepare (Turner et al. 1986). Another dispositional characteristic that reduces preparedness is denial (Crozier et al. 2006). If people believe that they have no control over an earthquake and/or its activity, they can attempt to cope with this by denying the seriousness of the risk. Household and personal preparedness is also less likely if people believe that risk management agencies are responsible for all aspects of public safety and so transfer responsibility for community preparedness from themselves to agencies (Paton and McClure 2013). Certain characteristics of people's social relationships influence preparedness.

If people believe that their significant others (parents, spouses, friends, peer group, etc.) hold favorable attitudes toward preparedness or that performance of a specific behavior is likely to be interpreted favorably by significant others, they are more likely to perform these actions (Smith and Terry 2003). Prevailing social norms regarding preparedness expectations of significant others and personal motivation to act in ways consistent with these expectations increases the likelihood of preparing (McIvor and Paton 2007). The work on individual predictors has been further developed in several theories of earthquake preparedness.

Person-relative-to-event (PrE) theory (Duval and Mulilis 1995) describes how the degree to which people perceive themselves at risk from an earthquake interacts with person (self-efficacy, outcome efficacy) and event (severity of event and probability of occurrence of the event) variables to predict preparedness. The PrE model argues that someone who appraises their resources as sufficient in both quality and quantity *relative* to the perceived magnitude of a particular threat will engage in more problem-focused coping activities than one who appraises their personal resources as insufficient relative to the seriousness of the threat. This work introduces a need to include perceived vulnerability, severity, response efficacy (outcome expectancy), problem-focused coping, and anxiety (fear-arousing persuasive communication) as predictors of earthquake preparedness (see Fig. 1).

Building on ideas advanced in the PrE theory, Paton et al. (2005) developed a theory that identified how critical awareness or the relative social salience (i.e., the extent to which people think and talk about earthquakes and earthquake preparedness with others in their community) of earthquakes was a key motivator of preparedness. Paton et al.'s (2005) critical awareness theory demonstrated that the anxiety, outcome expectancy (response efficacy), self-efficacy, and problem-focused/action coping mediated the relationship between critical awareness and preparedness and so identified a need for these variables to be included as predictors of earthquake

preparedness (see Fig. 1). Other theories have focused on how people's information search and evaluation influences the degree to which they take protective action.

The Protective Action Decision Model (PADM) (e.g., Lindell and Hwang 2008) argues that people's decisions about earthquake preparedness reflects the judgments they make about three factors: the threat posed by an earthquake, identifying the actions available and capable of protecting them against earthquake consequences, and identifying the sources from whom information about hazard and protective measures can be obtained. The PADM proposes that this involves people proceeding through several stages of information seeking and evaluation: detection/warning, psychological preparation, logistical preparation, and protective action selection and implementation (see Fig. 1). The information required for people to act at each stage can be sourced from the physical environment and/or people's social context (e.g., other people in their community, emergency management, media, etc.).

Lindell's work discussed the fact that people do not take information from expert sources at face value and introduced a need to consider both information about earthquake risk and preparedness and the quality of the (communication) relationship between the sources and recipients of earthquake risk information. An important contextual element of this relationship is that it occurs under conditions of uncertainty. People may have no or limited experience of earthquakes, and the infrequent nature of earthquake activity makes it impossible for them to independently test the validity of the information about risk and preparedness. Under these circumstances, an important aspect of the relationship between source of information and its recipients is the degree to which recipients trust sources of information. Levels of risk acceptance and people's willingness to take responsibility for their own safety is increased, and decisions to take steps to actively manage their risk more likely, if people believe that their relationship with risk management agencies is fair and empowering (e.g., agencies are perceived as trustworthy, as

acting in the interest of community members) (e.g., Paton 2008).

Paton (2008) developed a community engagement theory that captured key elements of these relationships, empowerment and trust, and the personal beliefs and social competencies that influenced preparedness decision-making under uncertainty. This theory has demonstrated an ability to predict earthquake preparedness (Paton 2013).

Paton (2008) argued that if people hold negative outcome expectancy beliefs (belief that earthquakes are uncontrollable and their consequences are too catastrophic for personal action to make any difference to peoples' safety), their likelihood of preparing is reduced. In contrast, holding positive outcome expectancy beliefs (beliefs that personal actions can enhance personal safety and/or mitigate hazard consequences) motivates people to start to prepare. However, the infrequent and complex nature of earthquakes means that believing that preparing can be effective does not necessarily equate with knowing what to do or how to prepare. To reduce uncertainty and guide action, people look to other community members and to expert sources (Paton 2008). Paton's community engagement theory introduced a need to include outcome expectancy, community participation and collective efficacy (which serve to socially construct risk beliefs and identify how risk can be reduced through social action by articulating community members preparedness plans), empowerment, and trust as predictors of earthquake preparedness (see Fig. 1).

Figure 1 summarizes the several variables that were implicated as predictors in the theories discussed above. It also includes how the PADM suggestions about information search and action might relate to these other variables. Collectively, this depiction could serve as a framework for future research into earthquake preparedness. The theories introduced above have empirically demonstrated their ability to account for differences in levels of earthquake preparedness. This confers upon them a capacity to inform the development of risk communication and community outreach strategies (see below)

by identifying how information content and personal and social competencies and relationships complement one another in ways that facilitate the ability of people to make earthquake preparedness decisions under conditions of uncertainty. However, given the fact that earthquakes affect people in countries characterized by considerable social and cultural diversity, it cannot be automatically assumed that they will retain their predictive utility if applied in different cultural contexts. Developing a comprehensive understanding of earthquake preparedness requires considering this cultural dimension.

Cross-Cultural Issues in Earthquake Preparedness

One reason for exercising caution in this regard derives from the fact that the theories introduced above were developed and tested in countries that are culturally highly individualistic. The variables they tested reflected this. In contrast, Asian countries, where a disproportionate number of significant and damaging earthquakes occur, tend to fall at the collectivistic end of the cultural spectrum in which social processes play relatively more important roles in people's decisions and actions (Triandis 1995). This raises issues regarding the applicability of Western-developed theories in Asian cultures that typically lie at the collectivistic end of these cultural dimensions. Examining whether theory can be applied across the individualistic-collectivistic spectrum is important (Paton et al. 2013).

A preliminary investigation of cultural equivalence was undertaken by examining whether Paton's (2008) community engagement theory (see above) of preparedness could account for differences in earthquake preparedness in countries (New Zealand, Japan, and Taiwan) that differ with regard to their relative positions on the individualistic-collectivistic cultural spectrum (see Fig. 2). This theory was selected for this initial comparison because its inclusion of both individual-level (outcome expectancy) and community-/social-level process (community participation and collective efficacy) variables provides a useful starting point for studying cultures that

Sustained Earthquake Preparedness: Functional, Social, and Cultural Issues, Fig. 2 Summary of cross-cultural studies of earthquake preparedness and the

relative contribution of culture-general (etic) and culture-specific (emic) processes to earthquake preparedness

differ with regard to their implicit emphasis on individual (individualistic cultures) and social (collectivistic) characteristics. For example, the relative position of a country on the I-C dimension could influence the comparative importance of person-level versus group-level factors on preparedness decisions (Paton et al. 2013). Empirical analysis of the ability of this theory to predict earthquake preparedness in New Zealand, Japan, and Taiwan (Fig. 2) supports the view that Western theory can be used across cultural borders (Paton et al. 2013). In Fig. 2, the R^2 value refers to how well the model can explain differences in people's intention to prepare for earthquakes (e.g., in Taiwan, the model explained 33% (or .33) of these differences). Models that predict over 28% are regarded as offering a good explanation (Sheeran 2002).

Evidence for cross-cultural equivalence should not, however, be taken to imply that cultural factors can be ignored. Cultural studies distinguish between etic (culturally universal) and emic (culture-specific) processes. While the cross-cultural analyses discussed above identified how the same process (Fig. 2) could operate across different countries (i.e., it describes an etic process), this does not mean

that the process is enacted in the same way in different cultures. For example, community participation was important in each country. However, the origins of participatory activities and how they are sustained and enacted to influence people's risk beliefs and preparedness options differ from country to country. Thus, emic processes (i.e., how and why participation occurs in a specific culture) capable of affecting earthquake preparedness need to be identified. Doing so can provide valuable insights into the theoretical and practical aspects of earthquake preparedness (see below). This is illustrated here with reference to New Zealand Māori and to how Jishubo (in Japan) and the Hakka Spirit (in Taiwan) describe emics that affect earthquake preparedness.

The importance of accommodating emic characteristics was evident in New Zealand. Analysis of unique cultural characteristics capable of facilitating social preparedness was evident in Māori populations. The Māori cultural value of "aroha ki te tangata" (love to all people) represents an emic characteristic (Fig. 2) capable of informing understanding of how community participation influences preparedness in this population (Paton et al. 2014).

Jishu-bosai-soshiki (Jishubo) are neighborhood-based “autonomous organizations for disaster reduction” unique to Japan (Bajek et al. 2008). Jishubo is a resource available to local government that can be used to organize earthquake preparedness events within communities (e.g., drills, workshops) and facilitate local response and rescue activities (e.g., rescue residents, provide initial first aid, supply food and water to survivors) should an earthquake occur. Jishubo are organized and operate through Chonaikai (“community councils”), a traditional Japanese neighborhood governance system that includes within its functions the maintenance of safe and secure communities through implementing various community activities (e.g., disaster risk reduction and crime prevention). This example illustrates how culture-specific (emic) characteristics can influence how community (Jishubo) and community-agency (Chonaikai) relationships (i.e., they represent unique ways of enabling community participation and empowerment) inform earthquake preparedness in ways unique to Japanese society (Bajek et al. 2008) (see Fig. 2). Another example of how culture-specific social mechanisms can influence earthquake preparedness is found in Taiwan.

Jang and LaMendola (2006) discussed how the Hakka Spirit, a cultural characteristic of the Hakka people residing in Tung Shih in Taiwan (affected by the 921 earthquake that hit Taiwan in 1999) influences earthquake preparedness. The Hakka Spirit describes an emic process, a unique set of cultural beliefs and practices that encompasses qualities such as frugality, diligence, self-reliance, responsibility, and persistence that combine to predispose people to prepare for adversity. Jang and LaMendola discussed how farming practices that evolved to limit the impact of typhoons on people’s livelihoods generated enduring outcome expectancy beliefs (regarding the effectiveness of collective actions in response to hazard consequences). These were linked to increasing the likelihood that people would act to secure their homes from earthquake consequences. Culturally specific reciprocal support and collaborative problem-solving practices, developed over time as part of an adaptive response to meeting

the challenges imposed by agricultural life in remote mountain communities, represent the source of the community participation and collective efficacy described in the above analyses (Fig. 2).

Practical Implications

Being able to identify (Fig. 1) factors that facilitate and hinder earthquake preparedness can inform the development of practical risk communication and community outreach strategies. For example, fatalistic attitudes can be reduced by asking people what can be done to help specific vulnerable groups, such as people living in unsafe buildings or young children in schools (McClure et al. 2001; Turner et al. 1986). When people deliberated about preparedness in vulnerable groups, they became less fatalistic and were more likely to perceive preparedness actions as more manageable. Denial and negative outcome expectancy can be countered by providing information that focuses people’s attention specifically on how preparedness actions can mitigate the consequences of hazard activity and increase the degree of control people perceive themselves having over earthquake consequences (Lehman and Taylor 1987) and by sourcing information about preparedness and its effectiveness from comparable (to the target one) communities (Paton and McClure 2013).

Positive outcome expectancy beliefs can be developed by presenting people with a small number of items initially, starting with relatively easily adopted items and introducing progressively more complex tasks over time (Lindell and Perry 2000). By presenting specific explanations about how preparedness actions reduce risk and mitigate hazard consequences progressively over time, sustained adoption is more likely (Paton and McClure 2013). Social and relationship predictors (e.g., community participation, collective efficacy, social norms, etc.) can be enhanced by integrating community development and risk management strategies and by ensuring that community outreach adopted empowerment and community engagement principles (Paton and McClure 2013). This raises the possibility that one reason for the success of

Chonaikai is by integrating its disaster risk reduction activities with other community activities.

The work discussed above introduced how earthquake preparedness theory can possess etic quality that allows it to be used in a broad range of cultural contexts. Demonstrating that occidental theories retain their predictive utility in oriental contexts has several theoretical and practical benefits. For example, it would provide a common theoretical basis for collaborative learning and research across national borders. Demonstrating a degree of cross-cultural theoretical equivalence provides risk management agencies in different countries with access to a wider range of risk management options (which are implemented by accommodating local emic processes). It would make information about how to facilitate preparedness available to countries that lack the resources to undertake this work themselves and inform the development of humanitarian aid planning knowing that they have a robust framework that could be used to assist earthquake recovery irrespective of the country they find themselves being deployed at short notice. It remains important, however, to accommodate emic, culture-specific processes in the development of comprehensive earthquake preparedness theory and practice (e.g., by mapping local cultural practices (emic) onto this etic framework). Researching emic cultural influences on how earthquake preparedness and recovery processes are developed, sustained, and enacted also opens up new research and outreach opportunities for developing progressively comprehensive theories of earthquake preparedness.

Summary

The three countries that were specifically discussed in this chapter, New Zealand, Japan, and Taiwan, along with many others, all sit on the circum-Pacific seismic belt (the Pacific Ring of Fire). Approximately 90 % of the world's earthquakes and 81 % of its largest earthquakes occur along the Ring of Fire. Earthquakes will remain an inevitable aspect of the natural history of these countries. However, people can prepare in ways

that can reduce their risk of experiencing adverse earthquake consequences and recover more promptly and effectively should an earthquake occur. This chapter first identified a need for preparedness to cover structural, planning, psychological, livelihood, community, and community-agency relationship categories (Fig. 1). Despite the evident advantages of being prepared, the fact that some people prepare comprehensively and others less so or not at all identifies a need for robust theories of hazard preparedness to inform DRR practice. This chapter also recognized the need for preparedness theory and strategy to accommodate the social and cultural diversity inherent in countries whose citizens must live with seismic risk. By demonstrating how theory can predict earthquake preparedness in culturally diverse countries, the chapter illustrated the potential for collaborative learning, research, and practice across national borders. However, it is important to ensure that national work accommodates the unique cultural resources present in each country that can be used to facilitate sustained earthquake preparedness.

Symmetric Triaxial Seismometers

Bruce Townsend

Nanometrics, Inc., Kanata, Ontario, Canada

Synonyms

Galperin configuration seismometer; Homogeneous triaxial seismometer

Introduction

Of the class of seismic instruments measuring ground motion known as triaxial seismometers, most provide three signal outputs that represent mutually orthogonal motions in the East, North, and Vertical (or X, Y, and Z) directions (see entry “► [Principles of Broadband Seismometry](#)”). Of these, some are designed with three independent internal sensors that are respectively sensitive to motions in the three XYZ directions, and so directly measure the single vertical and two horizontal motion degrees of freedom. Some triaxial seismometers use a different configuration known as a Galperin arrangement (Galperin 1955), also known as a “symmetric triaxial” or “homogeneous” design (Melton and Kirkpatrick 1970).

In the Galperin configuration, the sensing elements are also arranged to be mutually orthogonal, but instead of one axis being vertical, all three are inclined upwards from the horizontal at precisely the same angle, as if they were aligned with the edges of a cube balanced on a corner. The operational principles of a design based on the Galperin configuration have many similarities as well as some important differences relative to one based on the conventional XYZ arrangement. The Galperin configuration presents some significant benefits for the users, owners, and manufacturers of seismometers that use this topology, as well as implying some trade-offs users should be aware of.

Benefits of a symmetric triaxial seismometer include being able to more easily distinguish external noise sources from internal ones, that mass centering does not compromise mutual orthogonality of the three axes, assurance of well-matched responses of the three outputs, and ability to achieve higher performance in smaller packages. A trade-off made by the Galperin approach is that unlike conventional XYZ seismometers that can suffer the failure of one axis element while continuing to provide valid output signals for the remaining two directions, all elements in a symmetric triaxial system must function for any of its XYZ outputs to be valid.

The first modern broadband seismometer to be based on a Galperin configuration was the Streckeisen STS-2, an observatory-grade vault instrument introduced in 1990. Nanometrics introduced a symmetric triaxial seismometer with a 240 s lower corner period, the Trillium 240, in 2004. There are now a wide variety of symmetric triaxial seismometers available including models designed for borehole, posthole, ocean bottom, and vault installation and ranging from ultracompact to the large form factors.

Principles of Operation

Inertial Sensing Principles

Measuring motion must always be done relative to some frame of reference. Seismometers by definition use an inertial reference; that is, motion

is sensed relative to a proof mass that is suspended in such a way that the proof mass tends to remain stationary while the seismometer that is coupled to the earth (or a structure) moves relative to it. The sensing element includes some means of measuring the motion of the sensing frame to its suspended proof mass. The proof mass in most broadband seismometers is a boom hinged at one end and balanced near a null point by a mainspring. A capacitive displacement transducer is often used to sense boom deflection.

A broadband seismometer achieves its wide response and exceptional linearity by means of a force-feedback electronic control loop that includes a forcing coil constantly working to keep the mass at dead center. The electric current required to counteract any deflection of the proof mass is proportional to the acceleration of the frame. In a sense, the forcing coil must at each instant apply exactly the same acceleration to the proof mass as the seismometer is experiencing for the proof mass to “keep up with” (stay stationary relative to) the seismometer. The seismometer output is derived from a signal within the control circuit that is proportional to the time integral of acceleration, providing a signal representative of velocity.

Broadband Axis Essential Elements

A typical arrangement for a broadband seismometer axis is to have a boom hinged at one end with two capacitor plates and a wire-wound coil mounted on it to serve as the displacement transducer and forcing coil, respectively. The mounting frame has one fixed capacitor plate arranged to sit between the two on the boom, and a permanent magnet and yoke fitting into and around the boom’s forcing coil. This arrangement is mounted within the pressure vessel of the seismometer in one attitude for the vertical axis (the boom and capacitor plates horizontal) but in the upright attitude for the horizontal axes (the boom and capacitor plates vertical with the hinge at the bottom). Usually, the electronic feedback circuit together with the power conditioning, output signals, controllers, and related circuitry is on printed circuit boards arranged above the three sensing elements.

Symmetric Triaxial Seismometers, Fig. 1 Force-feedback seismometer vertical axis construction. (a) Perspective view. (b) Side view (© Nanometrics)

Figure 1 shows conceptual mechanical diagrams of a typical broadband axis construction configured to sense vertical motion; both perspective and side views are shown. This and subsequent diagrams are highly simplified for the purpose of illustrating solely the essential functional elements. The hinged boom with its attached forcing coil (shown in cutaway) and two outer capacitor plates have a combined proof mass M and together with the mainspring make a mechanical oscillator. The electric forcing coil attached to the movable boom acts around a permanent magnet fixed to the frame and is driven by force-feedback control loop electronics to maintain the proof mass at its measurement null point, which is where the fixed center capacitor plate is equally centered between the two outer capacitor plates. The boom is pulled down by gravity with force F_g that must be counterbalanced by the mainspring applying torque at the hinge point.

Figure 2 shows the essential construction of a horizontal axis. The principles of the horizontal and vertical designs are evidently the same, but with the horizontal axis oriented so as to be sensitive to sideway acceleration and insensitive to vertical motion. A significant difference between

Symmetric Triaxial Seismometers, Fig. 2 Force-feedback seismometer horizontal axis construction (© Nanometrics)

the two designs is that the horizontal axis mainspring only supplies a restoring force when the boom deflects from its rest position and does not counterbalance any gravitational force ($F_g = 0$), whereas the vertical axis mainspring both supplies a restoring force and counterbalances the weight of the boom against gravity ($F_g = Mg$).

See entry “► [Principles of Broadband Seismometry](#)” for more information on the operational principles.

The XYZ Sensor Configuration

The conventional vertical/horizontal or XYZ arrangement within a triaxial seismometer has one sensing element arranged so that it is sensitive to vertical (Z) motion and two sensing elements that are sensitive to horizontal motions in the X and Y directions. This corresponds to the output signals preferred for most seismology purposes; one generally wants to record the vertical, East and North components. However, the design of the vertical sensing element is unavoidably distinct from that of the two horizontal elements. The constant gravitational acceleration of the Earth that acts on (in fact, defines) the up direction and is absent in the horizontal directions means the vertical and horizontal elements must be of different designs.

The essential differences forced on the design by the presence or absence of the constant $g_o \cong 9.81 \text{ m/s}^2$ acceleration of gravity are the spring suspending the boom and the mass centering mechanism if there is one. Other design differences may also arise from practical design considerations such as the physical orientation of the vertical axis sensor being different with respect to the seismometer case, common electronics circuit boards, connectors, and the like. The vertical axis will have a hinged boom lying in the horizontal plane needing a strong spring to suspend it against gravity, and will tend to be tall and narrow as in Figure 1. A horizontal axis, having an inverted pendulum oriented in the vertical plane, will tend to be wider and shorter as in Figure 2. This creates challenges for the designer when attempting to fit one vertical and two horizontal axis elements in a single enclosure and can result in larger enclosures and/or further asymmetries between the horizontal and vertical designs to optimize physical fit.

The primary function of the mainspring that suspends the proof mass is to apply a restoring force to the mass in the direction of its center position, so that when the mass is deflected by some acceleration acting on it, the spring acts in the opposite direction to restore the position of the mass. The spring constant (the force the spring applies per unit of deflection) is generally as weak as can be practically achieved, so as to

ensure the mass may freely move relative to the frame in which it is suspended. However, the mainspring of a vertical sensor must also balance the suspended proof mass against the acceleration of gravity, whereas the mainspring of a horizontal sensor does not. For example, a proof mass of $M = 200 \text{ g}$ in a vertical axis of the type shown in Fig. 1 experiences a downwards force due to gravity of $F_g = Mg = 1.96 \text{ N}$ that applies a torque at the hinge point, and the spring must apply the equivalent counteracting torque to keep the mass balanced at the center position.

Adjusting the sensing axis so that the boom is positioned at the center position of the displacement transducer is known as “mass centering.” This is a mechanical operation which is done for some seismometers by the operator turning an adjustment screw, and for others by microprocessor-controlled motors within the seismometer making the adjustments automatically, initiated by an external command or signal. On a horizontal axis, this is often done by tilting the axis (e.g., Guralp CMG-3T, Streckeisen STS-1) one way or the other within a range of a few degrees, which allows gravity to act sideways on the axis in proportion to the sine of the tilt angle (which for small angles is directly proportional to the tilt angle). If the mass is decentered either because the spring is applying a decentering force or because the seismometer is tilted off level, applying a small amount of gravity to one side or the other of the axis by tilting it in the opposite direction deflects the mass back to its center position. This method is depicted in Fig. 3, showing a horizontal axis on its internal mounting plate in an off-level situation. In Fig. 3a, gravity has pulled the boom off-center and its two capacitor plates are not centered about the middle capacitor plate that is fixed to the frame. In Fig. 3b, the axis has been tilted mechanically to re-center the boom mass. Note that the direction of sensitivity changes as the axis is tilted.

Tilting a vertical axis to center the mass is not practical because the effect of gravity on the axis is proportional to the cosine of the tilt angle, which for small angles has almost no effect: a vertical axis would have to be tilted by 10.7°

Symmetric Triaxial Seismometers, Fig. 3 Mass centering a horizontal axis by tilting. (a) Tilted axis on unlevel ground. (b) Axis internally tilted to re-center mass (© Nanometrics)

Symmetric Triaxial Seismometers,

Fig. 4 Two methods for mass centering a vertical axis (© Nanometrics)

to counteract the same deflection as for a 1° tilt of the horizontal axis element. Instead, the mass centering for a vertical axis is done in one of two ways: by adjusting the tension of the main spring to change the force applied to the boom (e.g., Guralp CMG-3T) or by changing the position of the center of gravity of the hinged proof mass by moving an adjustable slug horizontally along the mass relative to the hinge point (Streckeisen STS-1). Figure 4 shows how both

methods work in principle. In practice the mechanisms are of course more elaborate and are often motorized. Note that, unlike the method of tilting the axis, the direction of sensitivity does not change as the spring tension is changed or the center of mass of the boom is adjusted.

A non-Galperin three-component broadband seismometer includes two horizontal axes and one vertical axis, usually mounted within a common pressure vessel. Because axis tilting

Symmetric Triaxial Seismometers, Fig. 5 Vertical and horizontal component non-orthogonality (© Nanometrics)

is used for mass centering the horizontal elements but not the vertical element, the mutual orthogonality of the XYZ components is compromised by the degree of tilt applied. This phenomenon is illustrated in Fig. 5, which shows one of the two horizontal axes and the vertical axis side by side on the same tilted base, the two axis elements having been centered by different methods resulting in non-orthogonal directions of sensitivity.

Practical design considerations also tend to encourage differences in implementation between the vertical and horizontal sensors. Asymmetries between the vertical and horizontal sensor elements arise for several practical reasons, despite the principles of operation being much the same. Besides the mainspring designs that must be different (one counters gravity, the other does not) and the significantly different mass centering mechanisms, the physical orientation and aspect height/width ratio of the two types of axis are asymmetrical. As the two horizontal axes and one vertical axis mount side by side on a common base plate (or are stacked vertically for a borehole configuration), such practical details, such as mounting features, wiring harness, and circuit board connectorization,

fit, and placement within the enclosure and other considerations generally lead to substantive design differences between the vertical and horizontal elements.

The Galperin Sensor Configuration

An alternative configuration to the conventional XYZ horizontal/vertical arrangement was proposed by Galperin, in which the three sensing elements of a triaxial seismometer are arranged in such a way that permits them to be identical in every respect. This is achieved by rotating the orthogonal sensing axes from the XYZ frame of reference to an orientation where each of the three (still mutually orthogonal) axes is inclined up from the horizontal plane at the same angle.

Figure 6 illustrates a symmetric triaxial arrangement. The directions of sensitivity of the new U, V, and W axes are shown overlaid on the XYW coordinate system. In this orientation, the edges (or directions of sensitivity, or axes) are often given the designations U, V, and W (Wielandt 2002), creating a new “UVW” coordinate system. The projections downwards of the three UVW axes onto the horizontal plane are lines radiating from the center equally spaced 120° apart. This arrangement is called symmetrical

Symmetric Triaxial Seismometers,

Fig. 6 Isometric view of UVW and XYZ coordinate systems (© Nanometrics)

because each axis “sees” the same proportion of gravitational acceleration and this allows the axes to be constructed identically. It is possible to choose any upwards inclination angle θ for the three axes for this arrangement to be symmetrical (such as 45°), but setting $\theta = \tan^{-1}\left(\frac{1}{\sqrt{2}}\right) \cong 35.26^\circ$ also makes the UVW axes mutually orthogonal.

The UVW system is then a simple rotation from the XYZ. This can be visualized by thinking of the XYZ directions of sensitivity as the three edges of a cube radiating from one of its eight corners, where the cube is resting on a horizontal surface. The X and Y directions are along two perpendicular edges of the cube’s bottom face, and the Z direction is the vertical edge of the cube that joins the same corner where the X and Y edges meet. Now visualize the cube being tilted upwards with only the common corner resting on the flat surface, and balance it so that the topmost corner of the cube is directly above its bottom corner. The edges that meet at the bottom corner are still of course mutually orthogonal but now form the same angle upwards with respect to the flat surface base.

The trigonometry of this “balanced cube” arrangement results in the angle formed between any of the UVW axes and the horizontal plane being $\theta = \tan^{-1}\left(\frac{1}{\sqrt{2}}\right) \cong 35.26^\circ$. The complementary angle with respect to the vertical is then $\theta_0 = 90^\circ - \theta \cong 54.74^\circ$.

Figure 6 employs the convention used in Nanometrics Trillium seismometers whereby the projection of U in the XY plane points in the X direction, and the UVW system is right-handed like the XYZ coordinate system (Nanometrics Inc. 2013). The convention for Streckeisen seismometers is that the projection of U in the XY plane is antiparallel to X and that the UVW coordinate system is left-handed (Streckeisen and Messgeräte 1995).

Note that the term “symmetric triaxial” is not in itself sufficiently specific to fully define the Galperin configuration, as any triaxial orientation with horizontal projections spaced 120° apart and where each axis of sensitivity forms the same angle with respect to vertical (say, e.g., 45° instead of 54.74°) is a symmetric arrangement. Each axis still experiences gravity equally and they are arranged symmetrically with respect to

Symmetric Triaxial Seismometers, Fig. 7 Oblique axis construction suitable for a symmetric triaxial seismometer. (a) Perspective view. (b) Side view (© Nanometrics)

each other, but they no longer meet at right angles as the edges of a cube. The Galperin topology requires the three axes to be mutually orthogonal as well as having the same angle with respect to the vertical direction, which then fully constrains their mutual orientation. Nevertheless, the “symmetric triaxial” designation is usually assumed to refer to the more specific Galperin topology.

Figure 7 shows conceptual mechanical diagrams of the structure of an axis suitable for a symmetric triaxial seismometer, showing the boom set at an oblique angle, but otherwise based on the same principle as a vertical axis, with the mainspring suspending the weight of the boom against gravity ($F_g = Mg \sin \theta$). For the specific case of a Galperin axis set at a $\theta \cong 35.26^\circ$ angle, $\sin \theta = \frac{1}{\sqrt{3}}$. Because each axis experiences the same static acceleration due to gravity, $\frac{1}{\sqrt{3}}g_0$, the mainspring counterbalancing gravity is identical on all three axes. Because the direction of sensitivity of each axis is inclined by the same angle $\theta_0 = 90 - \theta$ with respect to the vertical, the physical design of the axis can be made identical for all three UVW component directions.

The directions of sensitivity with respect to the X or East direction are of course different for each axis – they are equally spaced 120° apart

as shown in Fig. 6 – but that is achieved by arranging the three identical sensing elements next to each other on the same horizontal base and pointing them in different but equally spaced directions as shown in Fig. 8. This is typically how vault seismometers are configured internally. Seismometers for borehole or posthole installations usually have the three axis elements stacked in a vertical column, one above the other pointing in different directions, but the principle is the same. The diagrams in Fig. 8 illustrate that there is more than one suitable way to dispose the three Galperin axis elements within a seismometer. Note that the relative directions of X, Y, Z, U, V, and W are the same in both arrangements; the three axis elements have just been translated to different positions on the base. The leftmost arrangement of axis elements is employed in the Nanometrics Trillium 120P vault instrument, for example, while the Streckeisen STS-2 vault instrument employs an arrangement similar to the one shown on the right.

Mass centering of a Galperin-type axis may be achieved by any of the methods used with horizontal or vertical axes: tilting the axis, adjusting the mainspring, or manipulating the center of gravity of the boom. Examples of each method

Symmetric Triaxial Seismometers, Fig. 8 Two Galperin-type axis arrangements for a vault instrument (© Nanometrics)

used on Galperin-type instruments are the Streckeisen STS-2 vault instrument that moves a slug on the boom, the various models of Nanometrics Trillium observatory-grade seismometers that adjust the tension on the main-spring, and the Geotech KS54000 borehole seismometer that tilts each axis in its vertical stack.

Mutually orthogonality UVW (and therefore XYZ) directions of sensitivity are maintained because the masses of all three axes are centered using the same technique, taking advantage of the symmetry of the design. Unlike in Fig. 5 that shows how a vertical and horizontal axis can become mutually non-orthogonal, the Galperin designs do not adjust one axis using a different technique than the others. For example, the direction of sensitivity of the Galperin axis depicted in Fig. 7 is fixed by its geometry to be at 90° to the face of the boom. Adjusting the tension of the spring to re-center a deflected mass does not alter the direction of sensitivity, and because the three axes are permanently fixed to a common mounting plate as in Fig. 8, the three UVW directions remain mutually orthogonal.

The commonly desired XYZ horizontal/vertical signals are readily derived from the UVW signals using a vector algebraic transformation:

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \frac{1}{\sqrt{6}} \begin{bmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \\ \sqrt{2} & \sqrt{2} & \sqrt{2} \end{bmatrix} \begin{bmatrix} u \\ v \\ w \end{bmatrix}$$

The inverse transformation derives UVW from XYZ:

$$\begin{bmatrix} u \\ v \\ w \end{bmatrix} = \frac{1}{\sqrt{6}} \begin{bmatrix} 2 & 0 & \sqrt{2} \\ -1 & \sqrt{3} & \sqrt{2} \\ -1 & -\sqrt{3} & \sqrt{2} \end{bmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix}$$

The transformation to the conventional XYZ frame of reference may be done at any point, such as by seismic analysis processing software just before the signals are plotted or used as input to seismic analysis algorithms that assume the XYZ reference frame. However, as a convenience to the operators of seismic signal data centers and the users of the seismic data, most Galperin-type seismometers effect the signal transforms within the instrument by summing the UVW signals in the required proportions using a precision analog mixing circuit. Some seismometers (e.g., Nanometrics Trillium models) allow the operator to optionally configure the instrument to output raw UVW instead of the mixed XYZ if desired, though this is primarily used for instrument troubleshooting rather than for routine recording of seismic data.

Benefits and Drawbacks of the Galperin Configuration

The choice between a Galperin and a conventional configuration is usually regarded as a secondary consideration in specifying an

instrument, as the internal topology of the seismometer does not of itself dictate the performance or reliability of an instrument. However, while either configuration is capable of achieving reliable high performance, the symmetric triaxial configuration does offer some significant benefits to users. The two topologies have distinct characteristics that are useful to consider when selecting, installing, operating, or troubleshooting a broadband seismometer.

Commonly Cited Trade-Offs

Response Matching

Because the designs of a horizontal axis and a vertical axis differ significantly, it requires special effort in design and diligence in manufacture to match the transfer functions of the two different constructions, if they are to provide the same response to ground motion in terms of passband sensitivity, lower corner frequency/phase response, and the upper corner response. Indeed, there is no constraint other than designer or user preference that requires the response of the vertical to match the response of the horizontal component; the two could be markedly different with the manufacturer providing the specifications for each component by giving, for each axis, a frequency/phase response plot or a set of poles and zeros and passband sensitivity. In contrast, because the Galperin configuration requires its cardinal XYZ outputs to be derived as weighted sums of all the UVW components, the design and the manufacturing must ensure that all three components are very closely matched; otherwise the transfer functions of the XYZ outputs become complicated. The symmetrical nature of the Galperin topology helps produce matched responses because the three axes are constructed identically. Manufacturers of Galperin seismometers supplement this advantage with precision machining, trimming of electronics values, and other calibration measures to precisely match axis responses. The precision matching of U, V, and W components in a Galperin design provides assurance to the user that the X, Y, and Z transfer functions are likely to be consistent and the same as any of the U, V, or W transfer functions.

Response matching is easily tested on a Galperin instrument by providing a vertical signal on a high-quality vertical shake table or by injecting the same calibration signal into all three UVW components simultaneously (which is equivalent to providing a calibration input in the vertical direction). The output should be pure vertical; the extent to which signal is present on the X and Y outputs is a measure of response difference between the UVW elements. By sweeping the frequency of the input and recording the vertical and horizontal outputs, the quality of the response matching can be measured across the frequency band.

In contrast, subjecting a conventional XYZ design seismometer to a pure vertical stimulus tests only the vertical axis and does not provide any insight into how well the responses of the three axis components are matched.

Manufacturing Trade-Offs

Some aspects of the design and manufacture of Galperin instruments are simplified or facilitated, while others are made more complex. Obvious advantages to the manufacturer derive from having only one electromechanical axis design within a seismometer. That means there are fewer unique part types to manage, only one style of axis to build and test, and the identical axes can be readily swapped for troubleshooting or repair purposes. On the other hand, a symmetric triaxial seismometer requires a UVW-to-XYZ analog electronic mixing circuit that is not needed in an XYZ design, adding somewhat to the cost of manufacture.

Because the vertical output signal of a symmetric triaxial design is an equally weighted sum of the UVW components, a clean vertical signal provides complete assurance that all three components are well behaved. As the horizontal signals at most surface sites are usually noisier than the vertical due to tilt effects, especially at long periods, it is often feasible to test and qualify the vertical channel but more difficult to do so for the horizontals. This permits the manufacturers of Galperin designs to reliably test the performance of all three sensor elements by qualifying the vertical signal, providing

assurance to the users that all three outputs meet the published specifications. In contrast, the X and Y components of a conventional design cannot be assessed by examining the vertical channel signal.

Reliability Trade-Offs

An often-cited drawback relating to the Galperin configuration is that all three UVW components must be functional and well behaved for any of the XYZ outputs to work (Graizer 2009). It is held that this contrasts with a conventional seismometer where any one of the three components could fail without compromising the other two. This can be seen as a corollary of the fact that a good vertical output from a Galperin configuration provides assurance that all three sensor elements are good.

The spontaneous catastrophic failure of just an individual axis element within an operating seismometer is relatively uncommon. It is more likely for catastrophic failure to occur or be evident at installation time (in which case most operators would choose not to deploy even if there was a good vertical still operating) or for a failure to occur in a way that affects the entire system, such as an electronics fault.

Many seismometers with Galperin configurations provide the ability to remotely choose between UVW and XYZ outputs. In this case, if a failed axis is detected and a site visit is not feasible, high-quality biaxial data can still be recorded after the flip of a switch.

It is possible for an element to develop noise spontaneously, and in this case the conventional design has the advantage: a Galperin design would mix the noisy channel into its vertical output (where it is most easily detected), whereas the conventional XYZ design would only manifest the noise on the output associated with one degraded axis.

A manufacturer can minimize the likelihood of excessive channel noise by ensuring the seismometer self-noise is tested before leaving the factory and by designing the instrument for long-term operation to ensure performance is maintained through the instrument's operating life.

Other Benefits of a Symmetric Triaxial Design

Using the UVW Orientations to Discriminate Noise Sources

The symmetric triaxial configuration makes it possible to distinguish phenomena that occur within one axis element from those that occur independently of one axis element. The operator can use this to advantage, helping diagnose and resolve problems associated with the environment, installation, ancillary equipment, or the seismometer itself. This is discussed in greater detail in the section "Using the Galperin Topology to Help Discriminate Noise Sources" below.

Assuring the Mutual Orthogonality of Component Signals

The three identical and symmetrically arranged sensor elements of the Galperin configuration are fixed to be mutually orthogonal during manufacture. A mass centering operation, whether moving a slug to shift the boom center of gravity or adjusting mainspring tension to return the boom to center, does not alter the mutual orthogonality of the directions of sensitivity. In the first case the sensitivity direction of each axis is shifted by the same amount and so they remain mutually orthogonal. In the latter case, the tension of the main spring does not alter direction of sensitivity and so orthogonality is also preserved. However, a conventional XYZ design tilts the horizontal axes but adjusts the mainspring tension for the vertical, causing the horizontal directions of sensitivity to change relative to the Z axis. This causes the horizontal components to shift relative to the vertical by an angle equivalent to the tilt of the seismometer housing itself. Effectively, the vertical of an XYZ design remains aligned to the housing while the horizontals remain perpendicular to gravity.

Using the Galperin Topology to Help Discriminate Noise Sources

Using a seismometer that has a Galperin design can facilitate identifying noise sources by showing whether they are specific to one axis element

or not. This section discusses noise sources and some methods for troubleshooting noise artifacts that use the characteristics of the symmetric triaxial configuration to advantage.

Noise Sources

A noise artifact is usually apparent only once it is in the seismic record. This record is furthermore the sum of all effects applied by the entire system including the environment, site, seismometer mount, the seismometer itself, cables and connectors, the digitizer, and signal transmission and post-processing. [In this context the “seismometer mount” is a general term that refers to the structure the seismometer is mechanically coupled to. That may be a concrete pier, a gimbal mount such as for an ocean bottom system, surrounding granular substrate as in the case of a buried instrument, a metal bracket affixed to a building structure, and others.] All these components of the end-to-end system must be considered when investigating noise or other signal impairments.

Noise may be generated by processes within the seismometer or by external processes acting on the seismometer. Some noise is expected or unavoidable, such as the manufacturer’s characterized self-noise, or may be indicative of instrument defects such as persistent spurious transient noise event (“pops”) or installation deficiencies such as thermally driven noise or the seismometer shifting or tilting. It is first useful to review some typical sources of internal and external noise.

The sources of noise (defined as any type of additive unwanted signal) in a seismic record include inherent instrument noise (self-noise), environmental effects, excessive instrument noise, installation-driven noise, and ancillary equipment noise. A seismometer’s self-noise is usually specified by the manufacturer, typically as a power spectral density (PSD) plot, and this establishes a performance baseline for an installation. Good installation practice will include mitigating sources of environmental noise as much as is practical. Excessive instrument noise is defined as noise originating within the seismometer in addition to its published self-noise characteristic and may represent variability in the

manufacturing, defects, or failures. Installation-driven noise is defined as a non-seismic signal that originates from poor or defective installation practices. Lastly, noise may also be added by downstream ancillary equipment such as the digitizer.

Environmental and Installation-Driven Sources of Noise

Seismometers respond in varying degrees to many stimuli besides seismic motion, and while seismometer designers try to maximize the immunity or insensitivity of the instrument to everything except translation ground motion, this is difficult to achieve. The installation must also be designed to maximize the effectiveness of the seismometer. An inadequate installation of even the highest performance seismometers can yield very poor results, showing high noise levels and susceptibility to non-seismic environmental inputs. There is therefore significant benefit in tools and techniques that help diagnose installation deficiencies and distinguish them from instrument problems.

Environmental influences on a seismometer that may cause unwanted output signal (noise) include temperature changes, seismic wave-induced tilt, Earth’s magnetic field or fields generated from local equipment, wind-induced ground motion, atmospheric pressure changes, electrical interference induced on the output signal, and other effects. Many environmental influences can be mitigated, such as by providing a temperature stable vault and locating the installation far from vertical structures such as trees that conduct wind noise into the ground. Some are more difficult or even impossible to eliminate, such as apparent vertical accelerations induced by changes in atmospheric pressure, because the apparent acceleration due to gravitation cannot be distinguished from other kinds of acceleration and is relatively insensitive to the depth of the site (Zörn and Wielandt 2007).

Installation-driven noise sources are those that induce motion on the seismometer due to defects in the installation itself. A common example is poor mechanical coupling of the instrument to the ground, which may allow the seismometer to

move relative to the structure being monitored. This can be due to poor mounting, inadequate substrate, poor coupling to the ground, improperly locked mounting feet, or cables applying strain on the seismometer. Such problems most commonly produce tilt noise, but vertical noise is also possible, such as for a seismometer “bouncing” up and down on adjustable feet that have not been tightly locked. Another example is convection-driven air currents within a vault inducing low-frequency horizontal tilt noise. Such noise is produced by slow-moving air currents acting on the seismometer to expand or shrink the sides of its case unevenly and thus tilting it.

A seismometer exhibiting excessive response to environmental stimuli may be indicative of an instrument defect. For example, a leak in the pressure vessel that allows atmospheric air pressure changes to pump air in or out of the seismometer will manifest as a non-seismic vertical signal as the buoyancy of the proof masses responds to internal air density changes. This is most commonly seen in instruments that have access ports that an operator may open, such as to insert a screwdriver for manual mass centering, and that may not be properly closed or where the seals may have degraded.

Sources of Internally Generated Seismometer Noise

All seismometers generate noise internally, that is, they would produce a signal even if the ground was not moving at all. This inherent noise is characteristic of the design and is usually specified in some detail by the manufacturer, although in the case of passive seismometers, the manufacturer will instead usually provide a few parameters from which the self-noise can be estimated. Noise is inherent in electronics circuits due to a multitude of phenomena in conductors and semiconductors, such as thermal noise and flicker noise. The suspended mass and spring has inherent noise due to the Brownian motion of air molecules buffeting the mass, air damping the boom motion, as well as other energy-loss mechanisms. The summation of these effects produces a stationary noise spectrum that is commonly

referred to as the seismometer’s “self-noise,” often represented as a PSD graph and commonly shown together with the New Low Noise Model (NLNM) and New High Noise Model (NHNM) (Peterson 1993). Reputable manufacturers provide this information for each model and produce instruments with performance consistent with their published specifications.

Excessive instrument noise is internally generated noise that exceeds the self-noise specification of the seismometer. There are three broad classes of excessive internal noise:

1. Stationary broadband noise that significantly exceeds the instrument’s published self-noise specification
2. Nonstationary transient noise events, such as pops or spikes
3. Stationary narrowband noise, such as tones or oscillations

A common technique for measuring noise is frequency domain analysis, such as plotting the acceleration power spectral density (PSD) of the seismic data over some time period. While tones are readily distinguishable from broadband noise, nonstationary events such as pops have a broadband spectral characteristic (typically proportional to $1/f^2$) that can mislead the troubleshooter. However, small pops may not be readily identified by examining the time-domain time-series data as they may have amplitudes too small to be distinguished from the background seismic activity.

The Galperin Topology and Noise Source Identification

Being able to demonstrate that a noise phenomenon is peculiar to one particular axis element and not the other two, or conversely that a noise is registered by more than one axis, can be a powerful technique to help isolate and identify noise sources and causes. The Galperin topology facilitates this because its sensor reference coordinate system (UVW) is rotated from the vertical/horizontal (XYZ) coordinate system, providing a powerful way to distinguish instrument noise

Symmetric Triaxial Seismometers, Table 1 Channel characteristics of some possible noise sources (© Nanometrics)

Channels showing non-seismic noise	Potential noise sources						
	Axis mechanics or electronics	Tilt motion	XY oriented seismometer mount (e.g., gimbal)	UVW-XYZ conversion electronics, cable, digitizer	Varying temperature or pressure leaks	Varying magnetic fields	Power supply, electrical/magnetic interference
U, V or W only	Probable						
X or Y only		Possible	Possible	Possible			
Z only				Possible	Possible		
X and Y in some proportion but not Z		Probable					
Equally on all X/Y/Z channels				Possible			Possible
Unequally on X/Y/Z channels						Possible	Possible

sources from environmental or installation phenomena. Many external noise phenomena have a characteristic direction – often horizontal or vertical – and in any case are unlikely to align with one of the U, V, or W directions. Likewise, noise that is associated with a U, V, or W direction provides a clear indication that the noise source is internal and associated with that axis.

Table 1 provides general guidelines for narrowing down the sources of an observed noise signal and provides a starting point for troubleshooting. This presumes the operator is able to perform the essential basics of signal analysis: conversion from XYZ to UVW domains, plotting time series and frequency domain plots such as a PSD, removing instrument frequency response, and the like. Table 1 also presumes the seismometer has a Galperin topology.

Once a noise artifact is recognized and classified (e.g., stationary broadband, nonstationary transient, or stationary narrowband) and characterized as much as possible, the next step is to determine whether it consistently manifests on a specific X, Y, Z, U, V or W channel or a particularly suggestive combination of these channels.

This is equivalent to asking which direction the signal represents. Signals specific to X, Y, or Z suggest East/West, North/South, and up/down motions or phenomena that mimic these. Signals specific to U, V, or W suggest motions in those axis directions or, more likely, phenomena within the axis mimicking this direction. A signal that manifests on X and Y but not (or very little) on Z represents motion in a horizontal direction that is not East/West or North/South, or a phenomena such as tilt that mimics that. A signal that is equal on X, Y, and Z is more likely to be a common-mode electronics noise problem than a real motion in the direction represented.

Because it is unusual to have real seismic motion act exactly along any of these X, Y, Z, U, V, or W directions, signal artifacts with these characteristic directions are more likely to be of non-seismic origin. An exception could be a site expected to have motions exactly along a specific direction, such as a seismometer located near the top of a swaying structure, oriented so that its X channel (say) is aligned with the direction of sway.

Having narrowed the potential sources, it is usually possible to make further deductions from

the character of the signal artifact observed. The next sections discuss typical phenomena and their classifications according to possible sources listed in Table 1.

Axis Mechanics or Electronics: UVW Channel Noise

Noise artifacts apparent on one U, V, or W channel and not on the others point squarely to a noise source associated with that axis. Of course this can only be recognized by transforming the seismic data into the UVW domain to observe that a noise previously apparent on all XYZ channels is suddenly associated with just a single one of the Galperin axis elements. Noise that is vertical (Z only) or horizontal (some combination of X and Y) cannot have a source within a Galperin-type axis.

A noise event commonly attributed to highly sensitive broadband seismometers is that of pops, otherwise known as spikes or steps. These are sudden sharp excursions in the seismic waveform that appear as if there had been a sudden step in acceleration. This can be the result of spontaneous movements at a microscopic level within the axis mechanism or sudden shifting of the seismometer itself due to installation or mounting problems. If a pop is evident only on one U, V, or W axis, it is due to spontaneous movement within the axis, such as some mechanical stress or strain suddenly relaxing. Inadequate design, assembly flaws, component defects, or rough handling can give rise to excessive rate of pops in an axis. One indication of excessive axis pops is when the PSD is plotted for the U, V, and W signals and there is a well-defined $1/f^2$ spectrum in the lowest frequency band of one of the axes. It is well known that seismometers are more prone to pop noise when first manufactured, installed in a new location, or acclimating to a new environment as stresses are relieved.

Excessive broadband axis noise (specific to a U, V, or W axis) can be due to electronics noise, for example, excessive current noise due to components not meeting specification.

Excessive axis-specific narrow band noise is less common, but can occur if there is excessive

loop gain or insufficient phase margin in the control loop of one axis. This would generally suggest a manufacturing or design defect and could also be the consequence of component failure or rough handling.

A signal impairment specific to one U, V, or W axis such as zero signal or railed signal suggests an axis failure, such as failure to center, or a failure of the electronic circuitry associated with that axis.

Likewise, a non-seismic noise or other impairment (such as zero signal or railed signal) that is not limited to a U, V, or W channel but manifests as a horizontal or vertical signal cannot be an axis problem but must have some other origin, as indicated in Table 1. The following sections discuss these other potential noise origins.

Tilt Effects: XY Channel Noise

The most common sources of noise are installation deficiencies and environmental stimuli, often where inadequate installation fails to counter environmental drivers such as temperature changes or air currents. Some of these effects are quite subtle but can create significant noise artifacts. It is quite common to see horizontal noise levels for a seismic station be significantly greater than the vertical noise floor (Hanka 2002). While horizontal noise could be ascribed to noisier horizontal components in a conventional XYZ design, with a Galperin topology with identical UVW elements, noisier horizontal data can definitively be attributed to a process external to the seismometer.

Because tilt mixes gravitational acceleration into the horizontal channels in direct proportion to the tilt, and because gravity is significant compared with the small accelerations due to background seismicity, even sudden tilts of less than a millionth of a degree will be registered by broadband seismometers and appear as noise artifacts. The effect is far less significant for vertical because gravity mixes to the vertical in proportion to the cosine of the tilt angle, which is a near-zero effect for small angles.

Seismic waves traveling on the surface of the Earth that produce vertical translation motion (like a cork bobbing on the waves of an ocean)

also cause tilt: one can visualize a raft on the same ocean that tilts one way as it rises up one side of the wave and then tilts the other way as it falls. The rise/fall is vertical motion the seismometer will faithfully record, but the tilt induces a small varying sideways component of gravity producing a noise signal on the horizontal channels in addition to the real horizontal motion. Because tilt motion is inherent in seismic motion at the Earth's surface, horizontal tilt noise cannot always be mitigated. However, excessive tilt noise and in particular sudden discrete tilt events are usually indicative of installation problems that should be addressed.

Noise artifacts that appear on X and/or Y but not Z are horizontal and often represent the seismometer tilting in some manner. There are many potential causes and sources of tilt, and so it is useful to further characterize the noise. Sudden isolated transitions are suggestive of rapid discrete tilt events, oscillations can indicate rocking behavior, and broadband horizontal noise may indicate continual random tilting. Steps that occur with a consistent polarity suggest a series of tilts in the same direction, as may happen if the seismometer is slumping in discrete steps to one side. Steps that alternate polarity may indicate a back-and-forth tipping action. The direction of the tilt is indicated by the proportion of X-to-Y noise, and some combination of X and Y (with very little Z) noise is a further confirmation of probable tilt action.

Atmospheric pressure changes acting on a sealed vessel such as a seismometer will deform the vessel to some extent, and because tilts much less than 10^{-6} of a degree can generate noise, even miniscule deformations can matter. Seismometer designers generally take great care to ensure those deformations do not act to tilt the internal sensing elements; otherwise horizontal noise driven by weather changes would be inherent in the instrument (Widmer-Schmidrig and Kurrel 2006). In a well-designed instrument, pressure-driven tilt should not be evident. It is also difficult for a manufacturing or component defect to give rise to pressure-tilt sensitivity; the design either has sufficient pressure immunity or it does not. The inherent symmetry of a Galperin-

type topology also provides more opportunity to the designer to optimize pressure vessels with highly symmetric internal mounting arrangements that attenuate pressure vessel deformation effects.

XY-Oriented Seismometer Mount: X or Y Noise

For Galperin-type seismometers, tilt that is aligned strictly with either the X (East) or Y (North) direction is of special interest: while it is possible for tilt to coincide with the X or Y, there may be a specific reason for tilt to occur in a well-defined and aligned orientation. For example, an unlocked foot that is positioned in line with East or North could be suspected, or the seismometer may be mounted on some structure that may tend to tilt in a particular direction. With a conventional XYZ seismometer, X- or Y-aligned noise could either be related to the internal X or Y axes or be due to external tilting. A symmetric triaxial construction experiencing such noise clearly points to an external cause, and when the tilt direction is highly aligned with X or Y, or in some other specific direction in line with a particular mounting feature such as a foot, it provides a useful indication of the likely trouble spot.

A special instance of this is when a Galperin-type seismometer is mounted within a moveable platform, such as a leveling gimbal for ocean bottom deployment. If tilt events are clear in the data and strictly oriented in line with the potential movement of the platform, it is suggestive of gimbal platform movement.

Output Stage Electronics, Cable, and Digitizer: X, Y, Z, or XYZ Noise

Single X, Y, or Z Channel Noise

The only electronics internal to a typical symmetric triaxial seismometer which are specific to a single X, Y, or Z output channel are the UVW-to-XYZ coordinate-conversion circuits that combine the UVW signals to produce XYZ outputs, the signal output drivers, internal cabling, and external connector. It is rare to see noise problems originate from these areas, but it

is possible for the failure of an electronic component to cause a failure of one output channel (or one side of a differential output channel that then would manifest itself as a half-amplitude signal on one channel).

Because the signal is in the XYZ domain from the seismometer onwards, the cable and digitizer must be suspected when troubleshooting. Because the output stage electronics are relatively simple and usually reliable, it is more common for the cause of single-channel or common-mode XYZ failures or noise to be associated with the downstream digitizer or the cable connecting the seismometer to the digitizer.

It is useful to determine if noise apparent on a single output channel is predominantly or exclusively evident on that channel. If there is no attenuated version of that noise on the other channels, it is likely to represent a failure or deficiency of hardware associated with that channel, such as a connector pin or digitizer channel problem. Noise appearing predominantly on one output channel but also on the others in an attenuated form points to an effect predominantly aligned with that channel but not exclusive to it, such as tilt along the X direction.

Predominant But Not Exclusive Z Channel Noise

A special case of single-channel noise is Z channel noise. That is because the Z (vertical) channel is produced by an equally weighted sum of the UVW axis signals, and so any phenomena that affects all axis elements equally will manifest predominately on the Z channel. Therefore, Z channel noise could originate from within the seismometer due to a common-mode effect acting on all axis elements or from an external fault on the Z channel in the cable or digitizer. One can usually determine which by the nature of the noise or impairment and also by determining if the noise or impairment is exclusively or just predominately on the Z channel. A common-mode effect acting on all axis elements will predominately manifest on the Z channel, but usually there are slight differences in sensitivity to these effects from axis to axis, so some attenuated version of that noise on the X and

Y channels may be present. If the impairment is external, such as a noisy digitizer Z channel, it is much less likely to leak into the X and Y channels.

Common-Mode XYZ Channel Noise

A noise source or impairment that affects all output channels more or less equally (known as a common-mode characteristic) could be associated with the seismometer electronics that serve common functions such as power conversion and control circuits, but is more likely an external common-mode effect, such as noise induced on all input channels to the digitizer by electrical interference. Common-mode XYZ cannot be problems with any or all of the internal Galperin axis elements, because these would manifest in the U, V, W, or Z directions, respectively, never in the direction corresponding to equal XYZ signals.

Temperature Changes and Pressure Leaks: Z Channel Noise

The most common sources of predominately Z channel broadband noise are environmental effects acting on the seismometer, such as varying temperature or pressure leaks. Seismometers respond to temperature changes in part because thermoelastic effects act on the spring that suspends the proof mass against gravity, causing apparent changes in acceleration. These are slow effects and therefore affect low-frequency noise performance. The three axis elements will usually have a similar but not exactly equal sensitivity to temperature changes, manifesting as predominately Z channel noise with much smaller effects on X and Y.

A leak in the pressure vessel of the seismometer would allow air to pump in or out driven by atmospheric pressure changes, and this would cause the proof masses to rise or fall buoyed by changing air density inside the vessel. This creates a very pronounced noise that is strongly vertical. Pressure leaks mostly arise in seismometers that provide service access ports such as for manual mass centering that may not have been properly closed or where the seals have deteriorated.

Magnetic Field Effects: Unequal XYZ Noise

Broadband seismometers are designed to be as insensitive as possible to changes in external magnetic fields, but some sensitivity is almost inevitable (Forbriger et al. 2010). Springs designed to be relatively insensitive to temperature changes are often fabricated from magnetic materials and so have small but measurable forces applied by the Earth's magnetic field. These can manifest as low-amplitude noise at long periods. Each axis will be sensitive to the direction as well as the strength of the geomagnetic field. Because the direction of the Earth's magnetic field differs depending on location, the effect of changing magnetic fields is not equal on all axis elements, nor are the relative proportions among axis elements consistent or predictable. These are typically small effects and usually only of concern for very high-quality low-noise sites with very low-noise seismometers. Mitigation strategies can include augmenting magnetic shielding.

Electronic Interference: Equal or Unequal XYZ Noise

Noise that appears on all channels may arise from interference of nearby electrical equipment. A common-mode noise appearing equally (or nearly equally) on all channels could indicate a conducted or radiated noise source from a power source such as a battery charger cycling, a nearby motor, or similar problem. The interference is unlikely to be affecting the seismometer itself, as noise induced into the three Galperin axis elements manifests as predominately vertical (Z) channel signals. Induced noise affecting all channels is likely to suggest a cable or digitizer vulnerability or issue of some sort. Mitigation typically includes determining the source if possible, improving shielding or grounding, and changing cables, digitizers, or power sources if faults are suspected.

Summary

A seismometer that is designed using a Galperin arrangement has three identical sensing elements with their directions of sensitivity arranged to be mutually orthogonal, and inclined up from the

horizontal plane at an angle of $\theta_0 \cong 35.26^\circ$. This is a subclass of the more general “symmetric triaxial” configuration in which three axis elements are identical and symmetrically arranged with respect to each other. The signals from the three sensors, designated U, V, and W, are usually remixed by analog circuitry within the seismometer to provide a vertical and two horizontal outputs equivalent to a conventional XYZ seismometer. The benefits of the symmetric triaxial approach pertain to site and instrument troubleshooting, channel response matching, ease of manufacturing and testing, reliability, and channel orthogonality. The most frequently cited drawback is that all three axis elements must be functional for any of the three XYZ seismic signal outputs to be valid. The high reliability of the best seismometer designs largely mitigates this concern, and it is furthermore avoided by choosing a seismometer which allows the user to remotely select UVW signals to be output in place of the mixed XYZ in the event of a single axis failure. The second cited drawback inherent in the symmetric triaxial configuration is the requirement for an internal analog electronic mixing circuit to convert UVW to XYZ, although in a well-designed seismometer, this is invisible to the user.

A primary benefit of the Galperin approach is that, because the UVW coordinate systems are different from the XYZ horizontal/vertical reference system, noise sources and faults within an axis are distinguishable from problems that manifest in primarily vertical or horizontal directions. A corollary to this is that a properly functioning vertical channel on a Galperin instrument is a reliable indication that all three UVW elements are good, since the vertical is an equal sum of the three Galperin axes. Response matching is necessary for Galperin instruments to enable proper remixing to XYZ outputs, providing assurance of consistent response independent of the direction of motion. Galperin designs also generally assure rigid orthogonality of the XYZ outputs, whereas the tilting of the horizontal elements in the mass centering operation of conventional designs can produce deviations in X and Y orientation relative to the fixed vertical axis. Manufacturing benefits include having one

rather than two axis designs to build and improved ability to test and troubleshoot.

A review of noise sources and characteristics and how their directions align relative to the separate Galperin and horizontal/vertical coordinate systems demonstrates the powerful utility of using a symmetric triaxial configuration to help discriminate and diagnose potential noise problems with the site, installation, or seismometer.

In summary, the Galperin geometry has proven to offer significant benefits to seismometer users and manufacturers and through use and experience has proven to have significant additional benefits in terms of remotely troubleshooting station noise.

Damage identification; Nondestructive evaluation; Structural damage; Structural health monitoring; System identification

Introduction

Definitions

Structural damage	Changes in a structural system that adversely affect its performance
System identification	Process of extracting the properties (often dynamic) of a system from measured output or input-output data
Damage identification	Process of detecting, localizing, and quantifying damage in a system
Structural health monitoring	Process of global damage identification in a structural system
Nondestructive evaluation	Process of local damage identification in a structural system

Major structural failures in recent years have brought the public's attention to the urgent need for improved infrastructure monitoring and maintenance. In their latest report card for America's infrastructure (American Society of Civil Engineers 2009), the American Society of Civil

Engineers (ASCE) described an infrastructure that is poorly maintained, unable to meet current and future demands, and, in some cases, unsafe. Expanding and improving structural health monitoring [C1] (SHM) for damage assessment and maintenance is essential for establishing sustainable and resilient civil infrastructure systems and ensuring they can meet the needs of future users. SHM refers to the process of damage identification in a structural system. Damage identification can be performed at four levels: (1) detection, i.e., estimating the existence of damage; (2) localization; (3) quantification; and (4) prognosis, i.e., predicting the remaining useful life of the structure. System identification refers to the process of extracting a system's dynamic properties from the measured data. System identification can be performed to extract damage-sensitive features of a system from its measured data to be used for the estimation of damage (Aktan et al. 1997). It can also be used to “realize” (i.e., identify) a mathematical dynamic model that best predicts the measured output data from the measured input excitation or the statistical correlation structure of the measured output data in the case of output-only measurements. The realized model can then be used to predict the structural response to different deterministic input excitations or the response correlation matrix to different stochastic excitations. Recent advances in sensing and computational power provide an opportunity for improved system and damage identification of large-scale and complex civil structures. The ASCE technical report (Catbas et al. 2013) provides a comprehensive review of the current state-of-the-art approaches, methods, and technologies for effective practices of system and damage identification methods on civil structures. While many researchers have successfully applied various identification approaches to numerical and/or small-scale lab models of civil structures, the literature lacks successful applications to real-world structures in the real loading environment. A recent special issue of the ASCE Journal of Structural Engineering (Moaveni et al. 2013a) was devoted to help bridge this gap.

System Identification

As previously mentioned, system identification refers to the process of estimating the dynamic properties of a structural system from its measured data. System identification methods can be categorized into input–output versus output-only, parametric versus nonparametric, time-domain versus frequency-domain, or linear versus nonlinear methods. Input–output system identification methods also referred to as experimental modal analysis [C2] (EMA) methods extract the dynamic system properties based on measurement data of both the dynamic response and the input excitation. On the other hand, output-only methods or operational modal analysis (OMA) methods [C3] are used when only the measured (ambient) response of a structure is available. OMA methods are suitable when the input excitation is not measureable and can be assumed as a broadband random signal such as wind loads on a building or bridge or vehicular traffic on a bridge. These methods are very useful in situations involving large-scale civil structures which are difficult to excite experimentally.

A system identification method is considered parametric if a mathematical dynamic model (often formulated in state-space) is “realized” in a first step and the dynamic properties of the system estimated from the realized model in the second step. Nonparametric system identification methods directly estimate the dynamic parameters of a system from transformation of data, e.g., Fourier transform or power-spectral density estimation. Time-domain identification methods estimate the dynamic parameters of a system by directly using the measured response time histories, while frequency-domain methods use the Fourier transformation or power-spectral density estimation of the measured time histories. There is also a class of time-frequency methods such as the short-time Fourier transform and the wavelet transform. These methods are commonly used for identification of time-varying systems in which the dynamic properties are time-variant. Linear system identification methods are based on the assumption that the system behaves linearly and

the identified dynamic properties correspond to an underlying linear system. Nonlinear methods [C4] assume specific types of nonlinearities in the system and its dynamic response and provide parameter estimates of the considered nonlinear model class. Nonlinear system identification is a challenging task due to the complex nature of nonlinearities encountered in civil structures and is the subject of ongoing research by many investigators.

A large number of system identification methods have been used successfully for identification of civil structures. Some of the more commonly used system identification methods in the literature include the peak picking method (both input–output and output-only, nonparametric, frequency domain, linear); the frequency-domain decomposition and enhanced frequency-domain decomposition methods (output-only, nonparametric, frequency domain, linear); the class of prediction error methods such as the auto-regressive (AR), auto-regressive with moving average (ARMA), auto-regressive with exogenous input (ARX), ARMAX, ARIMA, CARIMA, output error, and Box-Jenkins methods (input–output except AR, parametric, time domain, linear); subspace-based methods such as the eigensystem realization algorithm (ERA), the natural excitation technique combined with ERA (NExT-ERA), stochastic subspace identification (SSI), and deterministic–stochastic subspace identification (DSI) (output-only except DSI, parametric, time domain, linear); time-frequency methods such as the short-time Fourier transform, the wavelet transform, Hilbert-Huang transform, and proper orthogonal decomposition in combination with Hilbert transform or the wavelet transform (output-only, nonparametric, time frequency domain, nonlinear); and time-varying prediction error methods such as TV-ARX and TV-ARMA (input–output, parametric, time domain, nonlinear).

Damage Identification

Damage identification methods for structural systems are generally categorized into two groups:

(1) global methods (also referred to as SHM methods) and (2) local methods (also referred to as nondestructive evaluation or NDE methods). The global methods are usually applied for macroscopic damage identification of large-scale structures when there is no a priori knowledge about the location of damage and the instrumentation of the monitored structure is relatively scarce. In this case, damage is generally detected as the equivalent or effective loss of stiffness in large segments of structure (i.e., substructures). The local methods are applied when the monitoring region is smaller in size (due to, e.g., knowledge about the potential damage location(s)) and more dense (spatially) sensor data are available. NDE methods are commonly applied for monitoring aerospace structures, pipelines, and train tracks among others. These methods are capable of providing more accurate detection, localization, and quantification of damage; however, they are not in general suitable for application to larger structural systems such as building and bridges. Among NDE methods, acoustic emission, infrared thermography, and ultrasound methods can be named. Among global damage identification methods, vibration-based methods [C5] have received increased attention in the civil engineering research community in the last decade. The basic concept behind vibration-based damage identification is that the dynamic parameters of a structure are functions of its physical properties (mass, damping, and stiffness). Therefore, in concept, changes in these physical properties due to structural damage are detectable through changes in the identified dynamic parameters. One of the most common classes of methods is finite element (FE) model updating (Friswell and Mottershead 1995) which is able to detect, locate, and quantify damage. This method consists of updating the physical parameters of a FE model of the structure by minimizing an objective function that expresses the discrepancy between FE-predicted and experimentally measured response or dynamic features extracted from the response that are sensitive to damage. Dynamic features that are most commonly used for damage identification are modal parameters (especially natural frequencies and mode shapes) and the

System and Damage Identification of Civil Structures, Fig. 1 Dowling hall footbridge (*left*) and placement of concrete blocks on the bridge (*right*)

process of extracting modal parameters from vibration data is referred to as modal identification or system identification.

Damage identification methods can also be categorized into model-based methods and model-free or data-driven methods. In model-based damage identification methods, a physics-based model of the structure such as a FE model is used in the process of damage identification. These methods account for the known information about the geometry and material properties of the structure and are usually capable of detecting, localizing, and quantifying damage (level 3). Data-driven methods directly make use of the measured data on a structure and are usually capable of detection and sometimes localization of damage (level 1 or level 2). Some of the damage identification methods in the literature include methods based on changes in modal parameters such as natural frequencies and mode shapes; methods based on changes in features derived from modal parameters such as curvature mode shapes, modal strain energy, and modal flexibility; methods based on signal processing such as principal component analysis, Kalman filtering, and Hilbert–Huang transformation; and finally methods based on FE model updating.

Sample Case Studies

In this section, applications of system and damage identification methods to four large-scale civil structures are reviewed. Note that this is

not a comprehensive list of successful applications by any means and only includes a few of the authors' past work based on which some of the conclusions are drawn.

Dowling Hall Footbridge

Dowling Hall Footbridge, a full-scale footbridge located on the Tufts University campus as shown in Fig. 1, is equipped with a continuous monitoring system that measures continuously ambient vibration and temperature of the bridge. Modal parameters of the footbridge are identified every hour using an automated SSI method (Moser and Moaveni 2011; Moaveni and Behmanesh 2012). Correlation of the identified natural frequencies with ambient temperatures was investigated and different models were proposed to capture the relationship. Effects of physical damage were physically simulated on this test-bed structure by loading a small segment of the footbridge deck with concrete blocks (Fig. 1, right) so as to locally modify the bridge inertia properties since no damage could be inflicted to the bridge to modify its stiffness properties. Deterministic and probabilistic FE model updating approaches were implemented for damage identification of the bridge (Behmanesh and Moaveni 2014). Both methods could successfully estimate the location and extent of damage (here change in mass). However, the probabilistic (Bayesian) method could also provide the level of confidence in the damage identification results by estimating the posterior probability distributions of the FE model updating parameters.

Lessons Learned: The maximum a posteriori (MAP) estimates of the updating model parameters match the values of the physically simulated damage (i.e., local change in mass) and are in good agreement with the optimum parameter values obtained from the deterministic FE model updating approach. Effects of the number of data sets used in the damage identification process (i.e., “value” of added data) were investigated by using different subsets of available data and it was found that the estimation uncertainty of the updating model parameters is significantly reduced by adding more data sets to the likelihood function, which yields more accurate model updating results. However, the reduction in estimation uncertainty becomes progressively less significant as the number of data sets keeps increasing. In the application of deterministic FE model updating, addition of more data sets does not necessarily reduce the estimation uncertainty of the model updating results. Thus, probabilistic FE model updating approaches based on multiple sets of measurement data are strongly recommended for structural damage identification purposes as they can provide a measure of confidence to the estimated damage values.

Seven-Story Shear Wall Building Section

A full-scale seven-story reinforced concrete (RC) shear wall building section, shown in Fig. 2, was tested on the UCSD-NEES shake table in the period October 2005–January 2006. The shake table tests were designed to damage the building progressively through several historical earthquake ground motions reproduced on the shake table. At several levels of damage, ambient vibration tests and low-amplitude white-noise base excitation tests were applied to the building which responded as a quasi-linear system with dynamic parameters evolving as a function of structural damage. Six different state-of-the-art system identification methods including three output-only and three input–output methods were used to estimate the modal parameters (natural frequencies, damping ratios, and mode shapes) of the building in its undamaged (baseline) and various damage states

System and Damage Identification of Civil Structures, Fig. 2 Seven-story shear wall test structure

(Moaveni et al. 2011). Deterministic and probabilistic finite element (FE) model updating strategies were applied for vibration-based damage identification of the test specimen (Moaveni et al. 2010; Simeon et al. 2013). Three damage identification cases are considered based on modal parameters identified using ambient vibration, 0.03 and 0.05 g white-noise base excitation test data, respectively. The damage identification results obtained for these three cases do not match exactly, but they are consistent with the actual damage observed in the building which shows a concentration of damage at the bottom two stories of the web wall. The ambient vibration data satisfy better the assumption of system linearity and therefore are more appropriate as input for linear FE model updating.

Lessons Learned: From the results of the system identification study, it was observed that the identified natural frequencies of the three longitudinal

(in the direction of shaking) vibration modes decrease with increasing level of damage, while the corresponding identified modal damping ratios do not follow a clear trend as a function of structural damage. The (effective) natural frequencies of the three longitudinal vibration modes identified based on higher amplitude structural response data are in general lower than their counterparts identified based on low-amplitude response data at all damage states considered, especially for the first longitudinal vibration mode. This is most likely due to the fact that the test structure was nonlinear (even at the relatively low levels of excitation considered in the system identification study) with effective modal parameters depending strongly on the amplitude of the excitation and therefore of the structural response. In general, higher modal damping ratios were identified for the three longitudinal vibration modes during the higher amplitude base excitation tests. This is due to the fact that the additional hysteretic energy dissipation (due to inelastic action of the material) at higher level of response nonlinearity is identified as equivalent viscous damping by the linear system identification methods used. It should be emphasized that these “inflated” identified equivalent viscous damping ratios are not to be used to represent the viscous damping component in a nonlinear FE model of a structure that explicitly accounts for the nonlinear material behavior. The damage identification results obtained using a linear FE model updating approach are sensitive to the amplitude of the white-noise base excitation to which the structure is assumed to respond quasi-linearly. With increasing level of base excitation and structural damage, the level of nonlinearity in the structural response increases. Therefore, the assumption that the structure behaves as a quasi-linear dynamic system is violated and a linear dynamic model is not strictly able to represent well the behavior of a damaged structure. The spatial distribution (i.e., relative amplitudes) of the identified damage factors however is not sensitive to the amplitude of base excitation and was found in good agreement with the

damage observed or inferred (from strain sensors) in the building specimen. The Bayesian FE model updating approach also succeeded in identifying the damage in the test structure and the results obtained were found in good agreement with their deterministic counterparts. The probabilistic model updating method also provided an estimate for the uncertainties in the identified damage values. It was found that the data used contained little information about the state of the top stories of the building, as shown by the fact that the uncertainty of the parameters representing this portion of the structure could not be reduced through Bayesian processing of the observed data.

Three-Story RC Frame with Masonry Infilled Walls

A deterministic linear FE model updating strategy was applied for vibration-based damage identification of a 2/3-scale, three-story, two-bay, infilled RC frame, tested on the UCSD-NEES outdoor shake table (Moaveni et al. 2013b). Figure 3 shows the test structure on the shake table. FE model updating was first used to calibrate the FE model at the undamaged state which served as the reference/baseline state and then applied for damage identification at a number of damage states of the structure. These damage states correspond to states of increasing damage of the physical specimen which was subjected to a sequence of earthquake excitations of increasing intensity. The damage identification results indicate that the severity of structural damage increases as the structure is exposed to stronger earthquake excitations. The damage identification method correctly identifies the spatial distribution of damage in the structure, with the most severe damage at the bottom story and the least damage at the top story. The method also captures the fact that the extent of damage is more significant in the infill walls than in the columns. The analytical modal parameters obtained from the updated FE models are in good agreement with their experimentally identified counterparts, an indication of the accuracy of the updated FE models.

System and Damage Identification of Civil Structures, Fig. 3 Front view (*left*) and side view of the three-story reinforced concrete frame with masonry infilled walls (*right*)

System and Damage Identification of Civil Structures, Fig. 4 Three-story precast concrete parking garage test structure

Lessons Learned: Comparison of the damage identification results and the seismic shake table test results shows that the level of damage identified may not reflect the loss of the structural strength, since the loss of stiffness (commonly defined as structural damage) is not well correlated to the loss of strength. This motivates the need for new research based on nonlinear FE model updating based on calibrated, mechanics-based, nonlinear FE models of structural systems able to capture stiffness degradation and strength deterioration phenomena.

Three-Story Precast Concrete Parking Garage

This study performed damage assessment through system identification of a three-story half-scale precast concrete building resembling a parking garage tested under earthquake type loading on the NEES-UCSD Shake Table in 2008 (Belleri et al. 2014). Figure 4 shows the parking garage test structure on the NEES-UCSD shake table. The system identification was performed using the DSI method. The effective modal parameters of the structure at different damage states show significant changes after

each of the high intensity earthquake tests. In general, the identified natural frequencies decrease and the identified damping ratios increase as the structure is exposed to base excitations of increasing intensity. Changes in the identified modal parameters are correlated with the observed damage in the structure. The analysis of the identified mode shapes allow to point to the location of damage. Specifically, localized changes in the first and second spatial derivatives of mode shapes, modal rotations, and curvatures indicate local losses of shear and bending stiffness, respectively. Local significant changes in modal rotations and curvatures allowed localizing both visually detected damage in the third floor mid-span joint and visually undetected damage in the second floor mid-span joint, thus providing a useful tool for precast floor damage detection.

Lessons Learned: The accuracy and spatial resolution of the damage identification results depend significantly on the accuracy and completeness of the identified modal parameters. The estimation variability (or uncertainty) of the modal parameters can be influenced by several factors such as the number and types of sensors, measurement noise, length of the data time windows used for system identification, and the system identification method used, in addition to changes in the environmental conditions such as the ambient air temperature and relative humidity during data collection. The variability in the identified modal parameters due to non-damage related factors needs to be smaller than the changes in these parameters due to damage or compensated for in order to identify the actual damage in the structure using vibration measurements.

Summary

This paper provides an overview of the concepts of system identification and damage identification of civil structures. First, the need for system and damage identification of civil structures is underlined and the current gap in the knowledge

is discussed. System identification and damage identification processes are defined and some of the popular methods for application to civil structures are mentioned. Finally, a few successful applications to large-scale civil structures are provided as illustrations and conclusions are drawn from these studies.

Introduction

As societies developed it was seen as desirable to build buildings in “permanent” materials such as stone and brick, rather than materials such as timber and thatch. This became more desirable as settlements increased in size and buildings were built closer together. This increases the risk of rapid fire spread between closely spaced buildings with timber claddings and thatch or other combustible roofs. Prior to the advent of modern fire fighting equipment and organizations, and automatic suppression systems in the late nineteenth century, noncombustible materials were the only way of preventing fire spread between and within buildings. This is reflected in the earliest building codes which predominantly dealt with designing buildings to prevent urban conflagrations, such as the Roman ordinances

reported by Klitze (1959). This desire for permanent materials, however, led to another risk, that of building failures in earthquakes.

Timber frame buildings have an inherent resistance to earthquakes. As the loads induced by earthquakes are directly proportional to building mass and increase with the stiffness of a structural system, timber buildings, with their light mass and low stiffness, result in reduced earthquake loads. Timber connections, in the main, are relatively flexible. This has the effect of reducing earthquake loads as movement in connections further reduces the stiffness of the structural system. In the event of failure, it is more survivable in a light weight structure than one with heavy elements. In earthquake-prone regions, the concept that permanent materials were better did not take hold, with no better example than Japan with its long history of both earthquakes and timber buildings. For the Kobe earthquake of 1995, the fatality rate in timber buildings was estimated at 2 % but 15 % in reinforced concrete buildings (Langham 1995). In New Zealand, a country with similar seismicity to Japan, timber buildings were common as European settlement increased in the nineteenth century, as timber was readily available. The predominantly British colonists however valued masonry buildings, but this attitude changed significantly after the magnitude 8+ Wairarapa Earthquake in 1855.

In the past the size of timber frame structures was limited by the available length and girth of

structural elements cut from timbers. In some significant buildings, very large timber elements were sourced to produce very large structures. Very long spans were achieved by joining separate timber elements into trusses or frames, for example, Westminster Hall in London and Kiyomizudera Temple in Kyoto. In the nineteenth- and twentieth-century, large timbers have been hard to source, and most timber frame structures were of small scale, until the advent of glue laminated timber (glulam), starting in the 1960s, and laminated veneer lumber (LVL) which became widely available in the 1990s.

As timber structures have tended to be low or medium rise, and the inherent mass and stiffness of timber structures is low, lateral loading is often governed by wind load rather than earthquake loads. For many buildings in many areas, design for wind loads was sufficient to provide adequate resistance to earthquake loads.

The design of timber frame structures has really split into two areas, light timber frame structures, most commonly used for low-rise residential dwellings and similar-sized buildings, and heavy timber frame buildings, most commonly as single-story long-span structures. Timber is suited to long-span roof structures because in roofs, most of the load is self-weight of the structural elements and timber has low self-weight. Light timber frame has been used for low- to medium-rise apartment complexes, a development originating in the Pacific Northwest of the United States and the western seaboard of Canada. More recent developments in connection details for glulam and LVL moment-resisting frame buildings have enhanced their suitability for multistory heavy timber frame buildings.

As concerns around sustainability grow, the use of timber in buildings is becoming more desirable as timber is grown rather than manufactured with low embodied energy (John et al. 2009). During the life of the structure, the carbon sequestered in the timber as it grew is stored and therefore not released to the atmosphere until after the building is demolished.

This entry will start with some background on timber properties and how they affect earthquake

resistance and then go into more detail on light and heavy timber frame buildings separately. For the purposes of this entry, light timber frames are defined as smaller timber elements that require panel bracing as secondary elements and heavy timber frames as other types of structures.

Timber Properties

Timber is a natural, not manufactured, material; therefore its properties cannot be determined by design. The strength of a piece of timber is predominantly determined by defects such as knots and sloping grain (grain that is running at an angle to the cut surfaces of the piece of timber). Strength and stiffness are variable even after timber has been graded visually or mechanically based on stiffness. Figure 1 shows the variation of strength and stiffness of the same species of timber within a grade.

Mechanically stress-graded timber is graded based on stiffness, but as can be seen in Fig. 1, strength is not directly proportional to stiffness.

The strength and stiffness of timber are highly dependent on species, with values of 4.7 MPa and 460 MPa for the strength and stiffness of balsa, respectively, to 84 MPa and 21.5 GPa, respectively, for “box,” an Australian hardwood. In structural terms “hardwood” and softwood” can be misnomers, as they are a botanical classification, with hardwoods being crudely, flowering trees, and softwoods trees that do not flower. Technically balsa is a hardwood.

At a microscopic level, timber consists mostly of long cylindrical cells, orientated along the trunk or branches of a tree (Fig. 2), held together by lignin which acts as a “glue.” This arrangement explains the difference in strength perpendicular and parallel to the grain in timber (Fig. 3), as the cells are orientated to take the load along the trunk of the tree. It also partly explains the weaker strength in tension, as it is easier to break the lignin in tension in a brittle failure, whereas in compression the lignin can yield and the cell walls buckle in a ductile fashion. Hence timber is brittle in tension and ductile in compression. In bending, the timber will initially yield in a ductile

Timber Structures,

Fig. 1 Typical variation of strength and stiffness for timber

Timber Structures,

Fig. 2 Cellular structure of timber (Buchanan 2007)

manner in compression but will eventually fail with a brittle tension failure in the extreme tension fiber which then rapidly propagates through the rest of the member, as the effective section depth decreases, and hence stress in the extreme tension fiber increases. Defects such as knots and sloping grain also have more effect in tension than compression, further explaining the

difference between tension and compressions strength. A material such as timber that has different properties in different directions is known as "anisotropic." As the physical makeup of timber varies over its volume, it is also known as "nonhomogeneous" or literally not the same.

Timber behaves better in compression and bending, the way in which trees resist their

Timber Structures, Fig. 3 Strength in timber in compression and tension, perpendicular and parallel to the grain (Buchanan 2007)

natural loading, as trees have evolved to resist compression from its self-weight acting down the trunk and bending from wind loads.

Good earthquake design for timber requires that timber elements are loaded in the fashion they are best suited to, that is, in bending or compression parallel to grain, where timber is both stronger and more ductile. However few building failures are caused by failure of the main structural elements. More failures are caused by poor detailing of connections, both timber to timber connections and timber connections to other materials such as concrete foundations.

Connections

Good performance of timber structures requires good detailing of connections, but for timber as well as taking care to ensure that connections are not compromised by secondary moments that caused eccentricities of loads at joints, joint design must take into account the anisotropic nature of timber. In particular care must be taken that fasteners do not produce excessive loads in tension perpendicular to the grain, the worst way to load timber. Timber codes have limits on minimum fastener spacing to avoid this problem, but as with any joint design, secondary moments may cause additional loading on

fasteners at the edges of fastener groups which if not addressed can lead to progressive “unzipping” failures of connections, where the most highly stressed fastener at the edge of a group fails, leading to higher stress on the next fastener which then fails and so it continues until the joint fails.

Timber connections can be designed for ductility but a feature common to most types of timber connections is that the hysteresis loops under cyclic loading are “pinched” (Fig. 4).

This “pinching” is caused by the system having less stiffness when unloaded than when loaded. The other feature to note is that the stiffness of the system decreases with each load cycle and is only recovered when the displacement exceeds the maximum displacement reached on the previous load cycle. The area within the hysteresis loop represents energy as it is a force times a distance, or work. This is the energy absorbed in each load cycle, which with a pinched hysteresis loop is less than that absorbed in other ductile materials with “fatter” loops so the vibration of the structure under earthquake loads has less damping. The decreased stiffness with subsequent load cycles will produce large displacements with a large number of cycles, which can eventually lead to a P-delta failure. With large displacements the line of force from gravity loads may be so far outside columns and load-bearing walls that they overturn or fail due to secondary bending moments caused by eccentric gravity loads.

Light Timber Framing

Light framing has been around for millennia, with the first structures likely to have been designed to resist wind load and hence earthquake load by cantilevering columns out of post-holes in the ground. The next innovation was almost certainly braced frames with diagonal braces cut-in between columns and beams acting only in compression as the connection need only act in bearing and not require a tensile connection. These developed into tension and compression braces as the technology developed with

Timber Structures,

Fig. 4 Hysteresis loop for timber connection; note that this right angle joint is stiffer in closing (right-hand upper quadrant) than opening

steel bolts and nails. These technologies, cantilever posts, and braces are still used for the foundations of many light timber frame structures such as single houses to brace the foundations against earthquake and wind loads.

Houses and other light timber frame structures built in the nineteenth and early twentieth centuries frequently had cut-in timber braces for lateral loads, but these only really held the frames together until claddings and linings were installed. Lateral load resistance was provided by claddings such as concrete plaster or bricks, which tend to have sufficient in-plane stiffness to resist moderate earthquakes, but are prone to out-of-plane failures. Timber weatherboard has some lateral load resistance, but it depends on the way they are nailed, and the resulting structure is very flexible. The widespread availability of plywood, and then reconstituted board products such as “particle-board” or “oriented strand board” (OSB), in the second half of the twentieth century led to their use as either bracing elements where high loadings occurred or, as is common north American practice, fully sheathing house framing with a panel product. In the 1920s and 1930s, interior linings of gypsum plasterboard started to become the norm in many countries. These linings are much stiffer than timber board linings and it was soon found they were much stiffer than cut-in braces or plywood bracing. Hence if a building is lined with gypsum plasterboard, then any other bracing element will only develop its full load after the gypsum plasterboard has failed. This has led to the

development of gypsum plasterboard as a bracing material, with some highly engineered products achieving high levels of bracing performance providing they are fixed in accordance with specifications (Winstones 2011). The approach of fully sheathing houses is probably more robust as it is less dependent on the quality of workmanship, but may result in more damage to internal linings in moderate earthquakes as these are not detailed to resist load, even though they will attract most load at low displacements due to their higher stiffness. Shear walls constructed as panel products nailed to timber framing can fail in four ways under lateral load (Thomas 1991), tension failure of tie-downs, panel shear, bending failure (as tensile or compressive failure of chords), or nail slip, allowing the panel to rotate on the framing. Nail slip is a ductile failure mode, with nails bending into an S shape between the panel and the framing, with localized crushing of both the timber framing and the panel material. The fastening size and spacing and the panel sheet thickness must be chosen so that the ductile nail-slip failure mode occurs and other details must be relatively oversized to prevent other failure modes. Although code requirements for bracing have significantly improved in the latter part of the twentieth century, performance of houses has not necessarily improved as the trend for more and larger windows in houses has compensated for this (Thomas et al. 2013).

The performance of small light timber frame structures such as houses has been demonstrated to be very good, with a low proportion of serious

Timber Structures, Fig. 5 Plywood shear wall and details (Thomas 1991)

failures and wholesale collapse being extremely rare (Graf 2008). Common cause of failure is poor bracing in older Japanese houses with heavy roofs (Langham 1995), poorly braced lower floors such as basement or ground floor levels used car parking (Graf 2008; Iqbal 2013), or poorly braced or poorly fixed foundations (Graf 2008; Thomas et al. 2013).

Most light timber frame structures in the world are low rise, but light timber frame is also suited to medium-rise residential buildings, which have relatively small room sizes. Their development originated in the Pacific Northwest of the United States and western Canada, areas with a long history of light timber frame structures. US practice has been codified by the American Wood Council (ANSI & AF&PA, 2008). Other relevant standards and information can be accessed via Woodworks (2013).

The development of medium-rise timber buildings required the development of lateral load-resisting elements that are sufficiently strong enough to resist earthquake and wind loads for taller buildings. The approach taken was to use

highly loaded plywood shear walls. In order for these to be successful, two shortcomings of light timber frame structures need to be addressed, that is, continuity between short elements and low tensile strength of timber elements.

The shear walls are designed to fail with nail slip allowing the plywood panels to rotate on the framing, a ductile failure mode (Deam 1997). The behavior of the nail-slip failure mode for shear walls under cyclic loading is similar to that in Fig. 4 but is symmetric in tension and compression. The tie-downs at the ends of the wall are oversized, as are the plywood sheet thickness and chord sizes. An over strength factor of 2.0 is normally used (Buchanan 2007). In order to provide for continuity over the length of the chords, which in the case of a five-story building may be 16 m or more long, the chords consist of timber studs interspersed with steel tension rods that can be coupled together to provide tensile strength and continuity and are anchored into the foundation (Fig. 5).

An example of this type of building is Martin Square (Fig. 6), with six floors of timber frame

Timber Structures,**Fig. 6** Martin Square Apartments, Wellington, New Zealand

construction with plywood shear walls, over a basement car park constructed from concrete. This building was completed in 2004, at which time was the highest timber building built in an earthquake-prone area (Wellington, New Zealand).

In light timber frame buildings, the floor diaphragms can be designed as simply supported between lateral load-resisting elements but would normally be designed as a continuous horizontal beam. The floor diaphragms are designed for elastic response. Unlike steel or concrete buildings where diaphragm forces are normally dealt with by typical construction and a check only is required, specific design is essential. With timber floor diaphragms, the connections to lateral load-resisting elements need to be designed to resist the shear transfer, and chords at the edges of the diaphragms need to be designed to take all the bending forces, as they act in tension and compression.

Heavy Timber Framing

Heavy timber frame buildings traditionally were built out of specially sourced large pieces of sawn

timber, usually for buildings of great significance. As stocks of virgin timber disappeared, it became harder and more expensive to source sufficiently large pieces of timber, and with the development of steel and reinforced concrete structures, heavy timber buildings became less common until the advent of glulam and LVL. Heavy timber buildings can really be divided into three types in terms of earthquake resistance; low-rise buildings which are dominated by wind load, structures with a lateral load-resisting system made of another material, such as concrete shear walls or braced steel frames, or more recently moment-resisting heavy timber frames with rigid beam-column connections and cross-laminated timber structures.

Wind Load Dominated

Heavy timber is ideally suited for long-span roof structures, as most of the load on a roof is self-weight, and timber is very light compared to other common structural materials. It can be more economical than steel for portal frame industrial buildings, especially when other implications

Timber Structures,

Fig. 7 Odlines building, Petone, showing concrete shear walls and glulam gravity frame (Photo: Peter Smith)

such as lighter foundation requirements are taken into account. Connections in portal frame buildings can be built using plywood or steel gussets or cross-lapped and glued or using steel brackets and epoxied steel rods. Plywood gussets can be fixed with nail guns, but steel plates need to be drilled and hand nailed. Nailing patterns tend to be hollow squares or rectangles which distribute loads into nails relatively evenly avoiding unzipping failures. As these structures tend to be dominated by wind load, they can be elastically responding in earthquakes or of low ductility, so detailing for ductility is either not required or relatively straightforward. Longitudinal loads can be taken by plywood shear walls or bracing in other materials, but the most economic option is usually steel tension bracing. The longitudinal bracing is usually designed for an elastic response or low ductility. With more complex arrangements such as trusses, very long spans can be achieved, for example, the Hamar Olympic Stadium built for the 1994 Winter Olympics with a span of 96.4 m.

Smaller buildings, building platforms for small buildings, and car-parking decks can be built using poles or naturally round timber, with the simple form of construction being a cantilever pole either driven into the ground or concreted into a bored posthole. Roof or floor elements can then be built up using solid

timber beams or trusses, joists, and flooring. Earthquake load resistance is provided by ensuring the poles have sufficient embedment to resist overturning.

Other Lateral Load Resisting Materials

Design and construction of gravity frames in heavy timber is relatively straightforward. In single-story structures, beams can rest upon columns with simple fastenings. In multistory structures, this is not desirable as perpendicular to the grain compression or bearing forces are developed in the beams. Timber is not as good at resisting such forces as compression parallel to the grain. Brackets can be bolted or sometimes nailed to the columns to support the beams which are then fixed to the brackets. The lateral loads are then taken by another structure, such as concrete shear walls ([► Reinforced Concrete Structures in Earthquake-Resistant Construction](#)) which may be around a service core containing the stairs and elevators. Odlines building (Fig. 7) is an example of this. Other options are steel tension bracing, cross bracing and K bracing, or eccentrically braced frames ([► Steel Structures](#)). In this type of building, the design of the lateral load-resisting structure is as it would be for a building made in its entirety of another material, but

Timber Structures,
Fig. 8 COCA building,
 Massey University,
 Wellington. The steel truss
 tower is temporary bracing

earthquakes loads may be lower due to the lighter mass of the timber structure.

Some timber buildings may have a timber moment-resisting frame (Moment Resisting Frames) in one direction and another have a structural system of another material in the other direction. The Massey COCA building (Fig. 8) is one such building, with concrete shear walls in the longitudinal direction. Other buildings may have other types of structural system in locations where timber structural systems would not work. An example is Martin Square (Fig. 6), which has three steel k braces in the outside walls of the building. Lateral load-resisting elements are therefore at the extremities of the building with a large separation between these elements to provide adequate resistance to torsion. It was not possible to install plywood shear walls on the external walls due to the large number of and small spacing between windows (Milburn and Banks 2005).

Moment-Resisting Frames

Designing and building a timber gravity frame structure is relatively straightforward, and light timber frame structures with plywood shear walls are restricted in terms of room size because of short floor plans and the requirement for lots of walls. Lateral load-resisting structures such as

concrete shear walls and steel bracing also restrict options in terms of building layouts. The only realistic way of building timber buildings as commercial space with long floor spans and large open areas is a moment-resisting frame structure. As timber does not perform well in cyclic loading outside the elastic range as it is brittle in tension, then ductility can only be achieved in the connections.

Nailed moment-resisting connections are designed to ensure nail slip as the steel nails yield, a ductile failure mode, rather than a brittle failure of the timber. These types of connections tend to have a pinched hysteresis loop similar to Fig. 4, with the same issues of poor energy absorption and degrading stiffness. These limit the height that buildings with nailed moment-resisting connections can be built to.

Better joint behavior can be achieved using steel rods running through columns and the ends of beams and epoxied into place. This system takes advantage of the ductile behavior of the steel rod which can yield not only in tension but also in compression as buckling is prevented by the surrounding timber. The cyclic load behavior is good, with characteristics similar to reinforced concrete.

The development of LVL which has better strength and stiffness properties than glulam, as well as being less expensive with a more automated production process, has resulted in LVL buildings being more economical than their

glulam equivalent and therefore more competitive against other materials.

Care needs to be taken in the design and connection of floor diaphragms as described in the section on light timber framing.

More recently timber “rocking frame” buildings have been designed based on a procedure developed at the University of Canterbury, New Zealand. This design is similar to the “PRESSS” system developed for reinforced concrete at the University of California San Diego in the 1990s (► [Reinforced Concrete Structures in Earthquake-Resistant Construction](#)) and is known as “Pres-Lam.” These types of systems use “damage avoidance design,” with systems that self-center after earthquakes and damage from earthquakes concentrated in easily replaceable energy-dissipating elements. In timber buildings frames or walls are posttensioned with steel tendons and fitted with external energy-dissipating devices. An experimental building with such frames in one direction and walls in the other has been tested at the University of Canterbury and after modification for use as an office building survived the 22 February 2011 Christchurch Earthquake. Buildings with posttensioned walls at Nelson Marlborough Institute of Technology and Massey University (Fig. 8), with LVL posttensioned frames in the transverse direction, have subsequently been built ([NZ Wood 2013](#)).

Cross-Laminated Timber Structures

Cross-laminated timber are large panels of glue-laminated timber, but the laminates run perpendicular to each other rather than parallel to form large panels. These panels are more suited to residential buildings with small room sizes and a large numbers of walls. The panels are relatively thick and very stiff and under earthquake loads rotate effectively as a rigid body, with any ductility coming from the connections (Pei et al. 2012). A seven-story experimental cross-laminated apartment building was successfully tested on the E-Defense shake table in Japan in 2009 (Merolla 2009).

Summary

Timber structures inherently have good earthquake resistance as they are lightweight and have low stiffness, but ductility can only really be achieved in the connections. For smaller and low-rise timber structures, design for wind load and good practice in detailing are sufficient to ensure adequate earthquake resistance. A desirability to use more timber in construction for environmental reasons has recently led to more interest in multistory timber buildings and innovative research in how to design these for earthquake resistance.

Introduction

Most of the current seismic design codes belong to the category of prescriptive design procedures (or limit-state design procedures), where if a number of checks are satisfied, then the structure is considered safe since it fulfills the safety criterion against collapse. A typical limit-state-based design can be viewed as one- (i.e., ultimate strength) or two-limit-state approach (i.e., serviceability and ultimate strength). Existing seismic design procedures are based on the principle that a structure will avoid collapse if it is designed to absorb and dissipate the kinetic energy that is induced during a seismic excitation. Most of the modern seismic norms express the ability of the structure to absorb energy through inelastic deformation using a reduction or behavior factor that depends on the material and the construction type of the structure. The concept of performance-based design (PBD) was introduced a few decades ago, for designing structures subjected to seismic loading conditions. In PBD more accurate and time-consuming analysis procedures are employed, to estimate nonlinear structural response. The progress that takes place in the area of computational mechanics, as well as in computer technology, continuously expands the capabilities and the applicability of PBD procedures. The main objective of this kind of design procedures is to achieve more predictable and reliable levels of safety and operability against natural hazards. According to PBD procedures, the structures should be able to resist earthquakes in a quantifiable manner and to present specific target performance levels of possible damages. PBD criteria try to define certain levels of structural performance for various levels of seismic hazard.

In the construction industry, decision making for structural systems situated in seismically active regions requires consideration of damage cost and other losses resulting from earthquakes occurring during the life span of a structure. Thus, nowadays, life-cycle cost analysis (LCCA) becomes an essential component of the design process used to control the initial and the future

cost of building ownership. In the early 1960s, LCCA was applied in the commercial area and in particular in the design of products considering the total cost of developing, producing, using, and retiring. The introduction of LCCA in the construction industry was made in the field of infrastructures as an investment assessment tool. In particular, in the early 1980s, it was used in the USA as an appraisal tool for the total cost of ownership over the life span of an asset. Later, in view of large losses due to extreme hazards, like earthquakes and hurricanes, there was a need for new design procedures of facilities that could lead to life protection and reduction of damage and economical impact of such hazards to an acceptable level. In this context LCCA was introduced in the field of constructions as a complex investment appraisal tool incorporating a structural performance criterion.

Over the last decades, risk management of structural systems has gained the attention of various economic and technical decision centers in modern society. The optimal allocation of the public resources for a sustainable economy requires proper tools for estimating the consequences of natural hazardous events on the built environment. The risk management addresses this claim indicating the way for implementing optimal choices. Thus, the main purpose of the risk management process is to choose among different options relying on technical and economical considerations. Risk assessment and decision analysis are the main steps of the risk management concept. It is therefore essential to establish a reliable procedure for assessing the seismic risk of structural systems. Seismic fragility analysis, which provides a measure of the safety margin for the structural system, is considered as the core of the risk assessment framework.

The implementation of PBD, LCCA, or seismic risk procedures requires a reliable computing tool for estimating the capacity and the demand for any structural system. Some of these computing tools (Fajfar 2000; Chopra and Goel 2002; Vamvatsikos and Cornell 2002) are based on time history seismic analyses, and they are considered as analysis methods for obtaining good estimates

of the structural performance in the case of earthquake hazard, and therefore, they are considered as appropriate methods to be incorporated into such design and assessment frameworks. In this entry, we provide an overview of the time history seismic analysis applied for design and assessment purposes.

Ground Motion Excitation

Selecting the seismic loading for design and/or assessment purposes is not an easy task due to the uncertainties involved in the very nature of seismic excitations. One possible approach for the treatment of the seismic loading is to assume that the structure is subjected to a set of records that are more likely to occur in the region where the structure is located.

Natural Records

For the implementation of dynamic seismic analysis, a scale factor is calculated for each hazard level considered and for each one of the records selected. In order to preserve the relative scale of the two components of the records in the longitudinal and transversal directions, the component of the record having the highest $S_A(T_1, 5\%)$ is scaled first, while the scaling factor that preserves their relative ratio is assigned to the second component.

Generation of Artificial Accelerograms

In order for the artificial accelerograms to be representative, they have to match some requirements of the seismic codes. The most essential one is that the accelerograms have to be compatible with the elastic design response spectrum of the region. Each accelerogram corresponds to a single response spectrum for a given damping ratio. On the other hand, on each response spectrum corresponds an infinite number of accelerograms. Gasparini and Vanmarke (1976) were the first to propose the creation of artificial accelerograms based on a specific response spectrum. The mean (μ) response spectrum is depicted in Fig. 1, along with its dispersion ($\mu + \sigma$ and $\mu - \sigma$ denoted with dotted lines) for the case of

Time History Seismic Analysis, Fig. 1 Mean response spectra of the records for the class of (a) artificial accelerograms and (b) natural records (*dotted lines* represent the $\mu + \sigma$ and $\mu - \sigma$ response spectra)

the natural class of records (NAT) selected by PEER (2012) and artificial accelerograms (ART) generated according to the procedure described below in this section. The response spectra for the NAT class of records were obtained after scaling the records to the same $S_A(T_1, 5\%)$, where $T_1 = 0.628$ s for the 40/50 hazard level, in accordance with the hazard curve of the city of San Diego, California. Comparing NAT and ART class of accelerograms, it can be seen that the dispersion of the response spectra for the ART class of accelerograms is lower than that of the NAT class.

Intensity Measures

Earthquake engineering is a scientific field strongly connected with the effect of strong ground motions on people and environment. Strong ground motions are extremely complicated and a lot of data is required for their full description. The definition of a number of ground motion parameters, namely, intensity measures (IMs), simplifies the description of a strong ground motion and links the seismic hazard with the structural data required for the solution of earthquake engineering problems. The most significant characteristics of a ground motion from an earthquake engineering point of view are the frequency content, the amplitude, and the motion duration. Some of the IMs are related to amplitude or to frequency content, to duration, or to more than one of the three essential ground motion characteristics. The IMs that are related

to the effect of more than one ground motion characteristics are considered more reliable for the description of a ground motion and are most suitable to reflect the potential damage that a ground motion can produce.

The most commonly used *amplitude* IMs derived from an accelerogram are the peak ground acceleration (high-frequency component), peak velocity (intermediate-frequency component), peak displacement (low-frequency component), sustained maximum acceleration and velocity, and the effective design acceleration. Amplitude IMs are used for the derivation of empirical attenuation relationships used in probabilistic hazard analysis, because their production is based on IMs' dependence, on the magnitude of the earthquake, and on the site-to-source distance. *Frequency content* IMs describe through different types of spectra how the amplitude of a ground motion is distributed among different frequencies. IMs related to frequency content are Fourier spectra and power spectra that correspond to the frequency content of the ground motion itself and the response spectra that correspond to the influence of the ground motion on structures with different first eigenperiods. Among these types of IMs are spectral parameters, like the predominant period, bandwidth, central frequency, shape factor, Kanai-Tajimi parameters, and the ratio $v_{\max}/a_{\max}$ which describes the frequency content of a ground motion. The most commonly used *duration* IM is the bracketed duration which is defined as the

time between the first and the last exceedance of a threshold acceleration, usually equal to 0.05 g.

Arias intensity (I_A), *characteristic intensity* (I_C), and *cumulative absolute velocity* (CAV) are three IMs that reflect the amplitude, the frequency content, and the duration of a strong ground motion, respectively, which correlate well with structural damage. *Arias intensity* is defined as the time integral of the square of the ground acceleration

$$I_A = \frac{\pi}{2g} \int_0^{\infty} [a(t)]^2 dt \quad (1)$$

where $a(t)$ is the ground acceleration and g is the acceleration due to gravity (9.81 m/s²) and is expressed in units of velocity, i.e., meter per second. The symbol of infinity in the time integration means that I_A is calculated over the entire duration and not over the duration of the strong ground motion T_d that is defined through specific methods.

Characteristic intensity is defined as

$$I_C = \alpha_{rms}^{1.5} T_d^{0.5} \quad (2)$$

where α_{rms} is the *rms acceleration* (root mean square acceleration) ground motion parameter and T_d is the duration of the strong motion.

Cumulative absolute velocity is defined as the integral of the absolute acceleration in a time history, and it is obtained through the following equation:

$$CAV = \int_0^{T_d} |a(t)| dt \quad (3)$$

where $|a(t)|$ is the absolute value of the acceleration time series at time t and T_d is the duration of the strong motion. CAV expresses the absolute area under the absolute accelerogram and corresponds to the cumulative absolute velocity that is well correlated with structural damage (Kramer 1996). These three IMs are used for investigating their dispersion with reference to the two classes

of seismic excitations considered. In particular, the *characteristic intensity* is a measure that is related to an index that quantifies the damage due to the maximum deformation and the absorbed hysteretic energy. In order to examine the influence of the class of seismic excitations considered on the values of the three IMs, the box plots depicted in Fig. 2 have been generated for the 40/50 hazard level (denoting 40 % probability of exceedance in 50 years).

For each IM considered and for each class of seismic excitation, a box plot was created. On each box, the central mark denoted with a bold black line is the median value of the IM in question. The edges of the box represent the 25 % and 75 % percentiles, while the whiskers denoted with black lines extend to the most extreme data points, i.e., represent the range of the IM values. For all three IMs, ART class of accelerograms has the narrower range and confidence bounds. On the other hand, the median values of ART are close to each other while NAT varies significantly for the case of I_C and CAV. For the case of I_A , the three median values are quite close. For the 25 % and 75 % percentiles, I_C and CAV, NAT class of seismic excitations, have similar box sizes denoting that they are related to the length of the range of values.

Analysis Methods

Having an appropriate model for the structure and its earthquake loads, structural analysis is the next step. The choice of linear elastic or nonlinear modeling of the element force-deformation behavior and the consideration, or not, of geometric nonlinearities essentially dictate the selection of the appropriate analysis method. Modeling of structural mass distribution and the dynamic nature of earthquake loads allows the use of dynamic rather than static methods of analysis. Thus, broadly speaking, four categories of analysis methods are available, each with its own modeling and solution algorithm requirements: (a) nonlinear dynamic, (b) nonlinear static, (c) elastic dynamic, and (d) elastic static (ASCE 41-06 2007).

Time History Seismic

Analysis, Fig. 2 Mean and 25 % and 75 % confidence bounds for the values of I_A , I_C , and CAV obtained for the classes of records considered

Linear Time History Analysis Methods

Although simple elastic linear methods may seem antiquated by modern research standards, they define, by overwhelming majority, the current standard of practice for seismic design. Despite the many efforts to offer building a design methodology on a nonlinear static or dynamic basis (Fib 2012), the vast majority of practical earthquake engineering work is still done at the elastic level using either (a) equivalent linear static, whereby a fixed lateral load pattern is applied to an elastic structural model, or (b) linear time history analysis and (c) modal response spectrum analysis, where the modal responses are combined to estimate the peak MDOF response (e.g., EN1998 2005). Inelastic response is universally taken care of by dividing the elastic seismic loads (i.e., design spectral acceleration values) by the appropriate reduction R (or behavior q) factor that is meant to represent the ductility and

overstrength of a yielding system. Although little recent research has been directed in the way of elastic methods, recent advancements in nonlinear analysis have helped to shed some light into the premise of using elastic results to capture nonlinear behavior.

The equilibrium equations for a system in motion can be written as

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{R}(t) \quad (4)$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the mass, damping, and stiffness matrices and $\mathbf{R}(t)$ is the external load vector, while $\mathbf{u}(t)$, $\dot{\mathbf{u}}(t)$, and $\ddot{\mathbf{u}}(t)$ are the displacement, velocity, and acceleration vectors of the finite element assemblage, respectively. The choice for a static or dynamic analysis (i.e., for including or neglecting velocity and acceleration-dependent forces in the analysis) is usually decided by engineering judgment.

Mathematically, Eq. 4 represents a system of linear differential equations of second order and the solution of this system can be obtained by standard procedures for the solution of differential equations. In practical finite element analysis, we are mainly interested in a few effective methods and we will concentrate in the next sections on the presentation of those techniques and in particular on the direct integration ones. In direct integration the system of linear differential equations in Eq. 4 is integrated using a numerical step-by-step procedure; the term “direct” means that no transformation of the equations is carried out prior to the numerical integration.

Central Difference Method

One procedure that can be very effective in the solution of certain problems is the central difference method where it is assumed that

$$\ddot{\mathbf{u}}(t) = \frac{1}{\Delta t^2} [\mathbf{u}(t - \Delta t) - 2\mathbf{u}(t) + \mathbf{u}(t + \Delta t)] \quad (5)$$

and the velocity expansion is defined by

$$\dot{\mathbf{u}}(t) = \frac{1}{2\Delta t} [\mathbf{u}(t + \Delta t) - \mathbf{u}(t - \Delta t)] \quad (6)$$

The displacement expression for time $t + \Delta t$ is obtained by substituting Eqs. 5 and 6 into Eq. 4:

$$\begin{aligned} \left(\frac{1}{\Delta t^2} \mathbf{M} + \frac{1}{2\Delta t} \mathbf{C} \right) \mathbf{u}(t + \Delta t) = \\ \mathbf{R}(t) - \left(\mathbf{K} - \frac{2}{\Delta t^2} \mathbf{M} \right) \mathbf{u}(t) \\ - \left(\frac{1}{\Delta t^2} \mathbf{M} - \frac{1}{2\Delta t} \mathbf{C} \right) \mathbf{u}(t - \Delta t) \end{aligned} \quad (7)$$

from which we can solve for $\mathbf{u}(t + \Delta t)$. It should be noted that the solution of $\mathbf{u}(t + \Delta t)$ is based on using the equilibrium conditions of

Eq. 4 at time t . For this reason the integration procedure is called an explicit integration method. On the other hand, the Houbolt, Wilson, and Newmark methods, considered in the next sections, use the equilibrium conditions at time $t + \Delta t$ and are called implicit integration methods.

Houbolt Method

The Houbolt integration scheme is somewhat related to the central difference method in the sense that standard finite difference expressions are used to approximate the acceleration and velocity components in terms of displacement. The following expansions are employed in the Houbolt (1950) integration method:

$$\ddot{\mathbf{u}}(t + \Delta t) = \frac{1}{\Delta t^2} [2\mathbf{u}(t + \Delta t) - 5\mathbf{u}(t) + 4\mathbf{u}(t - \Delta t) - \mathbf{u}(t - 2\Delta t)] \quad (8)$$

and

$$\dot{\mathbf{u}}(t + \Delta t) = \frac{1}{6\Delta t} [11\mathbf{u}(t + \Delta t) - 18\mathbf{u}(t) + 9\mathbf{u}(t - \Delta t) - 2\mathbf{u}(t - 2\Delta t)] \quad (9)$$

In order to obtain the displacement $\mathbf{u}$ at time $t + \Delta t$, we now consider Eq. 4 at time $t + \Delta t$, which gives

$$\mathbf{M}\ddot{\mathbf{u}}(t + \Delta t) + \mathbf{C}\dot{\mathbf{u}}(t + \Delta t) + \mathbf{K}\mathbf{u}(t + \Delta t) = \mathbf{R}(t + \Delta t) \quad (10)$$

Substituting Eqs. 8 and 9 into Eq. 10 and arranging all known vectors on the right-hand side of the equations, we obtain

$$\begin{aligned} \left(\frac{2}{\Delta t^2} \mathbf{M} + \frac{11}{6\Delta t} \mathbf{C} + \mathbf{K} \right) \mathbf{u}(t + \Delta t) = \mathbf{R}(t + \Delta t) + \left(\frac{5}{\Delta t^2} \mathbf{M} + \frac{3}{\Delta t} \mathbf{C} \right) \mathbf{u}(t) \\ - \left(\frac{4}{\Delta t^2} \mathbf{M} + \frac{3}{2\Delta t} \mathbf{C} \right) \mathbf{u}(t - \Delta t) + \left(\frac{1}{\Delta t^2} \mathbf{M} + \frac{1}{3\Delta t} \mathbf{C} \right) \mathbf{u}(t - 2\Delta t) \end{aligned} \quad (11)$$

As shown in Eq. 11, the solution of $\mathbf{u}(t + \Delta t)$ requires knowledge of $\mathbf{u}(t)$, $\mathbf{u}(t - \Delta t)$, and $\mathbf{u}(t - 2\Delta t)$.

Wilson- θ Method

The Wilson- θ method is essentially an extension of the linear acceleration method, where linear variation of the acceleration from time t to time $t + \Delta t$ is assumed. In the Wilson- θ method, the acceleration is assumed to be linear from time t to time $t + \theta\Delta t$, where $\theta > 1$ (Wilson et al. 1973). Let τ denote the increase in time, where $0 \leq \tau \leq \theta\Delta t$; then for the time interval t to $t + \theta\Delta t$, it is assumed that

$$\ddot{\mathbf{u}}(t + \tau) = \ddot{\mathbf{u}}(t) + \frac{\tau}{\theta\Delta t} [\ddot{\mathbf{u}}(t + \theta\Delta t) - \ddot{\mathbf{u}}(t)] \quad (12)$$

Integrating Eq. 12, we obtain

$$\dot{\mathbf{u}}(t + \tau) = \dot{\mathbf{u}}(t) + \ddot{\mathbf{u}}(t)\tau + \frac{\tau^2}{2\theta\Delta t} [\ddot{\mathbf{u}}(t + \theta\Delta t) - \ddot{\mathbf{u}}(t)] \quad (13)$$

and

$$\begin{aligned} \mathbf{u}(t + \tau) = & \mathbf{u}(t) + \dot{\mathbf{u}}(t)\tau + \frac{1}{2}\ddot{\mathbf{u}}(t)\tau^2 \\ & + \frac{\tau^3}{6\theta\Delta t} [\ddot{\mathbf{u}}(t + \theta\Delta t) - \ddot{\mathbf{u}}(t)] \end{aligned} \quad (14)$$

Using Eqs. 13 and 14, we obtain for the time $t + \theta\Delta t$

$$\dot{\mathbf{u}}(t + \theta\Delta t) = \dot{\mathbf{u}}(t) + \frac{\theta\Delta t}{2} [\ddot{\mathbf{u}}(t + \theta\Delta t) - \ddot{\mathbf{u}}(t)] \quad (15)$$

$$\begin{aligned} \mathbf{u}(t + \theta\Delta t) = & \mathbf{u}(t) + \dot{\mathbf{u}}(t)\theta\Delta t \\ & + \frac{\theta^2\Delta t^2}{6} [\ddot{\mathbf{u}}(t + \theta\Delta t) + 2\ddot{\mathbf{u}}(t)] \end{aligned} \quad (16)$$

from which we can solve for $\ddot{\mathbf{u}}(t + \theta\Delta t)$ and $\dot{\mathbf{u}}(t + \theta\Delta t)$ in terms of $\mathbf{u}(t + \theta\Delta t)$:

$$\dot{\mathbf{u}}(t + \theta\Delta t) = \frac{3}{\theta\Delta t} [\mathbf{u}(t + \theta\Delta t) - \mathbf{u}(t)] - 2\dot{\mathbf{u}}(t) - \frac{\theta\Delta t}{2}\ddot{\mathbf{u}}(t) \quad (17)$$

$$\begin{aligned} \ddot{\mathbf{u}}(t + \theta\Delta t) = & \frac{6}{\theta^2\Delta t^2} [\mathbf{u}(t + \theta\Delta t) - \mathbf{u}(t)] \\ & - \frac{6}{\theta\Delta t}\dot{\mathbf{u}}(t) - 2\ddot{\mathbf{u}}(t) \end{aligned} \quad (18)$$

To obtain the solution for the displacements, velocities, and accelerations at time $t + \Delta t$, the equilibrium equations given in Eq. 4 are considered at time $t + \theta\Delta t$. However, since accelerations are assumed to vary linearly, a linearly extrapolated load vector is used:

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{u}}(t + \theta\Delta t) + \mathbf{C}\dot{\mathbf{u}}(t + \theta\Delta t) \\ + \mathbf{K}\mathbf{u}(t + \theta\Delta t) = \bar{\mathbf{R}}(t + \theta\Delta t) \end{aligned} \quad (19)$$

where

$$\bar{\mathbf{R}}(t + \theta\Delta t) = \mathbf{R}(t) + \theta[\mathbf{R}(t + \Delta t) - \mathbf{R}(t)] \quad (20)$$

Substituting Eqs. 17 and 18 into Eq. 19, an equation is obtained from which $\mathbf{u}(t + \theta\Delta t)$ can be solved. Then substituting $\mathbf{u}(t + \theta\Delta t)$ into Eq. 18, we obtain $\ddot{\mathbf{u}}(t + \theta\Delta t)$, which is used in Eqs. 12, 13, and 14, all evaluated at time $\tau = \Delta t$ to calculate $\ddot{\mathbf{u}}(t + \Delta t)$, $\dot{\mathbf{u}}(t + \Delta t)$ and $\mathbf{u}(t + \Delta t)$.

Newmark Method

The Newmark integration scheme is an extension of the linear acceleration method. Under this scheme the variations of velocity and displacement are given by (Newmark 1959)

$$\dot{\mathbf{u}}(t + \Delta t) = \dot{\mathbf{u}}(t) + [(1 - \delta)\ddot{\mathbf{u}}(t) + \delta\ddot{\mathbf{u}}(t + \Delta t)]\Delta t \quad (21)$$

$$\begin{aligned} \mathbf{u}(t + \Delta t) = & \mathbf{u}(t) + \dot{\mathbf{u}}(t)\Delta t \\ & + [(0.5 - \alpha)\ddot{\mathbf{u}}(t) + \alpha\ddot{\mathbf{u}}(t + \Delta t)]\Delta t^2 \end{aligned} \quad (22)$$

where α and δ are parameters that can be determined to obtain integration accuracy and stability. When $\delta = 1/2$ and $\alpha = 1/6$, Eqs. 21 and 22 correspond to the linear acceleration method. In addition to Eqs. 21 and 22, for calculating the displacements, velocities, and accelerations at

time $t + \Delta t$, the equilibrium Eq. 4 is also considered at time $t + \Delta t$:

$$\mathbf{M}\ddot{\mathbf{u}}(t + \Delta t) + \mathbf{C}\dot{\mathbf{u}}(t + \Delta t) + \mathbf{K}\mathbf{u}(t + \Delta t) = \mathbf{R}(t + \Delta t) \quad (23)$$

Solving from Eq. 22 for $\ddot{\mathbf{u}}(t + \Delta t)$ in terms of $\mathbf{u}(t + \Delta t)$ and then substituting for $\ddot{\mathbf{u}}(t + \Delta t)$ into Eq. 21, we obtain equations for $\ddot{\mathbf{u}}(t + \Delta t)$ and $\dot{\mathbf{u}}(t + \Delta t)$ each in terms of the unknown displacements $\mathbf{u}(t + \Delta t)$. These two relations for $\ddot{\mathbf{u}}(t + \Delta t)$ and $\dot{\mathbf{u}}(t + \Delta t)$ are substituted into Eq. 23 to solve for $\mathbf{u}(t + \Delta t)$ after using Eqs. 21 and 22; $\ddot{\mathbf{u}}(t + \Delta t)$ and $\dot{\mathbf{u}}(t + \Delta t)$ can also be calculated. As a result of this substitution, the following well-known equilibrium equation is obtained at each Δt :

$$\mathbf{K}_{\text{eff}}\mathbf{u}(t + \Delta t) = \mathbf{R}^{\text{eff}}(t + \Delta t) \quad (24)$$

where

$$\mathbf{K}_{\text{eff}} = \mathbf{K} + \alpha_0\mathbf{M} + \alpha_1\mathbf{C} \quad (25)$$

$$\begin{aligned} \mathbf{R}^{\text{eff}}(t + \Delta t) = & \mathbf{R}(t + \Delta t) \\ & + \mathbf{M}[\alpha_0\mathbf{u}(t) + \alpha_2\dot{\mathbf{u}}(t) + \alpha_3\ddot{\mathbf{u}}(t)] \\ & + \mathbf{C}[\alpha_1\mathbf{u}(t) + \alpha_4\dot{\mathbf{u}}(t) + \alpha_5\ddot{\mathbf{u}}(t)] \end{aligned} \quad (26)$$

with $\delta \geq 0.50$; $\delta \geq 0.25(0.5 + \delta)^2$, while

$$\begin{aligned} \alpha_0 &= \frac{1}{\alpha\Delta t^2}, \alpha_1 = \frac{\delta}{\alpha\Delta t}, \alpha_2 = \frac{1}{\alpha\Delta t}, \alpha_3 = \frac{1}{2\alpha} - 1, \\ \alpha_4 &= \frac{\delta}{\alpha} - 1, \\ \alpha_5 &= \frac{\Delta t}{2} \left(\frac{\delta}{\alpha} - 2 \right), \alpha_6 = \Delta t(1 - \delta), \alpha_7 = \delta\Delta t. \end{aligned}$$

Nonlinear Time History Analysis

Nonlinear dynamic analysis is undoubtedly the most realistic and accurate analysis method available. It is also referred as “nonlinear time history analysis,” “nonlinear response history analysis,” or according to ASCE 41-06 (2007) as “nonlinear dynamic procedure” (NDP). Earthquake loading is taken into consideration as a natural or a synthetic ground motion on a structural model

that incorporates elements with inelastic (inelastic and nonlinear are typically used interchangeably for seismic applications) force-deformation relationships and at least a first-order approximation of geometric nonlinearities (P-Delta effects). The propagation of the ground motion throughout the structure generates complete response histories for any quantity of interest (e.g., displacements, stress resultants) leading to a wealth of data. While different levels of complexity are possible due to modeling choices, different ground motion records will produce demands that vary considerably. This record-to-record variation dominates the application of dynamic methods. Therefore, in order to get reliable response estimates, an appropriately selected set of several ground motion records is necessary, since a single time history analysis is of limited practical use. Furthermore, one or more levels of seismic intensity, typically corresponding to one or more levels of the IM, may need to be employed to investigate structural behavior at different regimes of response or damage (e.g., elastic, post-yield, or near-collapse). Thus, nonlinear dynamic analysis procedures may be categorized into the narrow- and broad-range assessment categories.

In most practical design/assessment situations, only a narrow, single-point estimate of structural response is required. This is consistent with current seismic codes that only provide a design hazard spectrum (typically at an exceedance probability of 10 % in 50 years) and require checking that a structure shall not sustain significant or life-threatening damage at such a level of intensity. Thus, seismic codes (e.g., ASCE 7-10 2010; EN1998 2005) prescribe using ground motion records that match or exceed the design spectrum in the period range of interest. If 3–6 records are employed, the overall maximum of the recorded peak responses is taken as the structural demand, while for 7 records and above, the mean of the peak responses can be employed.

Incremental Analysis Procedures

In the framework of seismic assessment of structures, a wide range of seismic records and more than one hazard levels should be considered in

Time History Seismic Analysis, Fig. 3 The MIDA procedure

order to take into account the uncertainties inherent in any seismic hazard for assessing the performance of a structure under seismic actions. The most reliable but also computationally intensive methodology for the performance-based assessment implements nonlinear dynamic analyses based on a single- or a multiple-hazard-level approach. In fragility analysis of structural systems or life-cycle cost analysis, the two most appropriate methods for performing this task are the multiple-stripe dynamic analysis and incremental dynamic analysis (Vamvatsikos and Cornell 2002). To be consistent with the current technical literature, IDA abbreviation is used for both methods. The main objective of an IDA study is to define a curve through the relation of the intensity level with the maximum seismic response of the structural system. The intensity level and the seismic response are described through an intensity measure (IM) and an engineering demand parameter (EDP), respectively.

Selecting IM and EDP is one of the most important steps of IDA. In Giovenale et al. (2004), the significance of selecting an efficient IM is discussed. The IM should be a monotonically scalable ground motion intensity measure, like the peak ground acceleration (PGA), peak ground velocity (PGV), the $\xi = 5\%$ damped spectral acceleration at the structure's first-mode period ($S_A(T_1, 5\%)$), as well as others. On the other hand, the damage may be quantified by using any of the EDPs whose values can be related to particular structural damage states. A number of available response-based EDPs were discussed and

critically evaluated in the past for their applicability in seismic damage evaluation. In the work by Ghobarah et al. (1999), the EDPs are classified into four categories based on maximum deformation, cumulative damage, and combinations of maximum deformation and cumulative damage. According to the multicomponent incremental dynamic analysis (MIDA) proposed by Lagaros (2010) which is an extension of IDA, a set of natural records, each one represented by its longitudinal and transverse components, are applied to the structure in order to account for the randomness on the seismic excitation. The difference of the MIDA framework from the original one-component version of the IDA stems from the fact that for each record, a number of MIDA representative curves can be defined depending on the incident angle selected, while in most cases of the one-component version of IDA, only one IDA representative curve is obtained. A schematic representation of MIDA procedure can be seen in Fig. 3.

Use of Time History Seismic Analyses

Structural Models and Numerical Simulation

Nonlinear analyses need detailed simulation of the structure in the regions where inelastic deformations are expected to develop. Either the plastic-hinge or the fiber approach can be adopted for this cause. Given that the plastic-hinge approach has limitations in terms of accuracy, the fiber beam-column elements are preferable (Fragiadakis and Papadrakakis 2008).

According to the fiber approach, every beam-column element has a number of integration sections, each divided into fibers. Each fiber in the section can be assigned concrete, structural steel, or reinforcing bar material properties. The sections are located either at the center of the element or at its Gaussian integration points. The main advantage of the fiber approach is that every fiber has a simple uniaxial material model allowing an easy and efficient implementation of the inelastic behavior. This approach is considered to be suitable for inelastic beam-column elements under dynamic loading and provides a reliable solution compared to other formulations. However, it results to higher computational demands in terms of memory storage and CPU time. When a displacement-based formulation is adopted, the discretization should be adaptive with a dense mesh at the joints and a single elastic element for the remaining part of the member. On the other hand, force-based fiber elements allow modeling a member with a single beam-column element.

The two multistory buildings shown in Figs. 4 and 5 are considered for the numerical tests presented herein. The first one is an eight-story steel-RC composite building and the second test example is an eight-story RC building having symmetrical plan view, while the second one is a five-story RC building with nonsymmetrical plan view. The building has been designed for minimum initial cost (Mitropoulou et al. 2010). Concrete of class C20/25 (nominal cylindrical strength of 20 MPa) and steel of class S500 (nominal yield stress of 500 MPa) are assumed. Each member is modeled with a single force-based, fiber beam-column element. The modified Kent and Park (1971) models are employed for the simulation of the concrete fibers. This model was chosen because it allows for an accurate prediction of the structural demand for flexure-dominated RC members despite its relatively simple formulation. The inelastic behavior of the reinforcing bars was simulated with the Menegotto and Pinto (1973) model. A bilinear material model with pure kinematic hardening is adopted for the steel fibers, while geometric nonlinearity is explicitly taken into consideration.

Critical Orientation of the Seismic Incidence

A structure subjected to the simultaneous action of two orthogonal horizontal ground accelerations along the directions Ow and Op is illustrated in Fig. 6. The orthogonal system $Oxyz$ defines the reference axes of the structure (structural axes). The angle defined with a counterclockwise rotation of the structural axis Ox to coincide with the ground motion axis Ow is called as incident angle of the record.

According to Penzien and Watabe (1975), the orthogonal directions of a ground motion can be considered uncorrelated in the principal directions of the structure. This finding was the basis for many researchers in order to define the orientation that yields the maximum response when the response spectrum dynamic analysis was applied. In the work by Wilson et al. (1995), an alternative code-approved method that results in structural designs which have equal resistance to seismic motions from all directions was proposed. Lopez and Torres (1997) proposed a simple method which can be employed by the seismic codes to determine the critical angle of seismic incidence and the corresponding peak response of structures subjected to two horizontal components applied along any arbitrary directions and to the vertical component of earthquake ground motion. The CQC3 response spectrum rule for combining the three orthogonal components of ground motion to the maximum value of a response quantity is presented in the work by Menun and Der Kiureghian (1998). In the work by Lopez et al. (2000), it is proposed an explicit formula, convenient for code applications, in order to calculate the critical value of the structural response to the two principal horizontal components acting along any incident angle with respect to the structural axes. In the work by Menun and Der Kiureghian (2000), a response spectrum-based procedure for predicting the envelope that bounds two or more responses in a linear structure is developed. In the work by Anastassiadis et al. (2002), a seismic design procedure for structures is proposed where the three translational ground motion components on a specific point of the ground are statistically noncorrelated.

Time History Seismic Analysis, Fig. 5 Eight-story RC building: (a) plan view and (b) front view

Time History Seismic Analysis, Fig. 6 Definition of the incident angle α

There are only few studies in the literature where the case of the critical incident angle is examined when time history analysis is employed. In these studies it was found that in the most general case, where nonlinear behavior is encountered, it is not an easy task to define the critical angle. In the work by MacRae and Mattheis (2000), it is shown the ability of the 30 % SRSS rule and the sum of absolute values methods to assess building drifts for bidirectional shaking effects, while it is also shown that the response is dependent on the reference axes chosen. MacRae and Tagawa (2001) have found that design-level shaking caused the structure to exceed story yield drifts in both directions simultaneously and significant column yielding occurred above the base. Shaking a structure in the direction orthogonal to the main shaking direction increased drifts in the main shaking direction, indicating that 2D analyses would not estimate the 3D response well. Ghersi and Rossi (2001) examined the influence of bidirectional seismic excitations on the inelastic behavior of in-plan irregular systems having one symmetry axis where it was found that in most cases the adoption of Eurocode 8 provisions to combine the effects of the two seismic components allows the limitation of the orthogonal element ductility demand. In the work by Athanatopoulou (2005), analytical formulae were developed for determining the critical incident angle and the corresponding maximum value of a response quantity of structures subjected to three seismic

correlated components. Rigato and Medina (2007) studied a number of symmetrical and asymmetrical structures having fundamental periods ranging from 0.2 to 2.0 s where the influence that the incident angle of the ground motion has on several engineering demand parameters was examined.

In order to examine the influence of the incident angle on the seismic response of the structure, three records have been selected at random and are applied to the steel-RC composite building of Fig. 4. The three records considered are the Loma Prieta, the Leona Valley, and the Lake Huger. The three records have been applied considering a varying incident angle in the range of 0–360° with a step of 5°. In order to examine the influence of the incident angle on the maximum interstory drift to different intensity levels, the three records have been scaled with respect to the 5 % damped spectral acceleration at the structure's first-mode period to 0.05, 0.15, 0.30, and 0.50 g, and the maximum interstory drift has been recorded for all the incident angles and the intensity levels considered. The variation of the maximum interstory drift with respect to the incident angle and the intensity level for the three records is depicted in Fig. 7. As it can be seen, the seismic response when the incident angle varies in the range of 0–180° almost coincides with the seismic response when the incident angle varies in the range of 185–360°. This is because the relative ratio of the two horizontal components of the records is close to one; thus, the two components are scaled to almost the same intensity level.

Fragility Analysis

In the second part of this numerical investigation, four-limit-state fragility curves are obtained for the RC building of Fig. 5. The limit states considered are defined by means of maximum drift values and cover the whole range of structural damage from serviceability, to life safety, and finally to the onset of collapse. The following $\theta_{\max}$ values are chosen, according to HAZUS (2003), for each of the four limit states: 0.25 %, 0.50 %, 1.50 %, and 4.0 %. For each limit state,

Time History Seismic Analysis, Fig. 7 Eight-story steel-RC composite test example – maximum interstory drift with respect to the incident angle of the record scaled to (a) 0.05 g, (b) 0.15 g, (c) 0.30 g, and (d) 0.50 g intensity levels

Time History Seismic Analysis, Fig. 8 Eight-story test example – fragility curves for four limit states using alternative number of records

the IDA and “vertical” statistics are implemented for computing the statistical parameters μ and β . “Vertical” statistics is performed for all four limit states described above. For the purposes of the present investigation, five cases have been examined for the calculation of the two parameters (μ_k , β_k , $k = 1, \dots, 4$), IDA_{20} , IDA_{40} , IDA_{60} , IDA_{80} , and IDA_{100} , where 20–100 records are implemented.

Figure 8 depicts the fragility curves corresponding to limit states that cover the whole range of structural damage developed for two buildings considered. The fragility curves corresponding to IDA_{100} are considered as the “correct” ones. For the case of the eight-story symmetric building, it can be seen that for all

limit states, IDA_{20} overestimate the structural capacity, while in the cases of IDA_{40} and IDA_{60} , the structural capacity is underestimated. Furthermore, it can be seen that 80 records provide a good estimate of the two parameters μ_k and β_k , since the fragility curves of IDA_{80} almost coincide with those of IDA_{100} case. Therefore, it can be said that IDA_{80} case is a good compromise between robustness and efficiency.

Some Remarks

The choice for a static or dynamic analysis is usually based on engineering judgment. The use of static analysis, however, should be justified

since otherwise the analysis results are meaningless. In particular, when nonlinearities are taken into account, the assumption of neglecting inertia and damping forces may be severe. In the last decade many efforts to formulate a design methodology based on a nonlinear static or dynamic basis have been done. In the seismic design and assessment of structures, a wide range of seismic records and more than one performance levels should be considered in order to take into account the uncertainties that the seismic hazard introduces into a performance-based seismic assessment or design problem. In the construction industry, decision making for structural systems situated in seismically active regions requires consideration of the cost of damage and other losses resulting from earthquakes which may occur during the life span of the structures. In this entry an overview of the time history seismic analysis procedures is provided along with indicative application of such procedures.

Summary

In the case of design or assessment purposes, the seismic capacity of the structural system should be computed for different seismic hazard levels by means of linear or nonlinear time history seismic analyses using a number of properly selected ground motions. The selection of the ground motions plays an important role in the efficiency and accuracy of the design or assessment procedure. In this entry, we provide an overview of the time history seismic analysis applied for design and assessment purposes.

Introduction

The detection and evaluation of time-dependent changes at volcanoes form the foundation upon which successful volcano monitoring is built. Temporal changes at volcanoes occur over all time scales and may be obvious (e.g., earthquake swarms) or subtle (e.g., a slow, steady increase in the level of tremor). Some of the most challenging types of time-dependent change to detect are subtle variations in material properties beneath active volcanoes. Although difficult to measure, such changes carry important information about stresses and fluids present within hydrothermal and magmatic systems. These changes are imprinted on seismic waves that propagate through volcanoes.

In recent years, there has been a quantum leap in the ability to detect subtle structural changes systematically at volcanoes with seismic waves. The new methodology is based on the idea that useful seismic signals can be generated “at will”

from seismic noise. This means signals can be measured any time, in contrast to the often irregular and unpredictable times of earthquakes. With seismic noise in the frequency band 0.1–1 Hz arising from the interaction of the ocean with the solid Earth known as microseisms, researchers have demonstrated that cross-correlations of passive seismic recordings between pairs of seismometers yield coherent signals (Campillo and Paul 2003; Shapiro and Campillo 2004). Based on this principle, coherent signals have been reconstructed from noise recordings in such diverse fields as helioseismology (Rickett and Claerbout 2000), ultrasound (Weaver and Lobkis 2001), ocean acoustic waves (Roux and Kuperman 2004), regional (Shapiro et al. 2005; Sabra et al. 2005; Bensen et al. 2007) and exploration (Draganov et al. 2007) seismology, atmospheric infrasound (Haney 2009), and studies of the cryosphere (Marsan et al. 2012).

Initial applications of ambient seismic noise were to regional surface wave tomography (Shapiro et al. 2005). Brenguier et al. (2007) were the first to use ambient noise tomography (ANT) to map the 3D structure of a volcanic interior (at Piton de la Fournaise). Subsequent studies have imaged volcanoes with ANT at Okmok (Masterlark et al. 2010), Toba (Stankiewicz et al. 2010), Katmai (Thurber et al. 2012), Asama (Nagaoka et al. 2012), Uturuncu (Jay et al. 2012), and Kilauea (Ballmer et al. 2013b). In addition, Ma et al. (2013) have imaged a scatterer in the volcanic region of southern Peru by applying array techniques to ambient noise correlations. Prior to and in tandem with the development of ANT, researchers discovered that repeating earthquakes, which often occur at volcanoes, could be used to monitor subtle time-dependent changes with a technique known as the doublet method or coda wave interferometry (CWI) (Poupinet et al. 1984; Roberts et al. 1992; Ratdomopurbo and Poupinet 1995; Snieder et al. 2002; Pandolfi et al. 2006; Wegler et al. 2006; Martini et al. 2009; Haney et al. 2009; De Angelis 2009; Nagaoka et al. 2010; Battaglia et al. 2012; Erdem and Waite 2005;

Hotovec-Ellis et al. 2014). Chaput et al. (2012) have also used scattered waves from Strombolian eruption coda at Erebus volcano to image the reflectivity of the volcanic interior with body wave interferometry. However, CWI in its original form was limited in that repeating earthquakes, or doublets, were not always guaranteed to occur. With the widespread use of noise correlations in seismology following the groundbreaking work by Campillo and Paul (2003) and Shapiro et al. (2005), it became evident that the nature of the ambient seismic field, due to its oceanic origin, enabled the continuous monitoring of subtle, time-dependent changes at both fault zones (Wegler and Sens-Schönfelder 2007; Brenguier et al. 2008b; Wegler et al. 2009; Sawazaki et al. 2009; Tatagi et al. 2012) and volcanoes (Sens-Schönfelder and Wegler 2006; Brenguier et al. 2008a) without the need for repeating earthquakes.

Seismic precursors to eruptions based on ambient noise were first detected at Piton de la Fournaise volcano on the island of Reunion (Brenguier et al. 2008a; Duputel et al. 2009). The studies at Piton de la Fournaise demonstrated the possibility of resolving small ($\sim 0.1\%$) decreases in seismic velocity in the weeks leading up to eruptions. Brenguier et al. (2008a) and Duputel et al. (2009) further showed how subtle spatial and temporal changes at the volcano could be mapped and used as a real-time tool for volcano monitoring and eruption forecasting. Traditionally, the forecasting ability of volcano seismology has rested on the assumption that volcanic unrest is preceded in advance by a significant increase in seismicity. However, some eruptions, such as Okmok in 2008 (Larsen et al. 2009), have begun with little or no precursory seismicity. For those eruptions, providing accurate and timely advance warnings is much more problematic, placing the public at risk of being exposed to the harmful effects of volcanic activity. Methods based on ambient noise have the potential to assist with forecasting of volcanic unrest in such cases, as well as for eruptions accompanied by ample seismicity and deformation.

Principles of Coda Wave Interferometry

CWI can in principle detect several types of temporal variations, among them changes in subsurface velocity, changes in the source location, changes in bulk scattering properties, and changes in the focal mechanism of earthquakes (Snieder 2006). The sensitivity to subsurface velocity changes initially led to the widespread adoption of CWI for applications at volcanoes. The sensitivity to subsurface velocity can be shown in simple terms with a model of a homogeneous half-space of velocity v with randomly distributed, small-scale scatterers. For this model, the travel time t for a particular scattering path is given simply as

$$t = \frac{d}{v} \quad (1)$$

where d is the total distance traveled for that path. Note that this distance is not necessarily along a straight-line path. To analyze variations in travel time, assume that the velocity changes by an amount Δv but the locations of the scatterers do not change. Since the locations do not change, the distance d traveled by each path stays the same. However, the change in velocity Δv causes there to be a resulting change in the travel time Δt , causing the relation in Eq. 1 to become

$$t + \Delta t = \frac{d}{v + \Delta v} \quad (2)$$

Assuming the changes are small and taking a Taylor series approximation of Eq. 2 yields

$$t + \Delta t = \frac{d}{v} \left(1 - \frac{\Delta v}{v} \right) \quad (3)$$

Combining Eqs. 1 and 3 finally gives the well-known result (Snieder 2006):

$$\frac{\Delta t}{t} = -\frac{\Delta v}{v} \quad (4)$$

Equation 4 is widely used in CWI, and it states that the fractional travel time change is equal to

the negative of the fractional velocity change. Thus, by measuring the fractional travel time change, the change in the subsurface velocity can be estimated. Three different methods have been proposed to measure the time-shifts in CWI: time-windowed cross-correlations (Snieder et al. 2002), the stretching method (Wegler and Sens-Schönfelder 2007), and the phase of the cross-spectrum (Poupinet et al. 1984). Note that Eq. 4 applies to direct waves as well as scattered or coda waves. However, for a given velocity change, the time-shift is greater for waves with longer travel times, i.e., scattered or coda waves. Thus, CWI, in contrast to many other seismic techniques, benefits from higher amounts of scattering since later-arriving waves have larger and more clearly identified time-shifts.

An alternative to the above derivation is for a changing 1D resonator of length d and with an internal propagation velocity v . Resonators have been discussed extensively in volcano seismology as models for sources acting in a crack or cavity (Chouet, 1996; Fee et al., 2010). This model is different from the model of randomly distributed scatterers but still produces a sequence of late-arriving waves. In this case, the derivation proceeds along the same lines as shown above, except that the length d is also allowed to vary, yielding the following expression for the travel time change:

$$\frac{\Delta t}{t} = \frac{\Delta d}{d} - \frac{\Delta v}{v} \quad (5)$$

Haney et al. (2009) have interpreted CWI delay times measured from repeating explosions at Pavlof volcano in the context of this resonator model. As a result, the observed travel time change could be interpreted as a change in the length of the resonator, a change in the velocity of the material inside the resonator, or a suitable combination of both types of changes (see discussion on page 173 of Garces and McNutt (1997)). The implication is that changing properties of the resonator, or conduit, control the changes observed in the coda of the repeating explosions at Pavlof. Landro and Stammeijer (2004) similarly make use of Eq. 5 for

interpreting time-lapse changes from a subsurface layer in an exploration seismic setting.

Overview of Coda Wave Interferometry at Volcanoes

Coda waves of repeating earthquakes, or doublets, have been used to observe temporal changes in the subsurface for several decades (Poupinet et al. 1984). As described by Snieder et al. (2002), CWI takes advantage of subtle time-shifts in the coda of repeating seismic events. In CWI, the time lag between events as a function of recording time is determined via time-windowed cross-correlation of the traces. From the observed time lags, a corresponding change in velocity can be determined. The technique can detect small changes at volcanoes (e.g., Haney et al. 2009; Nagaoka et al. 2010; Hotovec-Ellis et al. 2014), with temporal resolution on the same order as the rate of the repeating events (e.g., hourly resolution in Hotovec-Ellis et al. (2013)). However, the requirement of repeating events precludes the use of CWI at many volcanoes where repeating events are infrequent or short lived. In contrast, ambient noise occurs continuously and, if the signal is highly repeatable, offers the ability to observe temporal changes at volcanoes at will (Sens-Schönfelder and Wegler 2006).

Since the field of interferometry is in its early stages, only a handful of studies (Sens-Schönfelder and Wegler 2006; Brenguier et al. 2008a; Duputel et al. 2009; Baptie 2010; Mordret et al. 2010; Anggono et al. 2012; Obermann et al. 2014) have employed ambient seismic noise to study changes at volcanoes. The existing studies have typically found velocity decreases at volcanoes due to or preceding activity: -0.5% by Baptie (2010), -2.3 to 3.3% by Anggono et al. (2012), -0.8% by Mordret et al. (2010), and -0.4% by Brenguier et al. (2008a). The changes detected with ambient noise to date include seasonal variations (Sens-Schönfelder and Wegler 2006), eruption precursors due to magma pressurization (Brenguier et al. 2008a; Duputel et al. 2009; Anggono et al. 2012), posteruption changes in the volcanic edifice due to dome collapse (Baptie 2010), and

changes in the hydrothermal system (Mordret et al. 2010).

The determination of subtle changes in velocity using ambient noise interferometry is carried out in a similar way to the process used in CWI with repeating earthquakes. Following Duputel et al. (2009), a long-time-period seismic correlation between station pairs is computed, and this correlation represents the reference correlation function (CF). The reference CF must be determined over a period of quiescence at the volcano (Duputel et al. 2009). The reference CF in Duputel et al. (2009) was generated during a two-month period when Piton de la Fournaise was relatively quiet. To identify temporal variations in velocity, they determined the current CF as the seismic correlation between a station pair over a smaller period of time than the reference CF by averaging over a time period of 10 days. Duputel et al. (2009) and Hadziioannou et al. (2009) demonstrated that the stretching technique is a stable method of determining the relative velocity change between station pairs showing significant time lags. The stretching method is an alternative to the traditional method of time-windowed correlations (Snieder et al. 2002). In the stretching method, the reference CF is stretched or compressed to best match the current CF. This stretched/compressed CF is calculated using an assumed relative change in velocity. Over a set of possible relative velocity changes, the relative velocity change that yields the best correlation between the stretched/compressed CF and the current CF is selected. Note that the stretching method assumes a uniform velocity change in the subsurface when measuring time delays between signals. This need not be the case, as demonstrated by Pacheco and Snieder (2006) in their study of time delays from localized velocity perturbations. There remains debate over the relative performance of the stretching method and time-windowed correlations (Zhan et al. 2013). A third method, known as the cross-spectrum method (Poupinet et al. 1984), is closely related to the time-windowed correlation method, since the two represent equivalent processes implemented in either the time or frequency domain.

Tracking Changes in Volcanic Systems with Seismic Interferometry, Fig. 1 (a) Regional map of the Aleutian Arc showing the two volcanoes discussed in this entry, Pavlof and Okmok. (b) Local map of Pavlof volcano and the seismic stations in the monitoring network analyzed in this entry

In the following sections, case studies of CWI are given that use ambient noise and repeating earthquakes at two volcanoes in the Aleutian Islands of Alaska: Okmok and Pavlof. The locations of these volcanoes within the Aleutian Arc are given in Fig. 1a. The seismic stations at Pavlof and Okmok discussed in the following sections are shown in Figs. 1b and 2, respectively. These two case studies illustrate the relative advantages and disadvantages of using ambient noise or repeating earthquakes to measure changes at volcanoes. Following these two case studies, new developments in coda wave interferometry are discussed that will influence future studies at volcanoes.

Seasonal Changes from Ambient Noise at Okmok Volcano, Alaska

Okmok volcano is one of the most active volcanoes in the Aleutian Arc, with an average of one eruption every decade over the past 100 years. Its broad shield structure is interrupted by a roughly 10-km-wide caldera, the remnant of two historical caldera-forming eruptions in the past 10,000 years (Larsen et al. 2009). The most recent eruption of Okmok in 2008 occurred with almost no warning, the only precursory activity being a short-lived earthquake swarm during the 5 h prior to the eruption (Larsen et al. 2009).

Tracking Changes in Volcanic Systems with Seismic Interferometry,

Fig. 2 Local map of Okmok volcano and the seismic stations in the monitoring network analyzed in this entry. The three stations all sit within the 10-km-wide caldera and are broadband installations

At Okmok, as in most of the Aleutian Islands, the majority of the seismic stations are short-period installations. However, several high-quality broadband seismic stations have existed at different times within the Okmok network. These stations represent some of the most remote broadbands in the network operated by the Alaska Volcano Observatory (AVO), a partnership between the University of Alaska Fairbanks Geophysical Institute, the Alaska Division of Geological and Geophysical Surveys, and the US Geological Survey. Three of the five broadbands at Okmok have been sited within the large caldera. The locations of these stations are shown in Fig. 2. The stations have operated over different time periods: OKNC (2010–present), OKCE (2003–present), and OKCD (2003–2008). Station OKCD was destroyed during the initial explosive phase of the 2008 eruption, which emanated from a nearby intracaldera cone. Here, ambient noise correlations are analyzed for station pair OKCE-OKNC during late 2012 and station pair OKCE-

Tracking Changes in Volcanic Systems with Seismic Interferometry, Table 1 Parameters for ambient noise-based coda wave interferometry at Okmok

Parameter	Value
Length of time window considered	5–60 s
Frequency passband	0.5–1 Hz
Moving window length	20 s
Min correlation to accept Δt measure	0.9
Temporal averaging window	+/- 4 days

OKCD during 2006. During both of these times, Okmok volcano was in a period of quiescence. In Table 1, several parameters related to the practical implementation of CWI at Okmok are given. The values of the parameters depend on the desired time scale of resolution, quality control of the correlations, and desired frequency band. The use of the frequency band from 0.5 to 1 Hz represents a trade-off between having a high level of ocean-related noise and being sufficiently high enough in frequency to ensure the generation of scattered waves in the subsurface over the length

Tracking Changes in Volcanic Systems with Seismic Interferometry, Fig. 3

Reference and current correlation functions (CFs) between station pair OKCE-OKNC in late 2012. The reference CF is obtained by averaging over the final 135 days of 2012. The current CF is centered on September 9, 2012, with the average including ± 4 days around this center time. Panels (a) and (c) depict early lag times in the reference (blue) and current

(red) CFs for both the positive (a) and negative (c) lag. At early times, between 1 and 10 s lag, the CFs virtually overlap. Panels (b) and (d) depict late lag times of the same CFs for positive (b) and negative (d) lag. At late lag times, between 29 and 38 s, the current CF (red) shows a subtle time delay relative to the reference correlation function (blue) for both positive and negative lags

scale of a volcano. Note that CWI is subject to statistical considerations related to random scattering paths, and therefore the moving window measurement in CWI must be sufficiently wide to average over scattering from subsurface heterogeneities (Snieder 2006). At Okmok, the coda has been examined using the time-windowed correlation method between time lags of 5–60 s using a moving window of 20 s length. The sensitivity of late-arriving coda waves to changes is shown in Fig. 3 between stations OKCE and OKNC. The late-arriving coda waves (Figures 3b and 3d) are more sensitive compared to the early-arriving

direct and forward-scattered waves (Figures 3a and 3c). Furthermore, as discussed below, the changes in Fig. 3 are consistently observed for both positive and negative lags, which constitutes a redundancy check for CWI based on ambient noise (Breguier et al. 2008a).

Additional CWI parameters concern the similarity between the reference and current CFs and temporal averaging. For the application at Okmok, the peak of the time-windowed correlation is required to exceed 0.9 in order for the associated time-lag measurement within the moving time window to be considered when

fitting the linear relationship in Eq. 4. Wegler et al. (2006) employed a similar criterion based on a minimum correlation coefficient in a CWI study at Merapi volcano, Indonesia. In addition to those parameters, the use of ambient noise requires that the nonstationarity of the ocean noise source be taken into account. Brenguier et al. (2008a) found that temporal averaging of the cross-correlations over a time interval on the order of 1 week renders ocean noise a sufficiently repeatable source. In the following application at Okmok, the current correlation functions (CFs) have been averaged over 8 days centered on the current time (Table 1). The reference CFs are the result of averaging over the entire time period under consideration, either 365 days for the 2006 data or 135 days for the 2012 data.

As mentioned briefly above, CWI based on ambient noise is inherently redundant, since changes should be independently observed for both the positive and negative lags for a correlation between a single station pair (Brenguier et al. 2008a). However, if the distance between a pair of stations is relatively small compared to the wavelength or if the changes can be assumed to be uniform in space, then two additional redundancies exist based on the autocorrelations of the two stations. This is because the autocorrelations can be viewed as ambient noise Green's functions for the case of a coincident source and receiver. For such a configuration, coda waves are still measured. This suggests that changes can be observed in four independent ways for stations that are in relatively close proximity. CWI best practices should exploit these redundancies to apply quality control to the observed changes.

For CWI to be meaningful, error estimates on the relative travel time change given in Eq. 4 must be provided. Following Brenguier et al. (2008a), the standard deviation of the time lag (i.e., the root-mean-square uncertainty of the linear fit) is given by

$$\sigma_{\Delta t} = \sqrt{\frac{\sum_{i=1}^N \left(\Delta t_i - \frac{\Delta v}{v} t_i \right)^2}{N}} \quad (6)$$

where N is the number of time-lag measurements. From Eq. 6, the standard deviation of the relative travel time change follows from Brenguier et al. (2008a) as

$$\sigma_{\Delta t/t} = \sqrt{\frac{\sum_{i=1}^N \left(\Delta t_i - \frac{\Delta v}{v} t_i \right)^2}{N \sum_{i=1}^N t_i^2}} \quad (7)$$

Equation 7 provides the formal error bars on estimates of the relative travel time and, through Eq. 4, velocity changes. However, in addition to formal error bars, goodness-of-fit criteria must be taken into account as well (Press et al. 1986). In the implementation of CWI at Okmok, two goodness-of-fit criteria are required to be met in order to accept an estimate of relative travel time, irrespective of the error estimate in Eq. 7. It must be that either (a) the standard deviation in Eq. 6 is less than one time sample or (b) the Pearson linear correlation coefficient given by

$$r_{xy} = \frac{N \sum x_i y_i - \sum x_i \sum y_i}{\sqrt{N \sum x_i^2 - \left(\sum x_i \right)^2} \sqrt{N \sum y_i^2 - \left(\sum y_i \right)^2}} \quad (8)$$

is greater than 0.8, where, for CWI, the (x, y) variables in Eq. 8 are the travel time and the time lag $(t, \Delta t)$. Values of r_{xy} exceeding 0.8 are taken to indicate a strong linear relation. In practice, the first criterion means that measurements between similar waveforms in which the changes are not appreciable are automatically accepted. The second and possibly more important criterion requires that Δt and t have a strong linear correlation when the standard deviation is greater than one time sample, which in practice occurs when the changes are significant. Note that a linear relation between Δt and t may not resemble the measured Δt - t curve in general (Pacheco and Snieder 2006). However, if a linear model is being used, then it is at least consistent to require that the linear fit is good. Without considering the goodness-of-fit criterion in Eq. 8, it may be the

Tracking Changes in Volcanic Systems with Seismic Interferometry,

Fig. 4 Plotted in the *top* panel are the relative velocity changes computed from correlations of stations OKCE and OKNC in 2012 for positive lags (blue) and negative lags (black). The *bottom* panel shows the relative velocity changes for the OKCE (blue) and OKNC (black) autocorrelations. All four measurements are broadly in agreement, which they should be for velocity changes that are spatially extensive. This redundant property of ambient noise correlations can be used to measure the confidence of the velocity changes

case that the formal error in Eq. 7 is acceptable even though the linear fit is not good. This emphasizes the need for a goodness-of-fit criterion, as discussed in Press et al. (1986).

Taking into account the above considerations, Fig. 4 shows the relative velocity changes computed from both positive and negative lag portions of cross-correlations and autocorrelations for Okmok stations OKCE and OKNC over the final 135 days of 2012. The formal uncertainties for the measurements are also provided in Fig. 4. Note that the various time series are discontinuous at certain points due to the CWI measurements failing to satisfy the goodness-of-fit criteria. The relative velocity changes in Fig. 4 are observed to vary between $\pm 0.2\%$. Moreover, the changes are internally consistent in that they are observed independently for both positive and negative lags. Consistent changes are also observed for the autocorrelations, indicating that the spatial distribution of the change in the subsurface is generally uniform inside of the caldera. The source of the change will be discussed after examining data from 2006, but in principle it could be the result of magmatic or seasonal variations in the subsurface. Seasonal changes

observed with CWI measurements have been studied previously by Sens-Schönfelder and Wegler (2006), Meier et al. (2010), Tsai (2011), and Hotovec-Ellis et al. (2014). Sources of the seasonal changes include thermoelastic and hydrologic effects and, at high elevations or high latitudes, the annual snow cycle.

In Fig. 5, relative velocity changes are shown between stations OKCE and OKCD for all of 2006. Positive and negative lag correlations are plotted, in addition to the autocorrelation of OKCD (the autocorrelation of OKCE is not plotted in Fig. 5 since in 2006 it suffered from a type of uncorrelated electronic noise). In spite of this noise, the three correlations plotted in Fig. 5 show consistent estimates of relative velocity change during 2006. The subsurface velocity is observed to be slightly higher in winter and spring (days 1–180 and 350–365) and lower in summer and fall (days 180–350). These annual variations are highly similar to the relative velocity changes observed by Hotovec-Ellis et al. (2014) at high-elevation sites on Mount St. Helens. Although the observations at Okmok are based on ambient noise, the observations by Hotovec-Ellis et al. (2014) were derived from long-term

Tracking Changes in Volcanic Systems with Seismic Interferometry, Fig. 5 Plotted in the *top* panel are the relative velocity changes computed from correlations of stations OKCE and OKCD in 2006 for positive lags (*blue*) and negative lags (*black*). The *bottom* panel shows the relative velocity change for the OKCD autocorrelation. Station OKCE suffered from electronic noise that was not present on OKCD, and thus its autocorrelation is not

shown. Since the noise only appeared on OKCE, it did not affect the OKCE-OKCD cross-correlation. All three measurements are broadly in agreement, with subtle velocity increases in the winter/spring and velocity decreases in summer/fall. Station OKCE suffered from electronic noise that was not present on OKCD, and thus its autocorrelation is not shown

(decadal) records of repeating local earthquakes. Hotovec-Ellis et al. (2014) concluded that the annual variability at high-elevation sites on Mount St. Helens was controlled by the snow cycle and at lower-elevation sites by shallow fluid saturation (Fig. 6). The snow loading interpretation could apply at Okmok as well in spite of the low elevation of the caldera, since Okmok is located within the high-latitude chain of the Aleutian Islands. Returning to Fig. 4, the overall increase in velocity during the final 135 days of 2012 can be attributed to the onset of the snow-pack as fall transitioned into winter. Taken together, the relative velocity variations observed at Okmok during times of quiescence in 2006 and 2012 appear to be seasonal in nature and, due to the annual snow cycle, in agreement with the conclusions by Hotovec-Ellis et al. (2014) at high-elevation sites on Mount St. Helens.

Conduit Changes from Repeating Explosions at Pavlof Volcano, Alaska

The 2007 eruption of Pavlof volcano was Strombolian in character and generated lava flows, lahars, and small explosions (Waythomas et al. 2007). Seismicity consisted of volcanic tremor and repeating long-period signals associated with the small explosions at the summit of the volcano. Haney et al. (2009) have previously applied CWI to the repeating explosions during the 2007 Pavlof eruption and detected subtle changes. In contrast to CWI based on ambient noise, as discussed in the previous section, CWI based on explosions at Pavlof takes advantage of the highly repetitive waveforms to observe small changes in the later portion of their signals. In this section, we summarize the study of Haney et al. (2009) and give some additional supporting observations.

Tracking Changes in Volcanic Systems with Seismic Interferometry,

Fig. 6 Velocity as a function of months of the year at Mt. St. Helens, with demeaned raw solutions in *light gray* and average in *thicker black*. *Dashed line* corresponds to average yearly snow load at an SNOTEL station in Sheep Canyon. *Dotted line* corresponds to average lake elevation at Spirit Lake, plotted with an inverted y-axis to better illustrate the anticorrelation and interpreted to correspond to changes in shallow fluid saturation. *Shaded area* denotes months of the year with increased shallow seismicity (Reproduced from Hotovec-Ellis et al. (2014))

Tracking Changes in Volcanic Systems with Seismic Interferometry, Fig. 7 Reduced displacement (D_R) of volcanic tremor over the course of the month-long eruption of Pavlof volcano in 2007. The plot of D_R shows that the eruption began with low-level tremor during the first 10 days, with pulses of higher D_R occurring during times of lahars. After 10 days, the tremor level increased and remained elevated for over 2 weeks before tapering off at

the end of the eruption in mid-September. The vertical dashed lines indicate the 20 days when repeating explosions occurred. The overall tremor D_R is indicative of a low-level Strombolian eruption of VEI between 1 and 2. Note data dropouts for this station between days 24 and 25. The vertical dashed lines indicate the 20 days presented in Fig. 8

To put the entire Pavlof eruption in context, Figure 7 shows the reduced displacement (D_R) computed at station PVV on the east side of the volcano (see Fig. 1b). D_R is a measure related to the energy radiated by volcanic tremor (Aki and Koyanagi 1981). As indicated in Fig. 7, the 2007 Pavlof eruption began on August 14, and, over the next 10 days, the tremor level was relatively low. Short periods of elevated D_R during the first 10 days of the eruption were not the result of elevated tremor but instead corresponded with lahars flowing close to PVV. On August 24, 10 days into the eruption, the tremor increased from a D_R of 0.5 cm² to a D_R of 1.5 cm² and stayed at that level until the end of the eruption. It was during this period of relatively higher tremor amplitude that repetitive explosions occurred at the summit of Pavlof, at the rate of approximately one explosion every 3–6 min. These Strombolian explosions represented a subtle increase in the overall intensity and explosivity of the eruption.

As described in Haney et al. (2009), the waveforms due to the repeating explosions over the entire eruption were identified using the master event matched filter technique described by Petersen (2007). Once the catalog of repeating events had been identified, Haney et al. (2009) stacked the repeating waveforms within successive 12-h time periods to increase the signal-to-

Tracking Changes in Volcanic Systems with Seismic Interferometry, Table 2 Parameters for explosion-based coda wave interferometry at Pavlof

Parameter	Value
Length of time window considered	0 20 s
Frequency passband	1–4 Hz
Moving window length	6 s
Min correlation to accept Δt measure	0.7
Temporal averaging window	+/- 6 h

noise ratio and applied CWI using the stack from the earliest time period as the reference. Table 2 gives additional parameters used for the application of CWI with the repeating explosions. Plotted in Fig. 8 is the relative travel time change over the final 20 days of the eruption, along with the average rate of explosions during each 12-h time period. An overall increase in the relative travel time of 0.4 % is observed as the eruption progressively came to an end over its final 20 days. The relative travel time change is plotted in Fig. 8 instead of relative velocity change, since Haney et al. (2009) interpreted the change in terms of the resonator model of Eq. 5. According to this model, the increase in travel time can be interpreted as an increase in the length of the resonator or conduit; a decrease in the internal propagation velocity of the conduit; or a suitable combination of both types of change.

Tracking Changes in Volcanic Systems with Seismic Interferometry,

Fig. 8 The *upper* panel shows the relative travel time change for stacks of repeating explosions over the course of 20 days beginning on August 24, 2007. The number of Strombolian explosions per hour is plotted in the *lower* panel for comparison. The explosions occurred during a time period of elevated reduced displacement, as seen in Fig. 7

Without additional information, the source of the change at Pavlof cannot be resolved further among these possible models. Although the relative traveltimes changes are only shown for station PV6 in Fig. 8, Haney et al. (2009) also observed similar changes at station PN7A located to the west of the summit (Fig. 1b).

Based on the frequency content of the explosions and common spectral peaks between stations PV6 and PN7A, Haney et al. (2009) concluded that the relative travel time changes observed in Fig. 8 were the result of changes within the volcanic conduit at Pavlof. The interpretation by Haney et al. (2009) is significant since the changes are therefore the result of a varying source effect instead of a varying path effect. This is in contrast to the conclusions of most CWI studies at volcanoes. A notable exception is the study by Erdem and Waite (2013) in which relative velocity changes were detected with CWI at Fuego volcano with repeating explosions over short time scales, in as little as hours. Erdem and Waite (2013) concluded that the variations were occurring within the conduit due to the differences in the apparent relative velocity changes measured on seismometers at different distances from the volcano.

To illustrate the interpretation by Erdem and Waite (2013) based on seismometers at different distances, the resonator model shown in Eq. 5 needs to be reconsidered. For this, consider the travel time of the n -th reverberation within the conduit, given by

$$t_n = t_E + \frac{nd}{v} \quad (9)$$

in which t_E is the traveltime needed to propagate through the Earth from the conduit to the seismometer. Assuming small changes in the conduit length d , velocity within the conduit v , and travel time of the n -th reverberation t_n , but no changes in the traveltime through the Earth t_E , a first-order perturbation of Eq. 9 yields

$$\Delta t_n = (t_n - t_E) \left[\frac{\Delta d}{d} - \frac{\Delta v}{v} \right] \quad (10)$$

Equation 5 is a special case of Eq. 10 when $t_E = 0$ and t_n is identified as the travel time. In addition, Eq. 5 can be viewed as an approximation that applies at times much later than the time needed to propagate through the Earth from the conduit to the seismometer ($t_n \gg t_E$). When these

Tracking Changes in Volcanic Systems with Seismic Interferometry,

Fig. 9 In *left upper* and *left lower* panels are amplitude spectra of stacks of repeating explosions on August 30 (*blue*) and September 5 (*red*) for station PV6. The spectra are dominated by a peak frequency at ~ 2.4 Hz. In the *right* panel is a zoom-in of the peaks on August 30 and September 5 plotted together. The peak is observed to have shifted from 2.407 to 2.399 Hz over the course of the 6 days, in agreement with the CWI measurements

conditions are not met, the use of Eq. 5 underpredicts the actual velocity change, as noted by Haney et al. (2009). Erdem and Waite (2013) astutely noted that the amount of underprediction varies for seismometers at different distances from the volcano and used that fact to diagnose the source of time-lapse changes at Fuego volcano.

An additional piece of evidence for conduit changes at Pavlof, not presented in Haney et al. (2009), follows from the spectral properties of the repeating explosions. For a simple 1D resonator, the change in the resonance frequency is related to changes in the propagation velocity inside the resonator and the length of the resonator as follows (e.g., Garces and McNutt 1997):

$$\frac{\Delta f}{f} = \frac{\Delta v}{v} - \frac{\Delta d}{d} \quad (11)$$

Note that the right-hand side of this equation is the negative of the right-hand side of Eq. 5. Thus, the relative changes in resonance frequency and traveltime for the model of a resonator have the same absolute value but are opposite in sign.

Whereas the traveltime, or residence time, of a 1D resonator increases when its internal velocity is decreased, its resonance frequency decreases. In Fig. 9, amplitude spectra of the repeating explosions are shown at station PV6 for time periods one week apart. The dominant resonant peak in both amplitude spectra is approximately 2.4 Hz with a slight shift toward lower frequencies later in the eruption. Garces and McNutt (1997) reported on a larger -18% change in the spectral peaks of tremor before and after an eruption at Mount Spurr volcano in 1992. The change at Pavlof, observed in the spectral domain, is consistent with the change derived from CWI in the time domain. This consistency in the spectral domain supports the interpretation by Haney et al. (2009) of conduit resonance and hints at deeper connections between the methods of interferometry and spectroscopy in physics (Zadler et al. 2005). In fact, the CWI experiment described in Snieder et al. (2002), involving a sample of Elberton granite, could have been equivalently analyzed in the frequency domain since the waves traversed the finite-sized sample many times over the time window of the experiment.

New Developments in Coda Wave Interferometry

Two emerging areas of research in the use of seismic interferometry for monitoring changes at volcanoes are highlighted in this section. The first example addresses the use of new sources besides repeating earthquakes and the oceanic microseism. The second example concerns the use of decorrelation between repeating signals in addition to traditional time-lag measurements.

The simple relationship in Eq. 1 holds for the direct wave portion of the ambient noise Green's function in a homogeneous medium with d the interstation distance. However, if the distribution of noise sources is not uniform, spurious arrivals can appear in ambient noise Green's functions. This issue is a problem for ANT, since tomography requires accurate interstation travel times. However, as will be shown here, this isn't an issue for CWI with ambient noise. Consider an extreme case in which the noise source comes from a single azimuth, as shown in Fig. 10. For this case, the interstation travel time for the direct wave is given by

$$t = \frac{d \cos \theta}{v} \quad (12)$$

where θ is the azimuthal angle between the interstation azimuth and the back azimuth of the plane wave source. Equation 12 shows that for this case the arrival is spurious since it doesn't correspond to a physical wave in the Green's function, which would arrive at $t = d/v$. Proceeding as in Eqs. 1, 2, 3, and 4, assume that the subsurface velocity changes by an amount Δv . The change in velocity Δv causes there to be a resulting change in the travel time Δt . In addition,

consider that the source azimuth changes by $\Delta\theta$, giving the following relation:

$$t + \Delta t = \frac{d \cos(\theta + \Delta\theta)}{v + \Delta v} \quad (13)$$

Assuming small changes and taking a first-order Taylor series approximation of Eq. 13 yields

$$t + \Delta t = \frac{d}{v} \left(\cos \theta - \Delta\theta \sin \theta - \frac{\Delta\theta^2}{2} \cos \theta \right) \left(1 - \frac{\Delta v}{v} \right) \quad (14)$$

Combining Eqs. 12 and 14 yields

$$\frac{\Delta t}{t} = -\frac{\Delta v}{v} - \Delta\theta \tan \theta \left(1 - \frac{\Delta v}{v} \right) - \frac{\Delta\theta^2}{2} \quad (15)$$

An important outcome of this result is that, in the case of no change in the azimuth of the source ($\Delta\theta = 0$), Eq. 15 is the same as Eq. 4 in spite of the Green's function being incorrect due to the noise only coming from one direction. Equation 15 for a stable source ($\Delta\theta = 0$) shows the insensitivity of ambient-noise-based CWI to the direction of an oblique plane wave source. It is a simple demonstration that accurately detecting changes does not require the cross-correlations to be the true Green's function. Nonphysical arrivals in Green's functions constructed from ambient noise, so-called spurious arrivals (Snieder et al. 2008), still obey Eq. 4 when the source is stable. Hadzioannou et al. (2009) first took note of this property and concluded that time-lapse changes can be reliably estimated even when the Green's function is not properly reconstructed. Hadzioannou et al. (2009) further concluded that the only condition necessary for monitoring changes is the relative stability of the noise.

These results bring up the possibility of using unconventional, localized sources, that are nonetheless continuous and stable, to detect changes. An example of such a source is man-made cultural noise produced by machinery or traffic. Another example is stable volcanic tremor

Tracking Changes in Volcanic Systems with Seismic Interferometry,
Fig. 10 A plane wave source incident obliquely on a pair of seismometers

(Ballmer et al. 2013a), which at some volcanoes can persist for weeks, months, or even years. This also motivates the study of such noise sources to establish their stability prior to using them for detecting time-lapse changes. The wave fields from these localized noise sources do not even begin to satisfy the conditions necessary for imaging with a technique such as ANT however, the reduced requirement of relative source stability for monitoring permits a wider set of applicable noise sources.

A recent development by Obermann et al. (2014) addresses decorrelation instead of time-shifts in coda-wave measurements. In CWI, when two seismograms are cross-correlated over a small time window, the time delay is related to the time-lag of the peak. The value of the peak itself is the correlation coefficient C ; the decorrelation coefficient is simply defined as $D = 1 - C$. This approach offers a new type of measurement in addition to the widely used time delay in CWI. Obermann et al. (2014) applied a technique based on decorrelation at Piton de la Fournaise and found information about changes in the subsurface that was complementary to the information provided by conventional CWI based on time shifts. Specifically, whereas time-shift measurements detected velocity variations in the subsurface, decorrelation measurements detected changes in scattering. Newly created cracks in the subsurface related to magma intrusions were interpreted by Obermann et al. (2014) to be the source of the decorrelation signal. In the following, the expression for decorrelation due to a single scatterer presented in Obermann et al. (2014) is specialized for the case of randomly distributed scatterers in a homogeneous background medium. This expression forms the link between the decorrelation coefficient in Obermann et al. (2014) and similar expressions first derived in Snieder et al. (2002).

From Obermann et al. (2014), the decorrelation for a single scatterer with scattering cross section S in a background medium with wave speed v is expressed as

$$D(s_1, s_2, x_0, t) = \frac{vS}{2} K(s_1, s_2, x_0, t) \quad (16)$$

where s_1 and s_2 are the locations of the two stations, x_0 is the location of the single scatterer, and K is the CWI sensitivity kernel presented in Pacheco and Snieder (2005). The CWI sensitivity kernel expresses the spatial location of the sensitivity of a CWI measurement in a generally variable background medium. The derivation of Eq. 16 for the case of a single scatterer is quite complicated (Rossetto et al. 2011); however, as shown below, its generalization to a distribution of new scatterers leads to a simple and insightful expression (the terminology of “new scatterers” refers to scatterers that developed in the intervening time period between measurements taken at different times). Given N identical new scatterers in a small area dA , the effect of the individual new scatterers on the decorrelation can be assumed to be additive:

$$D(s_1, s_2, x_0, t) = \frac{NvS}{2} K(s_1, s_2, x_0, t) \quad (17)$$

Multiplying and dividing this expression by the small area dA leads to

$$D(s_1, s_2, x_0, t) = \frac{nvS}{2} K(s_1, s_2, x_0, t) dA \quad (18)$$

where $n = N/dA$ is the (2D) number density of the new scatterers. Integration of both sides of this equation over the whole spatial area considered gives the decorrelation due to a distribution of scatterers:

$$D(s_1, s_2, t) = \int \frac{nvS}{2} K(s_1, s_2, x_0, t) dA \quad (19)$$

which similarly assumes as before that the effects of the different areas are additive, although here the different areas may have variable scattering cross sections $S(x_0)$. The product of the number density and scattering cross-section is related to the inverse of the mean free path within the independent scattering approximation ($L = 1/nS$) (Obermann et al. 2014). Note that this mean free path is for the new scatterers not present in the background medium. Assuming the background velocity is constant finally gives

$$D(s_1, s_2, t) = \frac{v}{2} \int \frac{K(s_1, s_2, x_0, t)}{L} dA \quad (20)$$

where the mean free path L is taken to have a dependence on the spatial coordinate x_0 .

To further simplify the expression, a model is adopted in which the mean free path for the new scatterers is constant everywhere (globally). This is the opposite end member of a single scatterer, Eq. 16, among models. It is also similar to the global change in velocity that gives rise to Eq. 4. Given the following expression for travel time known as the Chapman-Kolmogorov equation (Pacheco and Snieder 2005)

$$t = \int K(s_1, s_2, x_0, t) dA \quad (21)$$

the decorrelation for a constant mean free path increases linearly with time according to

$$D(t) = \frac{v}{2L} \int K(s_1, s_2, x_0, t) dA = \frac{vt}{2L} \quad (22)$$

The linearly increasing decorrelation behavior with time is in fact the same type of behavior described by Snieder et al. (2002) for a model of moving scatterers, in which all scatterers are randomly perturbed by a distance Δ . This model is different from the model of Obermann et al. (2014) that consists of new scatterers appearing among otherwise stationary and unchanging background scatterers. From Snieder et al. (2002), the decorrelation for the moving scatterer model is given by

$$D(t) = k^2 \Delta^2 \frac{vt}{l} \quad (23)$$

where k is the wavenumber and l is the mean free path in the background medium. This result means that the two models – either the moving scatterers of Snieder et al. (2002) or the newly appearing scatterers of Obermann et al. (2014) – both predict a linear increase in decorrelation when the changes are global and are thus indistinguishable in that case. A possible way to discern these two models in the case of global

changes would be to carefully exploit the wavenumber dependence for the moving scatterer model in different frequency bands. It is not clear whether these models are indistinguishable for changes that are local, but the fact that they are indistinguishable for global changes does hint at some amount of intrinsic nonuniqueness in resolving the different models.

Equation 22, $D(t) = vt/2L$, can be rewritten as $D(d) = d/2L$, where d is the total distance traveled by the path. This relation clearly shows the mechanism of the decorrelation in the model of Obermann et al. (2014), which is scattering by the new scatterers. It is the fraction of the total distance divided by twice the scattering mean free path of the newly appearing scatterers. Note that this mean free path L is not necessarily close to the mean free path of the background medium. The advancements in the understanding of decorrelation reported in Obermann et al. (2014) should lead to increased use of this measurement in future studies of time-lapse changes at volcanoes.

Conclusion

As demonstrated by a flurry of research activity in recent years, tracking changes at volcanoes with seismic interferometry has the potential to become a powerful volcano monitoring tool. The ambient seismic noise arising from the interaction of the ocean with the solid Earth yields repeatable signals that can detect subtle time-dependent changes at volcanoes. In addition to the overview of previous studies discussed in this entry, two examples of detecting time-lapse changes were presented for Okmok and Pavlof volcanoes in Alaska. Interestingly, Newhall (2007) independently pointed out an approach similar to ambient noise CWI in a review of volcanology and volcano monitoring. Newhall (2007), when discussing the challenge of interpreting indirect geophysical measurements at volcanoes, suggested tracking changes at volcanoes in response to known, repeating natural signals. With the advent of ambient noise interferometry, the concept of using repeatable,

natural sources of energy from the ocean to probe volcanoes has been realized and offers a new opportunity to understand the fascinating and complex inner workings of magmatic systems worldwide.

Tsunamigenic layers; Tsunamiites; Tsunamites

Introduction

Tsunami waves are the result of a large mass of water being displaced by different processes. Earthquake-induced tsunamis have small wave heights offshore and very long wavelengths up to several hundred kilometers (line source tsunami). This is in contrast to tsunamis caused by mass movements (subaerial or underwater origin), volcanic eruptions and explosions, glacier calvings, or meteorite impacts, which have very high waves and very short wavelengths close to the origin (point source tsunami).

More than 85 % of tsunamis have tectonic causes such as fault movements (5 % are caused by volcanic activity, 5 % by landslides, and 5 % by a combination of all other causes; impact tsunamis are very rare), and 80 % of these occur in the Pacific Ocean; other oceans and seas have also been affected by tsunamis like the Mediterranean Sea. Tsunami evidence has also been

found on the shorelines of large and deep lakes, such as Lake Geneva in Switzerland.

Extreme waves can also be induced by storms and become tsunamis when approaching the coastline due to shoaling or shallowing. This can result in the superposition of waves and a dramatic reduction in wave velocity; sometimes also infragravity waves with high velocity have been observed during cyclones, e.g., the Haiyanstorm on the Philippines in 2014.

Tsunami action is mirrored in geological records and archives as phases of erosion, reworking, and redeposition leaving unconformities and unusual sedimentary layers. Tsunamites or tsunami deposits are proof that past or prehistoric tsunami events have occurred along coastlines or lakeshores. This article aims to describe the main environments, deposits of earthquake-derived tsunamis, and the limitations on their use.

Tsunami Processes

To understand how tsunami deposits may be preserved in the rock record, the process of tsunami generation, propagation, and landfall must be first understood.

The speed of a tsunami wave is calculated by the square root of the product of acceleration by gravity (9.8 m/s^2) and the water depth; in deep water, the wavelength of the tsunami must also be taken into account. The plural form is “tsunamis” or “tsunami.”

A tsunami train is a series of waves, which are destructive when they make landfall (Fig. 1). Refraction of tsunami waves (bending) may occur and mainly depends on the morphology and shape of the seabed in front of the coast. Wave reflection also occurs which describes the wave bouncing back after striking the shoreline. The first wave in the tsunami wave train is often not the largest wave and therefore leaves almost no deposits (or only in favorable setting) as the deposits are usually reworked by following waves. The time interval between waves hitting the coastline varies but can be around 10 min or more. Generally, three to four major wave

landfalls can be documented in the sedimentary record. The ecology and the geomorphology of coastlines are severely affected and modified during earthquake-induced tsunami landfall.

Several parameters obtained from recent or historical tsunamis are used in paleotsunami research, the most important of which are the inundation distance and run-up height (Fig. 2). The maximum run-up and inundation are delineated by the location of the wrack line or wrack line deposits. These are then used as basic parameters for coastal evacuation and emergency planning. Local effects of coastal morphology such as bays, fjords, and rias can amplify wave heights and inundations.

Coastal Environments for Paleotsunamis

Sedimentary evidence for tsunamis is found along the shorelines of marine and lacustrine environments. The shorelines of the Earth vary from place to place and can be simplified into two characteristic environments: flat sandy coasts or marshes and cliffed rocky coasts (Fig. 3a, b). The formation of a coast with sediments at the sea-shore depends on several parameters including the position of the sea level, the tidal influence, and the presence of river inlets (e.g., sculpted into bays, cusped forelands with mudflats, marshes, sandy beaches, or dunes). The geomorphology of a coast plays a major role in preserving tsunamigenic deposits.

Soft Coasts

Paleotsunami research focuses on suitable archives along affected coastlines. To have a suitable archive, the deposits must firstly have had the potential to be preserved, which means long-term subsidence and sedimentation should prevail and not uplift/erosion; secondly, the deposits should be distinguishable from storm layers (tempestites); and thirdly, the deposits should yield datable material. Lagoons or marshy flatlands have been widely used as archives for investigating tsunami deposits (Fig. 3a). In these settings, tsunami landfall has a huge effect on the

Tsunamis as Paleoseismic Indicators, Fig. 1 Tsunami wave train approaching the Japanese coastline after the 2011 Tohoku earthquake, note tsunami has already made landfall (*left*; Photo by Douglas Sprott is licensed under

CC BY-NC 2.0). Gauge data showing the wave train from the 1960 Chilean earthquake tsunami along the Japanese coast (Onagawa city) with tide data superimposed (*right*, Modified from Atwater et al. 1999)

Tsunamis as Paleoseismic Indicators, Fig. 2 General tsunami parameters

Tsunamis as Paleoseismic Indicators, Fig. 3 (a) Tsunami landfall and deposits along sandy shores, and various types of back wash deposits (*middle*). (b) Tsunami landfall at rocky coasts (*bottom*)

local sedimentary environment and ecology. Freshwater, brackish, or hypersaline lagoons will be affected by short durations of marine ingressions containing characteristic marine flora and fauna. Furthermore, coarse-grained deposits (sand sheets and washover fans) will be deposited in fine-grained lagoonal and organic clays or evaporitic sediments. After landfall, the lagoonal environment may then reestablish itself including sedimentation, and hence sand sheets can be preserved (Fig. 3a).

Hard Coasts

Along steep rocky shores, the locations of huge blocks and the arrangement of smaller blocks are used to delineate tsunami landfall. Tsunami boulders or “boulder trains” are chains of imbricated blocks interpreted as remnants of tsunami action (Fig. 3b). These “boulder trains” have been found all around the world (Scheffers and Kelletat 2003; Scheffers 2008).

Backwash Offshore

Offshore records of paleotsunamis are rare, and related deposits are ambiguous; therefore, they cannot be reliably associated with tsunami action. Backwash deposits into the sea/lake after tsunami landfall by the backflow of the water mass are also hard to identify. For relatively recent tsunamis, backwash deposits can be identified mainly by the presence of anthropogenic pollution as evidenced by some chemical proxies; however, older tsunamigenic deposits are complex and hard to recognize as they may not yield these characteristic constituents.

Due to Holocene sea level rise, many shorelines have developed relatively recently. Other shorelines have been affected by tectonic movements (uplift or subsidence). Due to the glacial sea level low stands, some tsunamis older than 10–15,000 years may not be preserved along the seashores as they are now drowned or have been reworked. However,

interglacial/-stadial tsunamigenic deposits (during a high stand, e.g., MIS 5) have the potential to be preserved.

Tsunami Sediments or Deposits (Tsunamiites, Tsunamiites)

Tsunami sedimentology has advanced considerably in the past 25 years since Brian Atwater in 1987 (Atwater 1987) associated sand layers on the Pacific Coast of Washington State with the occurrence of major tsunami-producing subduction earthquakes (Rhodes et al. 2006). The 2004 Indian Ocean and 2011 Tohoku-oki tsunamis and their deposits significantly changed our understanding of sedimentary features, sediment architecture, and the processes of tsunamigenic deposition, preservation, and postdepositional changes. Prior to 2004, the historical record and especially catastrophic events were too infrequent to be satisfactorily studied, and the identification of tsunami remains was equivocal. Paleotsunami sedimentology is complex, but more and more researchers have integrated sedimentological, geochemical, and paleontological analyses from post-tsunami field surveys and laboratory analyses. This multidisciplinary approach allows a datum to be assigned to the event layers using a combination of several dating methods. To some extent, a clear assignment of an event layer to tsunami action will always remain equivocal, but large storms have different wavelengths, have a major peak of wave action, and have no train of several major waves. Consequently, tsunami deposits should be different to those caused by storms. Some authors also refer to the recurrence periods of, e.g., tropical storms, which is generally an order of magnitude higher than that of major (paleo)tsunamis (e.g., Nanayama et al. 2003). The tsunami database has been expanded during the last decades and, in combination with an improved understanding of tsunami depositional mechanisms (Shiki et al. 2008; Goff et al. 2012), has helped to identify paleotsunami deposits in many parts of the world.

Identification

Recognizing and identifying paleotsunami deposits and assigning the magnitude and extent of (pre)historic tsunamis is an important part of paleoseismological studies. An outstanding example of this is from Japan, where tsunami deposits of a historical event in AD 869 were identified on the Sendai plain by Minoura et al. (2001). The 2011 Tohoku-oki tsunami deposits now cover the AD 869 deposits in the same area. The presence of the older deposits was used to determine/verify the occurrence of a previous large earthquake and tsunami event and proved that this area is susceptible to large-scale tsunami inundation. The world then realized that this part of Japan had experienced magnitude 9 earthquakes with associated tsunamis in the past. Sedimentary, geochemical (inorganic, organic, isotopic), and paleontological proxies are usually used for identification of tsunami deposits.

Despite the existence of a vast amount of publications on diagnostic features of paleotsunamis (e.g., Shiki et al. 2008), identification is not always easy in other parts of the world, and unambiguous evidence for tsunami deposit identification is not always present. In these cases, a range of features must be assessed in order to determine the origin of the deposits.

Soft Coasts

A tsunami is recorded sometimes only by a single sand layer of varying thickness. Sandy sheets of tsunami deposits in the sedimentary record are generally characterized by (a) a sheetlike geometry stretching in the inundation area; (b) a landward thinning of the sand layer(s) (wedging, tapering); (c) a landward fining of the sand sheet(s); (d) fining upward in the layer(s), normal grading (suspension sediment), partly reverse grading, and lamination (traction sediment; Fig. 5); (e) multiple layers of the sand sheet(s), showing all a fining and thinning upward (Fig. 4), representing the “wave train,” but sometimes multiple layers are not present or are overlain by mud in the landward limit (mud drape); (f) beach

Tsunamis as Paleoseismic Indicators, Fig. 4 Sedimentary record after tsunami landfall and variation of deposits along sandy shores, with respect to tsunami wave trains, run up and depositional environments. Different colors reflect deposits of differing ages and thickness. Note also the varying topographic height of deposits

of the identical ages. Time reflects several minutes between the arrival of major waves. The record in the lagoon contains three deposits from three waves, with thinning-up of the layers and fining-up within the layers

sediments and biogenic material (shells, corals, aquatic plants) are incorporated in the sand sheets; (g) rip-up clasts of semilithified clayey or sandy materials and incorporated (Fig. 5), partly armored mud balls; and (h) the sediments show a marine geochemical signature, including microfossils (foraminifera, ostracods, diatoms, pollen, nannoliths, etc., but all of those may be reworked), but also this feature is not always present or preserved (Goff et al. 2012). Identification of a muddy tsunami deposit is still difficult at present; (inorganic and organic) geochemical, microfossil, and x-radiograph approaches are promising (Goff et al. 2012). The best identification is always given if extraordinary layers are intercalated in sediments of different grain size (i.e., sand sheets in fine-grained lagoonal deposits, see Figs. 4 and 5). Tsunami deposits can also consist of complex layers of mud, sand (dune sands), and boulders, containing abundant stratigraphic evidence for sediment reworking (rip-up clasts: eroded out from the original

surface or lagoon, Fig. 5) and redeposition, including anthropogenic materials (ceramics, concrete fragments artifacts, biogeochemical tracers, like oils, fats, metal-rich deposits, charcoal, and others).

Hard Coasts

Tsunami boulder deposits are identified around the world along many sandy and rocky coasts, and the findings are still increasing (Scheffers 2008; Shiki et al. 2008; and e.g., Pacific/Japan: Goto et al. 2007, 2009, 2010; Pacific/Indian Ocean: Etienne et al. 2011; Indian Ocean: Hoffmann et al. 2013a; Fig. 6). Some of the tsunami boulders have weights larger than 100 t. Boulder deposits provide useful information to improve our understanding of recurrence intervals and paleotsunami size, if dated correctly, by using boulder orientation and inland variation in boulder size, blocks, and boulders with pot holes (bioerosion, up-side down or rotated), paleonotches, adhesive growth of animals, like

Tsunamis as Paleoseismic Indicators, Fig. 5 Close-up of a drill core from locality Sozopoli/northern Greece (From Reicherter et al. 2010), showing two cycles of the tsunami train. The lower layer has an erosive base at 3.15 m depth, and is fining-up. The second layer starts with coarse-grained sands and rip-up clasts at 2.74 m depth, and is generally finer-grained (thinning and fining up)

oysters, *Lithophaga* sp., bryozoans, corals, worms, and algae (providing carbonate for radiocarbon dating). The quarrying and subsequent transport of a block depends on several parameters such as weight (mass of block), shape, density (of water and block), porosity, water velocity, water depth, duration, roughness of platform, steepness of beach, direction, and rate of flow (Keating et al. 2011). Additionally, the height of uplifted blocks above present sea level, wave length, and the coefficients of drag and of

friction have to be taken into account and considered in calculations (Goto et al. 2009, Hoffmann et al. 2013a). Even for one of the simplest formulas, the “transport figure” (T_f) by Scheffers and Kelletat (2003) and Scheffers (2008), these parameters are needed to quantify the energy of displacement of a boulder by the equation $T_f = W \times D \times V$; where W is the weight of the boulder (in tons); D is the distance moved from the cliff line (m), and V is the vertical distance, i.e., cliff height (m). A value of 2,000 is considered the upper limit of storm wave transport energy (Scheffers 2008). The hydrodynamics of boulder and block transport during tsunami has also been discussed by Benner et al. (2010), who calculated wave velocities based on the conservation of energy; by Paris et al. (2010), who created a formula for the minimum wave velocity of a sliding boulder; and by Etienne et al. (2011), who chose an approach to calculate the minimum wave velocity necessary for overturning a boulder.

Mapping of Paleotsunami Deposits

Field surveys aim to map the three-dimensional distribution of a sand sheet and associated layers and to find evidence for a regional continuity of the layer. Indicative for washover fans are a tapering and fining landward, a common height above mean sea level, and the content of marine fossils. These observations can be easily achieved by shallow drillings (e.g., Wilson et al. 2014) and GPS control or ERT (electric resistivity) of the drill points for large strips along a coast. For boulder deposits, the orientation of the long axis of min. 50 boulders needs to be measured (where a is long axis, b is intermediate axis, and c is short axis) to obtain paleocurrent direction and boulder volume/weight information. Terrestrial laser scanning or LiDAR is applied to establish precisely the boulder volume (see Hoffmann et al. (2013a) for methodology). Post-tsunami field surveys are extremely useful that have been carried out for more than a decade now (Dominey-Howes et al. 2012). The aim of mapping is also focusing and aiming on return periods of events and magnitude of those.

Tsunamis as Paleoseismic Indicators, Fig. 6 (a) Imbricate boulders, boulder train (Fins, Sultanate of Oman) (b) Tsunami rampart and boulders in Fins, Sultanate of Oman (From Hoffmann et al. 2013a)

Preservation of Tsunami Deposits/ Postdeposition Changes

Postdepositional changes that tsunami deposits can undergo have to be considered. The processes that decrease preservation include physical and chemical weathering and bioturbation (Szczeniński 2012). These processes include (a) physical processes, like washing out the fine sediment at the surface, redeposition of sediment, leveling of the surface, disruption by frost heaving, and liquefaction. The (b) chemical processes include the removal of sea salt, the dissolution of carbonate materials, and the oxidation of metal-oids, whereas (c) biological processes cover bioturbation by roots and animals and human activity. Isotopic composition may be changed chemically by rain and freshwater, i.e., oxygen, carbon, nitrogen isotope ratios, Sr isotopes, Ca,

salt (by seawater intrusions), carbonate, organic components, metal-rich deposits, etc., and eventually terrigenous clays in these marine environments are enriched.

Deposits from the 2004 Indian Ocean and 2011 Tohoku-oki tsunamis provided opportunities to study the early stage of taphonomic processes for various types of tsunami deposits. For example, Nakamura et al. (2012) studied tsunami deposits along the Misawa coast in March 2011 and May 2012 and compared their thickness patterns. One year after the event and deposition, deposits were not significantly altered and retained their original structure and thickness. But thin tsunami deposits close to the inundation limit were hardly distinguishable as they had been eroded or mixed with organic soil; consequently, the geometry and inland extent of deposits changed significantly in only 1 year.

Dating Tsunami Deposits

Tsunami deposits can commonly be dated by radiocarbon ^{14}C , ^{210}Pb , ^{137}Cs , optically stimulated luminescence (OSL), and tephrochronological methods employing absolute dating methods. The most frequent methods are AMS radiocarbon and tephrochronology (i.e., volcanic ashes, dating with Ar/Ar, or K/Ar methods). For radiocarbon dating, the time of tsunami inundation is estimated based on the ages of the soil deposited just above and beneath the target tsunami deposit (the so-called bracket dating of the event layer), because the tsunami can have eroded significantly the original surface and again have redeposited the eroded soil within the tsunami layer. If a carbonate shell, preferably articulated, is encountered within the layer, it can also yield perfect ages. Tsunami deposits in peat lands show generally the best accuracy of the dating. Geochemically well-characterized and widely distributed tephra is also very useful to estimate the time of deposition, when tephra and tsunami deposits are close to each other in the stratigraphic record (e.g., in Japan or Italy). Boulder deposits should yield age clustering of the data; otherwise, no events can be modeled. In areas with a long human occupation, artifacts (e.g., ceramics) are excellent to date precisely the date of tsunami impact; furthermore, reconstruction periods can help in identifying tsunami-related structural damage. So archeology provides, besides historical reports, a significant tool in paleotsunami research.

Estimating Paleotsunami Size and Earthquake Magnitude from Tsunami Deposits

The assessment tsunami hazard at a certain coast is crucial; essentially, several parameters need to be known: the size of tsunamis (run-up) at each site, the maximum inundation, and the return periods. As discussed in the previous sections, the lateral extent and spatial distribution of tsunami deposits are significantly affected by the local topography of the coastal area and of the

inundated area and location and type of the source material. Only where a tsunami inundated flat areas and continuous deposits are preserved, the maximum inland extent of the deposits can be correlated and evaluated for obtaining indicators of the present coastal tsunami hazard (other parameters, like coastline retreat, sedimentation and subsidence rates, sea level changes, etc., have to be regarded and assessed as well). Along rocky coasts, (mega-)boulders may indicate past tsunamigenic action. For tsunamis and damage in historical times, reports and interviews of elder persons yield valuable information (Hoffmann et al. 2013b).

Several tsunami scales have been introduced in various parts of the world, both magnitude and intensity based (e.g., the Imamura-Iida Magnitude Scale, Soloviev-Imamura Tsunami Intensity Scale, or a scale by Papadopoulos and Imamura 2001; ITIS Integrated Tsunami Intensity Scale, Lekkas et al. 2013). These scales are of limited use in paleotsunami science, as most of the equations for tsunami magnitude need parameters like maximum or average or local tsunami height or the earthquake magnitude M_W . Parameters are hard to obtain in paleotsunami research, where only minimum parameters can be revealed. The ESI-2007 scale (Guerrieri and Vitori 2007; Guerrieri et al. 2007) refers to tsunamis as “Earthquake Environmental Effects” (EEE), which takes into account and refers to present-day tsunami action and describes and qualifies an intensity. However, unfortunately, the intensity scale lacks exact parameters for the classification (i.e., tsunami height, inundation extent and area, and more).

Summary

Tsunami deposits are highly variable in extent, sediments, and preservation through time. If tsunami deposits are used as paleoseismic indicators, other source mechanisms like mass wasting or volcanic eruption have to be ruled out. Also, in high seismic areas with more than one capable fault, it is difficult to assign tsunami generation to an individual fault rather than to an area.

As paleotsunamis are extremely variable and depending on many parameters to be assessed in the field or lab, also for exact dating, a highly experienced quaternary geologist or sedimentologist should always be consulted for dating tsunami-related sediments and features.

Introduction

In the last hundred years, the height of the tallest buildings (skyscrapers) went up from 283 m (Woolworth Building, New York City, 1913) to 830 m (Burj Khalifa, Dubai, 2013). Building such structures presents various architectural and engineering challenges, including the development of plumbing and air conditioning systems, fast elevators, etc. Nevertheless, the main effort is always directed toward safety and reliability of buildings and occupants. These concerns are not immanent to tall buildings only but important as well for any structures, whether it is a bridge or nuclear plant. Earthquake and wind load are the major reasons for worries when designing structures or buildings, especially tall ones, since these loads are hard to predict.

Tuned mass damper (TMD) is a concept (Den Hartog 2013; Hunt 1979), which has appeared in the beginning of the twentieth century. The concept seemed to be so attractive that it was properly developed and one of the first TMDs were installed in CN Tower, Toronto, and John Hancock Building, Boston, in 1976. Since then the number of different types of implemented TMDs has been rapidly increasing, approaching one hundred (Soto and Adeli 2013), including those which are used to mitigate the motion of tall buildings (Kareem et al. 1999), bridges, pumps, structures, etc. The basic idea behind a TMD is that an oscillatory two-degree-of-freedom (TDOF) system may have such a response that one of the masses (primary mass) will be motionless. Thus, if the response of the primary mass itself was high due to resonance, adding a second mass will significantly reduce the primary mass response amplitude. However, the response attenuation does not happen by default, so the properties of the added mass-spring-damper system have to be tuned to deliver the best outcome; therefore, the name tuned mass damper is used to reflect this feature. A concern may be related to the fact that adding another degree of freedom to the system will result in two peaks of the response amplitude curve rather than one, characteristic for a single-degree-of-freedom (SDOF) system, but this issue can be

handled by proper tuning as well. It has also been shown that the tuning of a stochastic system (a system subjected to a random excitation) is different from that for a deterministic system.

There are different types of devices, which serve as passive TMDs: conventional TMD, liquid TMD (TLD) (Di Matteo et al. 2014 and references therein), and parametric pendulum TMD (PPD). An excellent review paper by Ibrahim (Ibrahim 2008) provides a full description of various passive vibration isolators. It has been argued that the passive TMDs are effective means of mitigating buildings' vibrations due to seismic loading. It became a motivation for the development of a theory of active and hybrid TMDs (Soong and Spencer 2002), which use different types of control to enhance the effectiveness of dampers (Wang and Lin 2007).

Pendulum TMDs have not been studied as thoroughly as conventional TMDs due to the fact that their analytical analysis is much more complicated. Besides being a nonlinear system due to a pendulum restoring force, it is also parametrically excited since the excitation transmitted to the pendulum through its suspension point. Therefore, it is required to study a nonlinear parametric system, which is possible only by using approximate methods.

The entry reviews the fundamental theory of passive tuned mass dampers and parametric pendulum dampers as well as the major developments of the theory in the last hundred years. The motion of the primary mass subjected to a deterministic or stochastic excitation is considered. The principle parameters of the system influencing the dynamics of the primary mass such as mass and frequency ratios are identified. Different formulas derived by a number of authors based on the various optimization criteria are presented for optimal tuning of a damper. The effectiveness of a parametric pendulum tuned mass damper, which interaction with the primary mass is completely different from a conventional tuned mass damper, is discussed. The optimal values of the PPD damping are found numerically for the primary system subjected to a narrow-band noise. Vibrations of the primary mass with a parametric pendulum

tuned mass damper subjected to the three historical earthquake records are presented.

Deterministic Theory of Tuned Mass Dampers

In this section a classical deterministic theory of a tuned mass damper is revisited. This theory is based on the properties of a vibrating TDOF system. The first development of the TMD theory, besides the US patent no. 989958 registered by Frahm back in 1909, was proposed in Ormondroyd (1928) and latter extended to multi-degree-of-freedom (MDOF) systems, as well as nonlinear systems and nonlinear TMDs.

Undamped System

Consider a linear TDOF system with a primary mass subjected to a harmonic force 1, so that dynamics of the system can be described by the following equation of motion (Fig. 1):

$$\begin{aligned} M\ddot{x}_1 + (k_1 + k_2)x_1 - k_2x_2 &= A \sin \omega t \\ m\ddot{x}_2 - k_2x_1 + k_2x_2 &= 0 \end{aligned} \quad (1)$$

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 1 A primary mass M with a damper of mass m

where M and k_1 are mass and stiffness coefficients of the primary system, whereas m and k_2 are the corresponding coefficients of the secondary mass, served as a damper. Assuming the response of the form

$$\begin{aligned} x_1 &= X_1 \sin \omega t \\ x_2 &= X_2 \sin \omega t \end{aligned} \quad (2)$$

and substituting it into Eq. 1, the following system of two linear algebraic equations is derived:

$$\begin{aligned} X_1[-M\omega^2 + k_1 + k_2] - k_2 X_2 &= A \\ X_2[-m\omega^2 + k_2] - k_2 X_1 &= 0 \end{aligned} \quad (3)$$

Dividing the first equation by k_1 and the second equation by k_2 results in:

$$X_1 \left[1 - \frac{\omega^2}{\Omega_1^2} + \frac{\Omega_2^2}{\Omega_1^2} \mu \right] - \frac{\Omega_2^2}{\Omega_1^2} \mu X_2 = \frac{A}{k_1} \quad (4)$$

$$X_2 \left[1 - \frac{\omega^2}{\Omega_2^2} \right] - X_1 = 0 \quad (5)$$

$$\Omega_1^2 = \frac{k_1}{M}, \Omega_2^2 = \frac{k_2}{m}, \mu = \frac{m}{M} \quad (6)$$

where μ is called the mass ratio and is typically much smaller than unity. Resolving Eqs. 4 and 5 with respect to X_1 and X_2 , one gets the response amplitudes of each system, so that the dynamic amplification factors (DAF) are:

$$\begin{aligned} \frac{X_1}{A/k_1} &= \frac{1 - \frac{\omega^2}{\Omega_2^2}}{\left(1 - \frac{\omega^2}{\Omega_2^2} \right) \left[1 - \frac{\omega^2}{\Omega_1^2} + \frac{\Omega_2^2}{\Omega_1^2} \mu \right] - \frac{\Omega_2^2}{\Omega_1^2} \mu} \\ \frac{X_2}{A/k_1} &= \frac{1}{\left(1 - \frac{\omega^2}{\Omega_2^2} \right) \left[1 - \frac{\omega^2}{\Omega_1^2} + \frac{\Omega_2^2}{\Omega_1^2} \mu \right] - \frac{\Omega_2^2}{\Omega_1^2} \mu} \end{aligned} \quad (7)$$

It can be deduced from the first equation in Eq. 7 that the response amplitude of the primary mass can be zero when the secondary mass tuned to the excitation frequency, i.e., $\omega = \Omega_2$. Thus, the secondary mass acts as a damper, basically absorbing all the input energy, leaving the primary mass motionless. This fundamental result has become the basis for the theory of tuned mass dampers. Figure 2 demonstrates the results of this funding, where the left and right plots display the DAF of the primary mass and damper correspondingly for different values of μ , $v = \omega/\Omega_1$ and $\Omega = \Omega_2/\Omega_1 = 1$.

Note that it is not always the primary mass has zero displacement. Figure 3 demonstrates the influence of increasing frequency ratio onto the DAF of the primary mass for $\mu = 0.1$. It can be observed from Fig. 3 that the frequency value corresponding to the zero displacement of the primary mass has been shifted to the left and then vanished completely at $\Omega^2 = 1.5$.

Two natural frequencies of the system can be found from the corresponding characteristic equation, derived by equating the denominator of Eq. 7 to zero:

$$\left(1 - \frac{\omega^2}{\Omega_2^2} \right) \left[1 - \frac{\omega^2}{\Omega_1^2} + \frac{\Omega_2^2}{\Omega_1^2} \mu \right] - \frac{\Omega_2^2}{\Omega_1^2} \mu = 0, \quad (8)$$

so that:

$$\frac{\omega^2}{\Omega_2^2} = \frac{\Omega_1^2 + \Omega_2^2(1 + \mu) \pm \sqrt{[\Omega_2^2 \mu + (\Omega_1 + \Omega_2)^2][\Omega_2^2 \mu + (\Omega_1 - \Omega_2)^2]}}{2\Omega_2^2} \quad (9)$$

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 2 Dynamic amplification factor of the primary mass (*dot*) and TMD (*solid*) from Eq. 7 versus v ratio, (a) $\mu = 0.1$; (b) $\mu = 0.2$

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 3 Dynamic amplification factor of the primary mass from Eq. 7 versus v ratio, (a) $\Omega^2 = 1.2$; (b) $\Omega^2 = 1.5$

This result coincides with the classical one obtained by Den Hartog (Den Hartog 2013) for the case when both natural frequencies were equal $\Omega_1 = \Omega_2$:

$$\frac{\omega^2}{\Omega_2^2} = \left(1 + \frac{\mu}{2}\right) \pm \sqrt{\mu + \mu^2/4} \quad (10)$$

The assumption of $\Omega_1 = \Omega_2$ is very reasonable since the damper is needed when the primary mass is at resonance, whereas the maximum absorption is achieved, as it has been seen from Eq. 7, when $\omega = \Omega_2$. Expression 10 demonstrates the dependence of the natural

frequencies on the mass ratio, an increase of which broadens the distance between two frequencies.

Damped Absorber

Since any realistic structures and materials have some dissipation mechanisms, it seems reasonable to consider a damper with viscous damping. The equations of motion of the damped system will be similar to the one shown in section [Undamped System](#) with the additional damping term:

$$\begin{aligned} M\ddot{x}_1 + c(\dot{x}_1 - \dot{x}_2) + (k_1 + k_2)x_1 - k_2x_2 &= Ae^{i\omega t} \\ m\ddot{x}_2 + c(\dot{x}_2 - \dot{x}_1) - k_2x_1 + k_2x_2 &= 0 \end{aligned} \quad (11)$$

where i is the imaginary unit. Substituting $x_i(t) = X_i e^{i\omega t}$ into the above equations will lead to the following set:

$$\begin{aligned} X_1[-M\omega^2 + k_1 + k_2 + i\omega c] - (k_2 + i\omega c)X_2 &= A \\ X_2[-m\omega^2 + k_2 + i\omega c] - (k_2 + i\omega c)X_1 &= 0 \end{aligned} \quad (12)$$

Solution to these equations may be written as:

$$\begin{aligned} \frac{X_1}{A} &= \frac{k_2 - m\omega^2 + i\omega c}{(k_1 - M\omega^2)(k_2 - m\omega^2) - k_2m\omega^2 + i\omega c(k_1 - m\omega^2 - M\omega^2)} \\ \frac{X_2}{A} &= \frac{k_2 + i\omega c}{(k_1 - M\omega^2)(k_2 - m\omega^2) - k_2m\omega^2 + i\omega c(k_1 - m\omega^2 - M\omega^2)} \end{aligned} \quad (13)$$

Applying the complex analysis it is easy to derive the expression for the amplification factor of the primary mass:

$$\frac{X_1^2}{A^2} = \frac{(k_2 - m\omega^2)^2 + \omega^2 c^2}{[(k_1 - M\omega^2)(k_2 - m\omega^2) - k_2m\omega^2]^2 + \omega^2 c^2(k_1 - m\omega^2 - M\omega^2)^2} \quad (14)$$

Coming back to variables $v = \omega/\Omega_1$ and $\Omega = \Omega_2/\Omega_1$ will reduce Eq. 14 to:

$$\frac{X_1}{A/k_1} = \sqrt{\frac{(v^2 - \Omega^2)^2 + (2\eta v)^2}{[(v^2 - \Omega^2)(v^2 - 1) - \mu v^2 \Omega^2]^2 + (2\eta v)^2(v^2 - 1 + \mu v^2)^2}} \quad (15)$$

where $\eta = c/(2m_2\Omega_1)$. In the limiting case of $\eta = 0$, the result from Eq. 15 tends to the one obtained in Eq. 9, whereas in the opposite case, when the damping is too big ($\eta \rightarrow \infty$), Eq. 15 will be identical to the response of a single-degree-of-freedom system with mass $M + m$ to a harmonic excitation. Thus, there exists an optimal value of the damping coefficient η , which provides the minimal response amplitude of the primary

mass. Figure 4 shows the dependence of the amplification factor Eq. 15 as a function of v for the mass ratio $\mu = 0.05$. Solid line and dash-dot lines correspond to the limiting cases of $\eta = 0$ and $\eta = \infty$, respectively, whereas the dash and dot lines correspond to $\eta = 0.08$ and $\eta = 0.1$. To find the optimal value of the damping coefficient, let us note that for a given value of μ and Ω , all curves independent of the damping coefficient

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 4 Dynamic amplification factor of the primary mass for difference values of the TMD damping and $\mu = 0.05$

values intersect two points *A* and *B*. Den Hartog proposed (Den Hartog 2013) that the optimal value could be found when the ordinates of these two points were equal and the curve passing these two points should have the horizontal tangent line.

The values at points *A* and *B* can be found by taking into account that all curves can go through the same two points independent of the values of damping coefficient if:

$$\left[\frac{(v^2 - \Omega^2)}{(v^2 - \Omega^2)(v^2 - 1) - \mu v^2 \Omega^2} \right]^2 = \left[\frac{1}{v^2 - 1 + \mu v^2} \right]^2 \quad (16)$$

The nontrivial solution to this equation is:

$$v_A^2 = \frac{1 + (1 + \mu)\Omega^2 - \sqrt{\Omega^4(\mu^2 + 2\mu) + (1 - \Omega^2)^2}}{2 + \mu}$$

$$v_B^2 = \frac{1 + (1 + \mu)\Omega^2 + \sqrt{\Omega^4(\mu^2 + 2\mu) + (1 - \Omega^2)^2}}{2 + \mu} \quad (17)$$

The value of the amplitude at these points can be calculated by simply taking $\eta \rightarrow \infty$, which indicates that:

$$\left| \frac{X_1}{A/k_1} \right| = \frac{\pm 1}{1 - v^2 - \mu v^2} \quad (18)$$

or

$$\frac{1}{1 - v^2 - \mu v^2} = \frac{-1}{1 - v^2 - \mu v^2} \quad (19)$$

The latter results in the following equality:

$$v_A^2 + v_B^2 = \frac{2}{1 + \mu} \quad (20)$$

Having combined this result with a sum of $v_A^2 + v_B^2$ from Eq. 17, one arrives to the following expression:

$$\Omega = \frac{1}{1 + \mu} \quad (21)$$

For small values of the mass ratio, formula (21) indicates that the damper should be tuned to the natural frequency of the primary mass. To find the optimal value of the damping coefficient, Brock (Brock 1946) has differentiated expression (16) with respect to ν and equated it to zero at points A and B , correspondingly. By doing so he was able to recover two optimal values of the damping coefficient:

$$\eta_A^2 = \frac{\mu \left(3 - \sqrt{\frac{\mu}{\mu+2}} \right)}{8(1+\mu)^3} \quad (22)$$

$$\eta_B^2 = \frac{\mu \left(3 + \sqrt{\frac{\mu}{\mu+2}} \right)}{8(1+\mu)^3},$$

which resulted in the optimal mean value:

$$\eta_o^2 = \frac{3\mu}{8(1+\mu)^3} \quad (23)$$

The expression for the optimal value of the damping coefficient will be different when $\Omega = 1$:

$$\eta_c^2 = \frac{\mu(3+\mu) \left[1 + \sqrt{\mu/(2+\mu)} \right]}{8(1+\mu)} \approx \frac{3\mu}{8(1+\mu)} \quad (24)$$

Another approach for defining the optimal value of η was proposed by Krenk (2005), who suggested to equate the ordinates of three points A , B , and the point in the middle of the previous two points. By doing so he has derived a new value for the optimal damping coefficient, which is 15 % larger than the classical result (Eq. 24):

$$\eta_{Kr}^2 = \frac{\mu}{2(1+\mu)} \quad (25)$$

It has been shown that the above optimal set of parameters can be used to minimize the response of a continuous system, provided that the equivalent mass and stiffness are used and its natural frequencies are well separated. Warburton (1982) has investigated the influence of the optimal values of μ and Ω , derived in Den Hartog

(2013), onto the response of a TDOF primary system and the contribution of the higher modes to the overall response. A translation-rotation TDOF vibration absorber instead of an SDOF one was proposed in Jang et al. (2012), where the method of choosing the optimal set of parameters of the absorber was developed. Since the real structure has always some amount of damping, even when the latter is modeled as a viscous one, it becomes difficult to derive an analytical expression for design purposes; therefore, some methods have been developed to overcome this issue (Tsai and Lin 1993; Vakakis and Paipetis 1986; and references therein). Moreover, some experimental data, collected from the structures subjected to earthquakes, suggested that the energy dissipation mechanism was not linear but rather hysteretic. A system subjected to six historical earthquake records with a hysteresis damping model was investigated in Val and Segal (2005). It has been shown that the linear viscous damping model may not be accurate enough to describe the system behavior due to earthquake and can provide up to 30 % difference in the maximum displacement.

Stochastic Theory of Tuned Mass Dampers

The response of a linear system to a broadband excitation is different to one due to a harmonic excitation, since the former happens with the natural frequency(ies) of the system. In cases when the broadband excitation has an almost constant spectrum over the range of the natural frequencies, it is convenient to replace such an excitation with its limiting cases – a white noise. Without loss of generality consider a linear TDOF system with the primary mass subjected to a white noise excitation:

$$\begin{aligned} M\ddot{x}_1 + c_2(\dot{x}_1 - \dot{x}_2) + c_1\dot{x}_1 + (k_1 + k_2)x_1 - k_2x_2 &= M\ddot{\xi}(t) \\ m\ddot{x}_2 + c_2(\dot{x}_2 - \dot{x}_1) - k_2x_1 + k_2x_2 &= 0 \end{aligned} \quad (26)$$

Dividing both equations by the corresponding mass set (Eq. 26) can be written as the following:

$$\begin{aligned} \ddot{x}_1 + 2\zeta_2\Omega_2\mu(\dot{x}_1 - \dot{x}_2) + 2\zeta_1\Omega_1\dot{x}_1 \\ + (\Omega_1^2 + \Omega_2^2\mu)x_1 - \Omega_2^2\mu x_2 = \xi(t) \\ \ddot{x}_2 + 2\zeta_2\Omega_2(\dot{x}_2 - \dot{x}_1) - \Omega_2^2x_1 + \Omega_2^2x_2 = 0 \\ E[\xi(t)] = 0, E[\xi(t)\xi(t+\tau)] = D\delta(\tau) \end{aligned} \quad (27)$$

The first equation in Eq. 27 is different from Eq. 11 by the third term, which represents damping in the primary system, and $\xi(t)$ is zero-mean Gaussian delta-correlated white noise with intensity D . It is well known that the mean and the mean square response of an SDOF subjected to a white noise is ($m_2 = 0$, $k_2 = 0$, $c_2 = 0$):

$$E[x_1] = 0, E[x_1^2] = \frac{D}{4\zeta_1\Omega_1^3} \quad (28)$$

where $E[\cdot]$ denotes the averaging. Some methods for analyzing linear stochastic systems may be found in many textbooks, for instance, Crandall and Mark (1963). System (27) can be analyzed analytically using the method of moments or the spectral density and convolution integral approach. The latter has been applied by Crandall and Mark (Crandall and Mark 1963) to the similar system but excited through its base. Since the mean values of the responses are zero, it is required to calculate the second-order moments, which can be done by using the matrix approach

with $z_1 = x_1$, $z_2 = \dot{x}_1$, $z_3 = x_2$, $z_4 = \dot{x}_2$. Rewrite Eq. 27 in the form:

$$\begin{aligned} \dot{\mathbf{Z}} &= \mathbf{S}\mathbf{Z} + \mathbf{B}\xi(t) \\ \mathbf{Z} &= \begin{pmatrix} z_1 \\ z_2 \\ z_3 \\ z_4 \end{pmatrix}, \mathbf{B} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \\ \mathbf{S} &= \begin{pmatrix} 0 & 1 & 0 & 0 \\ -\Omega_1^2 - \mu\Omega_2^2 & -2\zeta_2\Omega_2\mu - 2\zeta_1\Omega_1 & \mu\Omega_2^2 & 2\mu\zeta_2\Omega_2 \\ 0 & 0 & 0 & 1 \\ \Omega_2^2 & 2\zeta_2\Omega_2 & -\Omega_2^2 & -2\zeta_2\Omega_2 \end{pmatrix} \end{aligned} \quad (29)$$

The equation for the second-order moments is:

$$\dot{\mathbf{M}} = \mathbf{S}\mathbf{M} + \mathbf{M}\mathbf{S}^T + \mathbf{D}\mathbf{B}\mathbf{B}^T \quad (30)$$

where $\mathbf{M}$ is a symmetric matrix of moments:

$$\mathbf{M} = \begin{pmatrix} M_{11} & M_{12} & M_{13} & M_{14} \\ M_{12} & M_{22} & M_{23} & M_{24} \\ M_{13} & M_{23} & M_{33} & M_{34} \\ M_{14} & M_{24} & M_{34} & M_{44} \end{pmatrix} \quad (31)$$

with the matrix elements defined as $M_{ij} = E[z_i z_j]$. It is not difficult to find a steady-state ($\dot{\mathbf{M}} = 0$) solution of Eq. 30; however, only two moments M_{11} and M_{33} are of special interest:

$$\begin{aligned} M_{11} = M_{x_1 x_1} &= \frac{D}{4\Omega_1^3} \frac{C_1 \zeta_1^2 + C_2 \zeta_1 + C_3}{D_1 \zeta_1^3 + D_2 \zeta_2^2 + D_3 \zeta_1 + D_4} \\ M_{33} = M_{x_2 x_2} &= \frac{D}{4\Omega_1^3} \frac{\Omega_2 [E_1 \zeta_1^2 + E_2 \zeta_1 + E_3]}{D_1 \zeta_1^3 + D_2 \zeta_2^2 + D_3 \zeta_1 + D_4} \\ C_1 &= 4\Omega_1^2 \Omega_2^2 \zeta_2, C_2 = 4\Omega_1 \Omega_2^3 \zeta_2^2 (1 + \mu) + 4\zeta_2^2 \Omega_1^3 \Omega_2 + \mu \Omega_1 \Omega_2^3 \\ C_3 &= \zeta_2 \left\{ (\Omega_1^2 - \Omega_2^2)^2 + \Omega_2^2 [\Omega_2^2 (2\mu + \mu^2) + 4\Omega_1^2 \zeta_2^2 (\mu + 1) - \mu \Omega_1^2] \right\} \\ E_1 &= 4\zeta_2 \Omega_1^2 \Omega_2, E_2 = \Omega_1^3 (1 + 4\zeta_2^2) + 4\zeta_2^2 \Omega_1 \Omega_2^2 (1 + \mu) + \mu \Omega_1 \Omega_2^2 \\ E_3 &= \zeta_2 \Omega_2 \left[(1 + \mu)^2 \Omega_2^2 + \Omega_1^2 (\mu + 4\mu \zeta_2^2 + 4\zeta_2^2) \right] \\ D_1 &= C_1, D_2 = C_2, D_3 = C_3 + \mu \zeta_2 \Omega_1^2 \Omega_2^2, D_4 = \mu \zeta_2^2 \Omega_2 \Omega_1^3 \end{aligned} \quad (32)$$

Since the above result is cumbersome, the optimal value of the damping coefficient ζ_2 is usually obtained numerically. It should be stressed that

the system response is finite when one of the damping coefficients is equal to zero. Putting $\zeta_1 = 0$ will reduce the expression for M_{11} to:

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 5

The optimal damper value ζ_2 for different values of μ and Ω , while $\zeta_1 = 0$

$$M_{11} = \frac{D}{4\Omega_1^3} \frac{C_3}{D_4} \quad (33)$$

Looking for ζ_2^* which delivers the minimum value of M_{11} , one differentiates the latter with respect to ζ_2 and equates the expression to zero. This results in the optimal value of ζ_2 :

$$\zeta_2^* = \frac{\sqrt{(\mu+1) [\Omega^4(\mu^2+2\mu) - \mu\Omega^2 + (1-\Omega^2)^2]}}{2\Omega(\mu+1)} \quad (34)$$

where Ω is defined in section **Damped Absorber**. Figure 5 shows the dependence of the optimal damping coefficient on the mass ratio for different values of the frequency ratio Ω . It can be seen that the case of $\Omega = 1$ quantitatively agrees with one declared by Wiesner (1979) for any value of ζ_1 .

It should be emphasized that the optimal value of the damping coefficient depends significantly on the frequency ratio, which is observed in Fig. 5. For the values of $\Omega_2 < \Omega_1$, the optimal value of ζ_2 is much higher than the corresponding value for the case of $\Omega_2 > \Omega_1$ and decreases with

increase of μ . It can also be observed that the value of ζ_2 is almost a constant for $\Omega = 0.75$

In the case of $\Omega = 1$ this result reduces to:

$$\bar{\zeta}_2 = \frac{\sqrt{\mu}}{2} \quad (35)$$

The result from expression (35) is compared in Fig. 6 to the classical result derived by Den Hartog (Eq. 24) and the result recently obtained by Krenk (Eq. 25). In Fig. 7 one can see the difference in performance of the primary mass when ζ_2 is calculated based on formulas (34) and (35).

Warburton in 1981 reported that formula (35) provided the minimum mean square velocity of the primary mass, whereas ζ_2^D and ζ_2^A :

$$\begin{aligned} \zeta_2^D &= \sqrt{\frac{\mu(1+3\mu/4)}{4(1+\mu)(1+\mu/2)}} \\ \zeta_2^A &= \sqrt{\frac{\mu(1-\mu/4)}{4(1+\mu)(1-\mu/2)}} \end{aligned} \quad (36)$$

provide the minimum displacement and acceleration of the primary mass subjected to a white noise excitation. The recommendations for the optimal set of parameters of a TMD can also be

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations,

Fig. 6 Comparison of different values of the optimal damper coefficient ζ_2 as a function of μ

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 7 Comparison of M_{11} for ζ_2 calculated based on Eq. 34—solid and Eq. 35—dash, (a) $\Omega = 0.5$; (b) $\Omega = 1.5$

found in Warburton (1981) for the deterministic case, i.e., when the primary mass is under a harmonic excitation.

It is obvious from Fig. 7 that the mean square response is lower when ζ_2^* ; however, this difference diminishes quickly as Ω trends to unity and then reappears again as Ω increases above unity.

Similar observations and conclusions were reported in Krenk and Høgsberg (2008) for the case of $\zeta_1 = 0$, whereas for the case of $\zeta_1 \neq 0$, the final expression was different. Nevertheless, the observed difference was so small that the recommendation was given to disregard the structural damping when designing a TMD.

A similar analysis can be applied to a linear multi-degree-of-freedom system to derive the mean square response of the system; however, the expressions for the second-order moments become extremely lengthy and difficult to work with; therefore, such systems are investigated numerically or experimentally (see, e.g., Adam et al. (2003)). The systems with 2, 5 and 10 degrees of freedom under a Gaussian white noise were numerically investigated by Wirsching and Cambell (1973). Their primary interest was how a TMD, which was supposed to reduce a motion of only a certain degree of freedom, would perform in the presence of other modes. They concluded that a TMD was capable of reducing the structural motion of the system by up to 30 % when $\mu = 0.1$ and produced a curve for the optimal damping coefficient of the damper, which was very similar to Eq 35. A different expression of the optimal damping coefficient was reported for an SDOF system in the presence of structural damping (Sadek et al. 1997):

$$\zeta_2^R = \frac{\zeta_1}{1 + \mu} + \sqrt{\frac{\mu}{1 + \mu}} \quad (37)$$

The latter was numerically obtained when the primary mass was subjected to various historical earthquake records. Note that expression (37) with $\zeta_1 = 0$ has been recently proposed in Krenk and Høgsberg (2014) based on bifurcation analysis.

Although the theoretical results demonstrate the effectiveness of a TMD, in fact there is a certain concern whether this is a reliable mean of protecting buildings from seismic vibrations. Sladek and Klingner (Sladek and Klingner 1983) studied an 8-node linear elastic building model subjected to a component of a realistic El Centro earthquake which happened in 1940. They were among the firsts who found that the optimally tuned TMD had no effect on the maximum displacement of the tip of the building model. Chowdhury et al. (1987) have also investigated the influence of a TMD onto a higher mode response by considering the primary structure as a vertically oriented cantilever beam the top of which was fitted with a TMD. Six historical

earthquake records were used to assess the performance of the primary system. They found that the higher mode response actually increased when the TMD was tuned to the fundamental frequency of the primary mass. Moreover, they have observed that although the overall response with a TMD is reduced, the peak value was not affected at all. It has also been reported that if the primary mass peak occurs without a significant pre-peak motion, then the passive TMD cannot get enough excitation and would not be effective; therefore, the effectiveness of the TMD depends not only on the tuning frequency and mass ratio but also on the pre-peak motion of the primary mass, the magnitude, and the acceleration of the ground motion (Chowdhury et al. 1987). In other words a passive TMD cannot give response within a short period of time, which is the reason for discrepancies between the transient and steady-state results. Based on that a number of authors (Chowdhury et al. 1987; Kaynia et al. 1981; Sladek and Klingner 1983) expressed skepticism toward the unconditional usage of TMDs.

The higher mode behavior of a multi-degree-of-freedom system with a TMD implies that the latter helps to transfer the system energy from lower to higher modes. There are some ways of dealing with this problem. For instance, the TMD energy can be dissipated by introducing an impact damper (Dimentberg and Iourtchenko 2004; Ibrahim 2009) on the top of the TMD. It seems also expedient for improving the structural performance to introduce multiple TMDs (MTMD) in a parallel or series configuration. The performance of spatially distributed MTMD was originally reported in Bergman et al. (1989) and later, for instance, in Kareem and Kline (1995) and references therein. The reported results indicated that the structural behavior could be improved when the MTMD were tuned to the corresponding frequencies of the structure, keeping the overall mass ratio the same as for a TMD. It has been shown that the increase in a number of dampers results in flattening out the response curve over a wider range of frequencies (Debbarma and Hazari 2013; Kareem and Kline 1995). The performance comparison of the TMD

and MTMD with 21 units suggested that the values of the optimal damper damping of MTMD were lower than that of a TMD. Later a number of algorithms were proposed for selecting the optimal values of the MTMD parameters (see Zuo and Nayfeh (2006) and references therein). The optimal value of a TMD damping coefficient based on various optimization procedures, including the optimization of the mean square displacement, velocity, or acceleration of the response for a variety of loadings, may be found in Bisegna and Caruso (2012), Sadek et al. (1997) and Tigli (2012). Efforts have been made to develop a theory of a nonlinear TMD, where either nonlinear stiffness or damping was involved. Recently a tuned mass damper with nonlinear damping was investigated (Carpineto et al. 2014; Rüdinger 2007) to understand the influence of nonlinearities onto the performance of a primary mass. A very simple model of a nonlinear stiffness TMD is a parametric pendulum TMD (PPD), which is discussed next.

Pendulum Tuned Mass Damper

Traditionally a TMD requires significant space for installation, which may cause significant problems for architectural design. In this case a PPD seems to be a very reasonable alternative. It should be stressed that the horizontal/vertical floor motion due to seismic activity will excite the pendulum's suspension point, therefore creating a parametric rather than external excitation, which happens in a conventional TMD. Therefore, it becomes essential to study the properties of a parametrically excited system. To explain the basic properties of a parametrically excited lumped mass pendulum, let us write its equation of motion in the following form:

$$\ddot{\theta} + 2\alpha\dot{\theta} + \left[\frac{g}{l} + \frac{\ddot{f}_v}{l} \right] \sin \theta + \frac{\ddot{f}_h}{l} \cos \theta = 0 \quad (38)$$

where f_v, f_h are the vertical and horizontal components of the excitation, and α is the damping

coefficient. It is well known that this system has a number of resonance frequencies defined as $\nu = 2/n$, $n = 1, 2, 3$, with the primary parametric resonance identified at the value of the doubled natural frequency. This system has been studied extensively for the deterministic and stochastic loadings (Bobryk and Chruszczak 2009; Xu and Wiercigroch 2007; Yurchenko et al. 2013; and references therein). Note that due to the nature of excitation entering the system parametrically, the pendulum has to be perturbed to start the oscillations.

One of the benefits using a PPD has already been mentioned and is related to the fact that it does not require much horizontal space. However, since the natural frequency of a lumped mass pendulum is inversely proportional to the square root of its length, a PPD may require excessive vertical space. To avoid this, there is a number of designs of small pendulums with very low natural frequencies (Ibrahim 2008; Yurchenko and Alevras 2013a). Another potential benefit of a PPD is that it can absorb the energy of multidirectional horizontal and vertical vibrations, whereas a conventional TMD can only be effective in a single direction. Until recently it has been common to assume that damages in buildings and structures were due to a horizontal relative motion of floors caused by a seismic event in a horizontal direction. However, field observations pointed toward damage patterns, which could only be caused by a vertical oscillations. Moreover, the vertical to horizontal spectral ratio was found to be above the overall accepted, and in some cases the vertical component was dominant (Elgamal and He 2004). It has also been found that higher frequencies (over 8Hz) can be expected from the vertical records rather than the horizontals. An overview on the vertical earthquake ground motion can be found in Elgamal and He (2004). Thus, it seems that a PPD has a certain benefits compared to its linear analogy.

Since the main goal is to investigate whether the primary mass response will be lower with a PPD, consider the dynamics of the following system with the primary mass subjected to a narrow-band excitation:

$$\begin{aligned}\ddot{z} + 2\alpha\dot{z} + \Omega_1^2 z &= f(t) + \gamma(\ddot{\theta} \sin \theta + \dot{\theta}^2 \cos \theta), \\ \ddot{\theta} + 2\beta\dot{\theta} + (\Omega_2^2 - \ddot{z}) \sin \theta &= 0, \\ \gamma &= \mu / (1 + \mu),\end{aligned}\quad (39)$$

Figure 8 shows the sketch of the system described by Eq. 39, which is qualified as an autoparametric system (Cartmell and Cartmell 1990; Tondl et al. 2000) and has been studied by a number of

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 8 A sketch of a primary system model with PPD

authors on the issue of stability of the pendulum. To analyze system Eq. 39 analytically, its inherent nonlinearity of *sine* and *cosine* type is either linearized or expressed in the Taylor series, keeping two or three first terms, thereby reducing to a polynomial nonlinearity. Deterministic response of system Eq. 39 ($f(t) = A \sin \omega t$) can be found in Song et al. (2003) and Warminski and Kecik (2009). The approximate analytical results for the third-order approximation derived in Song et al. (2003) agreed well with numerical results, presented in Fig. 9. The latter demonstrates the primary system deterministic response amplitude for mass ratio $\mu = 0$ (no PPD) and $\mu = 0.1$ versus ν with frequency ratio $\Omega = 2$. Clearly one can observe two peaks and the minimum value of the response amplitude in the case of $\mu = 0.1$, although the trough is shifted to the right from its original resonance frequency. Deterministic dynamics of a PPD comprising two independent pendulums was reported in Ikeda (2011), whereas the optimization of a friction PPD, implemented on Taipei 101 to reduce the wind load, was presented in Chung et al. (2013).

Stochastic response of Eq. 39 to a Gaussian white noise $f(t) = \xi(t)$ was investigated in Ibrahim and Roberts (1976). That paper considered vibrations of an autoparametric system consisting of a primary mass, subjected to a broadband excitation, and a vertically oriented cantilever beam.

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 9 The deterministic response amplitude of the primary mass with ($\mu = 0.1$) and without ($\mu = 0.0$) PPD

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 10 Comparison of the mean response amplitude of the primary mass for $\zeta_1 = 0.01$, $\Omega = 2.0$ and (a) $\zeta_2 = 0.00$; (b) $\zeta_2 = 0.01$

The dynamics of this system is very similar to the dynamics of the system, shown in Fig. 8.

Consider a linearized set of equations (Eq. 39) subjected to a zero-mean Gaussian white noise $\xi(t)$ in slightly another form:

$$\ddot{z} + 2\alpha\dot{z} + \Omega_1^2 z = \xi(t) + \varepsilon\gamma(\ddot{\theta}\theta + \dot{\theta}^2), \quad (40)$$

$$\ddot{\theta} + 2\beta\Omega\dot{\theta} + (\Omega^2 - \varepsilon\dot{z})\theta = 0$$

Eliminating the second-order derivatives in the right-hand side of the above equations, one arrives to:

$$\begin{aligned} \dot{x}_1 &= x_3 \\ \dot{x}_2 &= x_4 \\ \ddot{x}_3 &= -2\alpha x_3 - x_1 + \xi(t) \\ &\quad + \varepsilon\gamma(2\Omega\beta x_2 x_4 + \Omega^2 x_2^2 - x_4^2) \\ \dot{x}_4 &= -2\Omega\beta x_4 - \Omega^2 x_2 + \varepsilon(x_2 \xi(t) \\ &\quad - x_1 x_2 - 2\alpha x_2 x_3) - \varepsilon^2 \gamma x_2 x_4 \end{aligned} \quad (41)$$

Similar to Ibrahim and Roberts (1976), this set can be studied by the method of moments and Gaussian closure. It should be stressed that none of the papers so far, including the abovementioned, were focused on the optimization of the system's parameters to achieve the minimal displacement or velocity of the primary mass.

The behavior of the system similar to Ibrahim and Roberts (1976) has been studied by the method of moments (Cho et al. 2003) when the primary mass was excited by a narrow-band noise $f(t) = \lambda \cos q(t)$, $\dot{q}(t) = \omega + \sigma\xi(t)$. Recently the stochastic nonlinear dynamics of the original system (39) subjected to a narrow-band excitation has been investigated with the purpose of identifying the possible rotational domains of the pendulum (Yurchenko and Alevras 2013b). The building response with a PPD was studied numerically and experimentally in Majcher and Wójcicki (2014). The reported results indicated that there was a process of energy exchange between the primary system and the PPD, as expected. It would seem logical to expect that the minimal displacement (energy) of the primary mass corresponds to the maximum pendulum energy; however, the latter will go to infinity (become unstable) for the linearized pendulum model, leading to the instability of the primary mass. Thus, the derived analytical solution to the linearized model, although it brings some light onto the system dynamics, does not provide complete information about it. The numerical results of the original nonlinear system (Eq. 39) are presented in Figs. 10 and 11 for noise intensity $\sigma^2 = 0.1$. Since the original nonlinearity allows the pendulum to have a rotational motion, Fig. 11 presents the results when the pendulum

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 11

The mean amplitude of the primary mass with a PPD for different values of $\mu = 0.0$, the pendulum in 65 % rotational mode

has 65 % of the rotational motion, whereas in Fig. 10 the pendulum is in oscillatory mode all the time.

The overall effect of the bandwidth widening can be seen in Figs. 10 and 11 compare to Fig. 8, which is the result of random fluctuations of the phase. Furthermore, one can observe in Fig. 10 that the zero damping of the pendulum (Fig. 10 (left)) is not the optimal value of the damping ratio since $\zeta_2 = 0.01$ (Fig. 10 right) provides lower response amplitude. Although both Figs. 10 and 11 demonstrate the influence of a PPD onto the primary mass, the overall mean square response of the primary mass in Fig. 10 is smaller than that in Fig. 11 for the identical set of the parameters' values. Such a behavior can be explained by the centrifugal force, arising when the pendulum starts rotating, so that the latter pulls the system up and down.

The search for the optimal value of ζ_2 as a function of μ is conducted in this entry for nonlinear system (Eq. 35) subjected to a narrow-band excitation. It should be noted that for some combinations of ζ_2 and μ , the primary mass response has only a single peak, whereas for

others it has two peaks. Figure 12 shows the transition from one to two peaks for $\mu = 0.08$ and six different values of ζ_2 . The overall results of the numerical Monte Carlo simulations are presented in Fig. 13.

Figure 13 (left) presents the results of the nondimensional amplitude ratio $\rho = \langle A \rangle / \langle A_0 \rangle$, where $\langle A_0 \rangle$ is the mean response amplitude of the primary mass without a PPD, as a function of the mass ratio μ . Amplitude attenuation up to 60 % can be observed in that figure for small values of μ . Figure 13 (right) shows the optimal values of ζ_2 as a function of the mass ratio. Note that contrary to the TMD cases, the optimal value of the PPD damping is reducing with increasing μ .

Responses of a PPD to three earthquake records are presented in Fig. 14. All figures demonstrate the results of numerical modeling for $\mu = 0.0$ (no PPD), $\mu = 0.01$ and $\mu = 0.1$. Figure 14a demonstrates the record of El Centro earthquake and Fig. 14b shows the corresponding response of a primary mass with a PPD. It can be seen that a PPD is not very effective neither for small nor for bigger value of the mass ratio.

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 12

The mean amplitude of the primary mass with a PPD for different values of ζ_2 and $\mu = 0.08$

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 13 Nondimensional amplitude ratio ρ versus μ (a) and optimal values of $\zeta_2 = 0.01$ versus μ (b) for $\sigma^2 = 0.1$ and $\zeta_1 = 0.05$

The next two plots in Fig. 14c and d present the results for the Nisqually earthquake. The overall response of the primary mass is reduced especially when $\mu = 0.1$. Finally, the last set of plots shows the results for the Northridge earthquake. It can be observed that the high value of μ provides worse result compared to the low value of the mass ratio. These simulations clearly indicate the problems mentioned above for conventional TMDs, namely, their inability to perform well in the transient interval.

Summary

The entry revisits the development of the classical theory of passive tuned mass dampers with a primary mass subjected to either deterministic or stochastic excitations. Various formulas for optimizing the performance of the damper as well as opposite points of view on the efficiency of dampers to mitigate the seismic vibrations are presented. Pendulum tuned mass dampers are presented and their characteristics are outlined.

Tuned Mass and Parametric Pendulum Dampers Under Seismic Vibrations, Fig. 14 Earthquake records (left column) and the primary mass response (right

column) (b) for $\zeta_1 = \zeta_2 = 0.01$, $\Omega = 2.0$, and (a), (b) El Centro, (c), (d) Nisqually, and (e), (f) Northridge

The optimal values of the linear damping ratio of the PPD are expressed as a function of the mass ratio. It has been observed that the damping coefficient for a PPD decreases with the increase of

the mass ratio, which is opposite to what is observed for a conventional TMD. Due to the features inherent to a PPD system, it can be stated that the potential of PPDs has not been fully

investigated and comparison of their performance to a conventional TMD has not been made yet.

Introduction

The importance of reducing vibration amplitudes of structures under rare but severe loadings is well recognized. In the last decades, a fast increase in the development and application of passive energy dissipation devices, such as viscoelastic dampers, viscous fluid dampers, metallic yield dampers, friction dampers, and tuned mass dampers (TMDs), has been observed (Soong and Dargush 1997). One of the main applications of such devices is to reduce the dynamic response of structures subjected to strong earthquake ground motions.

To achieve the best structural performance, attention has been focused on determining the optimum parameters of TMDs in structures subjected to seismic excitation. Sadek et al. (1997) presented a methodology to find optimum parameters of TMDs for single degree of freedom (SDOF) and multiple degree of freedom (MDOF) structures subjected to a number of earthquake excitations. Joshi and Jangid (1997) carried out a study to determine the optimum parameters of MTMDs in SDOF structures

subjected to a base excitation, which was modeled as a stationary white noise random process. Results showed that the optimally designed MTMD system is more effective than the single TMD. Hadi and Arfiadi (1998) discussed the optimum design of single TMDs in MDOF structures subjected to earthquake excitation. The H2 norm was employed as the objective function, and genetic algorithms were applied to find the best TMD parameters. Chen and Wu (2001) presented a study focused on the optimal placement of MTMDs on structures subjected to seismic excitations. Because oscillators are placed one by one in sequence, their placement in a structure is selected from a restricted domain. Thus, the final results are indeed suboptimal. Hoang and Warnitchai (2005) presented a method that uses a numerical optimizer following a gradient-based nonlinear programming algorithm to search for optimal parameters of MTMDs. The developed method was applied to optimize MTMDs for a SDOF structure subjected to wideband excitation. Lee et al. (2006) presented an optimal design theory for structures implemented with TMDs. The proposed optimal design theory feasibility was verified by using a SDOF structure with a single TMD, a five-DOF structure with two TMDs, and a ten-DOF structure with a single TMD. Leung et al. (2008) employed the particle swarm optimization algorithm to obtain the optimum parameters including the optimum mass ratio, damper damping, and tuning frequency of the TMD system attached to a viscously damped single-degree-of-freedom main system, which is subjected to nonstationary excitation. In the sequence, Leung and Zhang (2009) employed again the particle swarm optimization algorithm to obtain the optimum parameters of a TMD system attached to a viscously damped SDOF main system under various combinations of different kinds of excitations. Lin et al. (2010) applied a two-stage optimum design procedure for MTMD to reduce structural dynamic responses with the limitation of MTMD's stroke. Shaking table tests of a large-scale three-story building with and without the MTMD under earthquake excitations were

conducted. Mohebbi et al. (2013) proposed a procedure for designing optimal MTMDs to mitigate the seismic response of MDOF structures. Genetic algorithms were used for solving the optimization problem.

Despite the importance of the studies mentioned in the previous entry, it is today widely acknowledged that deterministic optimization is not robust with respect to the uncertainties which affect the performance of engineering facilities. Deterministic design optimization (DDO) does not explicitly address the uncertainties inherently present in structural, especially environmental, loads, material strengths, and load effect and member strength models. Reliability-based design optimization (RBDO) has emerged as an alternative to model the safety-under-uncertainty part of the problem. However, both deterministic and reliability-based design optimizations suffer from the same drawback: these methods allow optimum structures to be designed but by considering conservative safety margins with respect to failure modes. Such methods are not appropriate for the optimal design of control structures such as TMD and MTMD. DDO is not appropriate because it is not robust with respect to the uncertainties. RBDO is not appropriate because control needs to be designed at the precise point (design point), and not within a conservative safety margin with respect to the design point. In fact, one can say that control is not control unless it is robust with respect to the uncertainties described above. Specifically, structural control should be made robust with respect to the uncertainties in the loading, mass, damping, and stiffness and in the inherent variability of materials properties, imperfect modeling of loads, load effects, system response, and so on (Taflanidis et al. 2007, 2009; Marano et al. 2010; Taflanidis 2011; Jensen 2005; Jensen et al. 2008; Jensen and Sepulveda 2011; Mohtat and Dehghan-Niri 2011). Thus, in the design and optimization of TMD passive control systems, it is of paramount importance to take uncertainties into account.

Within this context, this entry deals with the robust optimal design of TMD systems for structures subjected to seismic loading.

In section [Structural Model](#) the structural model is presented. Time-variant reliability analysis of oscillators is presented in section [Time-Variant Reliability of Oscillators](#). The robust optimization problem and a robustness measures are introduced in section [Robust Optimization Problem](#). Numerical examples are presented in section [Numerical Examples](#), in order to illustrate the importance of taking into account uncertainties in the optimum design of TMD systems. For the sake of simplicity and to focus on the formulation of the robust design optimization problem, the numerical analysis section deals with one TMD only. It should be remarked, however, that the extension to MTMD is straightforward. The chapter is finished with a Summary in section [Summary](#).

Structural Model

The differential equation that governs the motion of multi-degree-of-freedom systems, with *one* TMD located on the top floor (Fig. 1) and subjected to earthquake ground motions, may be written as

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = -\mathbf{M}\mathbf{B}\ddot{\mathbf{y}}(t) \quad (1)$$

in which $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ represent the $(n + 1) \times (n + 1)$ structural mass, inherent damping, and stiffness matrices, respectively, and n is the number of degrees of freedom of the model. $\mathbf{x}(t)$ is the $(n + 1)$ -dimensional relative displacement vector with respect to the base, and a dot over a symbol indicates differentiation with respect to time. $\mathbf{B}$ is a $(n + 1) \times d$ matrix of ground motion influence coefficients, i.e., this matrix contains the cosine directors of the angles formed between the base motion and the associated displacement direction with the considered degree of freedom. d is the number of considered ground motions (directions). $\ddot{\mathbf{y}}(t)$ is a d -dimensional vector representing the seismic excitation, i.e., the ground motion or base acceleration. For design purposes, assume that all relevant structural parameters (e.g., nominal values of mass, damping, and stiffness) can be

Tuned Mass Dampers for Passive Control of Structures Under Earthquake Excitations, Fig. 1 n -DOF building with single TMD on the *top* floor

assembled in a parameter vector $\mathbf{p}$. In the TMD design optimization process, the design variables are considered to be its stiffness and damping, which are then grouped in the design vector $\mathbf{d}$ (further details are given in section [Robust Optimization Problem](#)).

Time-Variant Reliability of Oscillators

The classical reliability problem for an oscillator is depicted in Fig. 2. During an excitation event of

Tuned Mass Dampers for Passive Control of Structures Under Earthquake Excitations,

Fig. 2 Classical time-variant reliability problem

specified duration t_E , a specific, scalar displacement response of the oscillator $x(t)$ (e.g., relative displacement between floors, displacement of top floor, etc.) should not exceed $\pm b$, where b is a given barrier which corresponds to a critical response level. In this entry, the displacement of top floor is chosen as the relevant displacement response. The critical response may represent permanent damage like cracking of concrete, or it may represent ultimate failure due to loss of equilibrium and is further addressed later in this entry. For a given barrier level b and excitation duration t_E , the failure probability is given by the classical Poisson model (Melchers 1999):

$$P_f(b, t_E) = 1 - \exp\left(-2 \int_0^{t_E} v_x^+(b, t) dt\right) \quad (2)$$

where v_x^+ is the up-crossing rate. For stationary excitation and for a time-invariant barrier $b(t) = b$, the crossing rate is also constant and $\int_0^{t_E} v_x^+(b, t) dt = v_x^+(b) t_E$. For a linear system excited by a Gaussian process, the response is Gaussian and the crossing rate can be evaluated as:

$$v_x^+(b) = \frac{\sigma_{\dot{x}}}{\sigma_x} \frac{1}{2\pi} \exp\left(-\frac{b^2}{2\sigma_x^2}\right) \quad (3)$$

where σ_x and $\sigma_{\dot{x}}$ are the standard deviation of the displacement and of the velocity response, respectively.

Many types of environmental structural loading can be described by the arrival of an unknown number of events (winds, storms, sea waves, earthquakes). By modeling the arrival of events as a Poisson process, and for a design life t_D , the failure probability becomes

$$P_f(b, t_D) = \sum_{i=1}^{\infty} P_f(b, t_E|i) p_i(t_D) \quad (4)$$

where $P_f(b, t_E|i)$ is the conditional probability of failure, given the occurrence of exactly i events during the design life, and $p_i(t_D)$ is the probability of having exactly i events, given by the Poisson distribution:

$$p_i(t_D) = \frac{(vt_D)^i \exp(-vt_D)}{i!} \quad (5)$$

In Eq. 5, v is the arrival rate of events. It can be shown that the conditional failure probability, assuming independence, is given by (Melchers 1999):

$$P_f(b, t_E|i) = 1 - (1 - P_f(b, t_E))^i \quad (6)$$

For convenience, failure probabilities can be converted into reliability index (β) by means of the classical first-order reliability result:

$$\beta = -\Phi^{-1}(1 - P_f(b, t_D)) \quad (7)$$

where Φ is the standard Gaussian cumulative distribution function. Clearly, the reliability index is a function of the vector of design parameters as well

as the vector of structural parameters $\mathbf{p}$. Hence, once can write $\beta = \beta(\mathbf{d}, \mathbf{p})$.

Robust Optimization Problem

This entry aims at pursuing the TMD design optimization of a given structure subjected to seismic loading, taking into account the uncertainties present in the structural system and its loading. That is, an approach for the robust design optimization of TMD is presented. In order to take into account these uncertainties, some parameters of the structure are modeled as random variables and the seismic loading is modeled as a random process.

One classical objective function in the deterministic design of TMD is the minimization of some mean square response of the structure. However, it has been reported in the literature that such an objective function does not necessarily correspond to the optimal design in terms of reliability (Papadimitriou et al. 1997; Scruggs et al. 2006). Hence, the probability of failure of the structure is chosen as the objective function to be minimized in this optimization problem. Such an objective function has been adopted, for instance, in the works by Taflanidis et al. (2007) and Taflanidis (2011), to name just a few. This probability of failure is given by Eq. 4, and the design variables are the stiffness (k_d) and damping constant (c_d) of the TMD. These two design variables are grouped into the vector $\mathbf{d} = [k_d \ c_d]$ for notation convenience. As commented in the previous section, the reliability index is chosen as the reliability measure. Since the higher its value is, the lower the probability of failure is, the objective function is given by $-\beta(\mathbf{d}, \mathbf{p})$. Thus, the optimization problem can be posed as:

$$\begin{aligned} &\text{Find : } \mathbf{d} \\ &\text{which minimizes : } -\beta(\mathbf{d}, \mathbf{p}) \\ &\text{subject to : } d_i^{\min} \leq d_i \leq d_i^{\max}, \quad j = 1, 2 \end{aligned} \quad (8)$$

This formulation leads to an unconstrained optimization problem, where the feasible design set is limited only by the bounds of the design variables. In this context, several optimization

algorithms can be used to solve this problem, e.g., gradient-based algorithm, Nelder–Mead algorithm, among others. In the numerical analysis section, a sequential quadratic programming (SQP) algorithm, coupled with a restart procedure, is employed in order to ensure the convergence to a global optimum. This coupling has been tested in several papers and has successfully solved complex optimization problems (Luersen and Riche 2004; Ritto et al. 2011; Lopez et al. 2013). For the interested reader, a detailed explanation of the optimization algorithm is given in these references.

Optimal TMD parameters found by the above formulation are intrinsically more robust than TMD parameters found by any equivalent deterministic formulation. However, it is important to demonstrate that indeed results obtained by the robust optimization are less sensitive to changes in the estimated structural parameters $\mathbf{p}$: mass, stiffness, and damping of the structural elements and of the TMD. Hence, a perturbation is introduced in vector $\mathbf{p}_\Delta$, such as to verify what would be the actual reliability index of the structure if parameter values were not the nominal values used in designing the TMD. Then, the perturbed reliability index β_Δ can be compared with the original, and a measure of robustness is obtained: the smaller the relative difference, the more robust is the design:

$$\text{robustness} \sim \frac{\beta}{|\beta - \beta_\Delta|} \quad (9)$$

The robustness measure proposed in Eq. 9 is employed in the next section to demonstrate that results of the optimal design of TMD considering uncertainties in structural and TMD parameters are more robust than optimal TMD designs obtained by considering only uncertain loading.

Numerical Examples

In this section, an example optimization problem is solved: robust design of TMD of a structure subjected to seismic excitation.

Problem Definition

A classical example, previously studied by several researchers (Hadi and Arfiadi 1998; Lee et al 2006; Mohebbi et al. 2013), was selected from the literature. The structure is a ten-story shear frame as illustrated in Fig. 1. In the top floor of this structure, a TMD is to be installed. The mass of the TMD (m_d) is chosen a priori to be 3 % of the total mass of the structure. The parameters to be determined by the designer are mean values of the stiffness (k_d) and damping coefficient (c_d) of such a TMD. Two variants of the example are solved: (a) only the seismic excitation is considered random; (b) the seismic excitation is random, but uncertainties are also considered in the mass, stiffness, and damping coefficient of the structure and the TMD. These are then modeled as random variables whose characteristics are presented in Table 1. Table 1 also shows the perturbations considered in order to evaluate the robustness of the solutions, following Eq. 9. These perturbations are applied to the random variables of the structure. The critical combination of perturbations is given by a reduction of stiffness and damping and an increase of the mass (this explains the signs on the perturbations presented in Table 1).

To determine the optimum TMD parameters, a stationary earthquake excitation is assumed, which can be modeled as a white noise signal with constant spectral density, S_0 , filtered through the Kanai–Tajimi spectrum. The PSD function is given by:

$$s(\omega) = S_0 \left[\frac{\omega_g^4 + 4\omega_g^2 \zeta_g^2 \omega^2}{(\omega^2 - \omega_g^2)^2 + 4\omega_g^2 \zeta_g^2 \omega^2} \right], \quad (10)$$

$$S_0 = \frac{0.03 \zeta_g}{\pi \omega_g (4 \zeta_g^2 + 1)}$$

where ζ_g and ω_g are the ground damping and frequency, respectively. In all the situations analyzed in this paper, the filter parameters are modeled as random variables. Their mean values were adopted as $\zeta_g = 0.6$, $\omega_g = 37.3$ rad/s (Mohebbi et al. 2013) and peak ground acceleration (PGA) = 0.20 g. These random variables are considered independent; Gaussian and their coefficients of variation were set to 20 %. Similar procedures were adopted in Taflanidis et al. (2007). It should be remarked that for more realistic situations, a nonstationary excitation should be employed. This procedure is detailed, for instance, in Jensen and Sepulveda (2011).

The upper bound and the lower bound value of the stiffness (k_d) and damping coefficient (c_d) of the TMD are 0–4,000 kN/m and 0–1,000 kNs/m, respectively. In all cases, the Newmark method ($\gamma = 1/2$ and $\beta = 1/4$) was employed to solve the dynamic problem. The time step adopted was $\Delta t = 0.02$ s. The mechanical model was calibrated and it is in accordance with the results provided in the literature.

Convergence of σ_x and $\sigma_{\dot{x}}$

Since MCS is employed to evaluate the standard deviations σ_x and $\sigma_{\dot{x}}$ required in Eq. 3 to approximate the probability of failure of the structure, a proper sample size needs to be selected. Thus, a study of the convergence of these standard deviations is shown in this section. Results are shown in Figs. 3 and 4. One may see from these figures that around 250 samples are required to stabilize the convergence curves. Thus, a sample size of 250 is employed herein to evaluate σ_x and $\sigma_{\dot{x}}$.

Minimization of the Probability of Failure

The optimization problem presented in sections [Robust Optimization Problem](#) and [Problem Definition](#) is solved in this section. An SQP algorithm from the MATLAB optimization toolbox, coupled with a restart procedure, is employed for this purpose. Three variants of each analysis are presented, by varying parameter b in Eq. 2: (i) $b = h/300$, (i) $b = h/400$, and (iii) $b = h/500$, where h is the total height of the shear

frame. Results of the analyses considering only excitation uncertainty are shown in Table 2. Results of the robust optimal design, i.e., considering uncertainty in excitation and structural parameters, are presented in Table 3. It should be remarked that the reliability indexes presented in these tables were evaluated considering uncertainty in the excitation and in the structural parameters, in order to allow for comparisons between the different analyses. For instance,

Tuned Mass Dampers for Passive Control of Structures Under Earthquake Excitations, Table 2 Results of the TMD optimization considering only excitation uncertainty

Case	k_d (MN/m)	c_d (MNs/m)	$\beta_{\text{uncontrolled}}$	β	β_{Δ}	Robustness
(i) $b = h/300$	3.69	0.146	2.23	5.23	4.51	7.26
(ii) $b = h/400$	3.69	0.146	0.48	2.95	2.26	4.28
(iii) $b = h/500$	3.69	0.147	<i>fail</i>	1.09	0.25	1.30

Tuned Mass Dampers for Passive Control of Structures Under Earthquake Excitations, Table 3 Results of the robust TMD optimization

Case	k_d (MN/m)	c_d (MNs/m)	$\beta_{\text{uncontrolled}}$	β	β_{Δ}	Robustness
(i) $b = h/300$	3.29	0.161	2.23	5.33	4.72	8.74
(ii) $b = h/400$	3.29	0.161	0.48	3.05	2.46	5.17
(iii) $b = h/500$	3.29	0.161	<i>fail</i>	1.20	0.50	1.71

optimal values of k_d and c_d in Table 2 were obtained solving the optimization problem given by Eq. 8 and considering uncertainty in the excitation only; whereas reliability indexes shown in this table were evaluated also considering uncertainties in structural parameters in order to allow for direct comparison of the reliability indexes.

In Tables 2 and 3 one observes that reliability index of uncontrolled structures ($\beta_{\text{uncontrolled}}$) is significantly smaller than the reliability index of the TMD-controlled structures (β). This result shows the effectiveness of the TMD in reducing the probabilities of failure of the frame structures under seismic loading.

The reliability indexes of the TMD-controlled structures (β), obtained by considering uncertainty in the excitation only (Table 2), are smaller than the β 's obtained by the robust optimization (Table 3). This result is a first indication that the optimization discussed herein, considering uncertainties in structural parameters, leads to more robust control by the TMD. To further demonstrate this result, the robustness measure introduced in Eq. 9, and evaluated for the perturbations presented in Table 1, is also shown in Tables 2 and 3. One can see that the robust design discussed herein, considering uncertainties in structural parameters, leads to larger values of the robustness measure. Hence, structural control obtained by the robust optimal design of TMD becomes less sensitive to fluctuations or uncertainties in structural and TMD parameters.

The optimization algorithm converged to the same optimum design independently of the starting point chosen by the restart procedure. An approximation of the objective function of case (iii), for the more general case considering uncertain load and structural parameters, is given in Fig. 5. One can see from this figure that the objective function is fairly smooth and without local minima.

Limitations of the Models

The goal of this entry was to present an introduction to the robust optimal design of TMD systems for structures subjected to seismic excitation. Hence, a simple model was presented herein. The reader should be aware of its main limitations, which are:

- Approximation of the crossing rates by Eq. 3, which assumes a stationary Gaussian excitation and linear, hence also Gaussian response; a more elaborate excitation model could involve non-Gaussian excitations and nonlinear structural responses, hence non-Gaussian displacement responses.
- The use of a stationary process to model the earthquake excitation: seismic excitation is nonstationary in nature; hence, a more elaborated model can be employed in real applications. This procedure is detailed, for instance, in Jensen and Sepúlveda (2011).

Tuned Mass Dampers for Passive Control of Structures Under Earthquake Excitations, Fig. 5 Objective function in the design space for the robust optimal design of a TMD (case (iii))

- The use of a linear structural model: the reader must be aware that nonlinear responses are expected for earthquake excitations.

Summary

This entry dealt with the robust optimum design of TMD systems for structures subject to seismic loading. First, the basic concepts of uncertainty quantification were presented focusing on the evaluation of the probability of failure of a given structure subject to seismic loading. It was detailed that the computation of the standard deviation of the stochastic process that define the displacement and velocity of a given degree of freedom of the structure and the definition of a threshold level for it were necessary to evaluate this probability of failure. Here, the MCS was employed to obtain these standard deviations; however, it may be remarked that other methods may be employed. Then, the robust design of the

TMD was posed having as the objective function the minimization of the structural probability of failure. The design variables were chosen to be the stiffness and the damping of the TMD. It led to an optimization problem in which the only constraints were the bounds of the design variables. An SQP-based algorithm, coupled with a restart procedure, was suggested as the optimizer to ensure the convergence to a global optimum. Then, a numerical example was presented to illustrate the importance of taking into account uncertainties in the optimum design of TMD systems for structures subject to seismic loading. This was achieved by introducing perturbations, which create a distance between parameter values considered in the design and parameter values “observed” in the actual structure. From the results of the numerical analysis section, it was shown that the structural control obtained by the robust optimal design of TMD becomes less sensitive to fluctuations or uncertainties in structural parameters.

Introduction

Structural health monitoring (SHM) refers to the process of developing and implementing a damage identification strategy for structural applications in civil, aerospace, and mechanical domains (Farrar and Worden 2007). Structural health monitoring techniques play a vital role in earthquake engineering, because they can be used to monitor the performance of structures that have been subjected to earthquakes. This is established through the use of a combination of strategically placed array of sensors and a variety of mathematical methods and techniques, all of which

constitute the overall structural health monitoring system.

An ideal SHM system allows rapid assessment of structure, which is particularly relevant in the aftermath of an earthquake, and supports decisions regarding repairs and replacements that are necessary for maintenance, rehabilitation, and structural retrofitting. The most important functional aspect of such an SHM system is damage diagnosis. Damage diagnosis consists of three major steps: damage detection, damage localization (or isolation), and damage quantification. The first step of damage detection attempts to detect abnormalities in the structure and finds out if there has been any structural damage or deterioration. The second step of localization focuses on identifying that component(s) of the overall structure has been subjected to damage. The third step of damage quantification quantifies the extent of damage, for example, the reduction of stiffness in a structural member.

Several structural systems are complex in nature and consist of several members and components. Usually, only a few response quantities are monitored by the SHM system, but the number of prospective damage candidates is very high. In such cases, it is almost impossible to achieve precise damage diagnosis. Further, the inputs to the system, the physical parameters, the sensor measurements, etc. may all be uncertain and hence render the results of diagnosis uncertain. The quantification of uncertainty in damage diagnosis is an essential step to guide

Uncertainty Quantification in Structural Health Monitoring, Fig. 1 Model-based framework for structural health monitoring

decision-making regarding the functioning of the overall structural system.

In several research articles, the uncertainty in diagnosis (Achenbach 2000) has been previously addressed using nondestructive evaluation (NDE) techniques, by estimating the probability of detection (POD). In such POD calculations, nominally identical damage is introduced in a number of nominally identical specimens, and the number of successful detections is used to calculate the probability of detection. Such an approach is completely different from the goal in structural health monitoring where the focus is on one structural system that is being monitored. Further, it is not possible to perform repeated tests since the goal in SHM is to make use of monitoring data in order to diagnose damage that has been caused due to external sources.

This chapter discusses statistical methods based on classical statistics (Sankararaman and Mahadevan 2011) and Bayesian statistics (Sankararaman and Mahadevan 2013) for quantifying uncertainty in damage diagnosis in the context of structural health monitoring. For this purpose, a generic model-based framework, as shown in Fig. 1, is used.

In this framework, a mathematical model (which may be developed using first principles of physics or using data-driven techniques) is used to predict the output ($y_m(t)$) of the structural system, and this output is compared with the measurements ($y(t)$) collected using sensors, to aid structural damage diagnosis. In the model, damage is represented by change in value of a particular model parameter. It is assumed that

only one parameter is damaged at a given instant, and the focus of this chapter is to identify that damage parameter and quantify the extent damage by estimating how much the value of that damage parameter has changed.

Until damage is detected, a tracking method (such as Kalman filtering (Kalman and Bucy 1961) or particle filtering (Arulampalam et al. 2002)) is used to estimate the state and the output of the system; the output estimated by the tracking method is denoted by $\hat{y}(t)$. Damage detection is performed by comparing $\hat{y}(t)$ against $y(t)$, and the residuals ($\hat{r}(t) = \hat{y}(t) - y(t)$) are subjected to hypothesis testing. Then, the uncertainty in detection is computed using classical hypothesis testing and Bayesian hypothesis testing methods. In classical hypothesis testing (Sankararaman and Mahadevan 2011), the choice of the significance level of testing is used to calculate the uncertainty in detection. In the Bayesian hypothesis testing-based approach, the likelihoods of two scenarios, i.e., “no fault” and “fault,” are calculated, and the uncertainty in the detection is quantified.

After damage is detected, tracking is completely stopped; from here on, only the model prediction ($y_m(t)$) is compared against experimental data ($y(t)$). Localization is performed in two steps. First, qualitative cause-effect relationships between model parameters and sensor measurements are used to isolate a prospective set of candidate damage parameters (Mosterman and Biswas 1999). Second, statistical tools are used to estimate the uncertainty in localization, by considering this set of candidate

damage parameters. In the classical statistics-based approach, a heuristic measure based on the least squares corresponding to each candidate damage parameter is used to quantify the uncertainty in damage isolation. In the Bayesian statistics-based approach, the probability of a particular parameter being faulty is calculated directly.

The third step of damage quantification is performed for each candidate damage parameter, using least square minimization or likelihood maximization. It is possible to approach damage quantification using system identification techniques that focus on parameter estimation in dynamic systems. The uncertainty in damage quantification is calculated using statistical confidence intervals and confidence bounds (Beck 1989; Dalai et al. 2005) in the classical statistics-based approach and using Bayesian inference techniques (Peterka 1981; Ching et al. 2006) in the Bayesian approach. Note that the latter approach directly calculates the probability distribution of the damage parameter, while the former approach provides a simpler measure of uncertainty.

Finally, the overall uncertainty in diagnosis is calculated by combining the uncertainties in the three stages of diagnosis using the principle of total probability, and the overall probability distribution of the candidate damage parameters are calculated. The methods for uncertainty quantification in damage detection, localization, and quantification are developed in the sections “[Uncertainty in Damage Detection](#),” “[Uncertainty in Damage Localization](#),” and “[Uncertainty in Damage Estimation](#).” The method for overall uncertainty quantification is presented in section “[Overall Uncertainty in Diagnosis](#),” and finally, all of the discussed methods are illustrated using the example of a structural frame in section “[Illustration: Structural Frame](#).”

Uncertainty in Damage Detection

Detection is based on comparison between healthy system response (provided by the tracking method, as $\hat{y}(t)$) and the observed system

response ($y(t)$). “Significant” deviation of system response from the expected performance indicates the presence of damage. It is necessary to perform a hypothesis test of significance for each individual output quantity that is measured using sensors (some structural systems may have multiple quantities that are being measured), since a deviation in any one output quantity indicates the presence of damage. Therefore, the rest of this section is presented using scalar residual quantities.

For the purpose of hypothesis testing (Fisher 1930; Romano 2005), the residuals $\hat{r}(t)$ are averaged over a moving window and the mean (μ) is subjected to a hypothesis test at a chosen significance level α , as follows:

$$H_0 \rightarrow \mu = 0 \text{ (No damage)} \quad (1)$$

$$H_1 \rightarrow \mu \neq 0 \text{ (Damage)} \quad (2)$$

The null hypothesis (H_0) in Eq. 1 states that the residuals are not significantly different from zero (thereby indicating no presence of damage), while the alternate hypothesis (H_1) in Eq. 2 states that the residuals are significantly different from zero (thereby, suggesting the presence of damage).

Classical Statistics-Based Approach

The uncertainty in detection is calculated as the probability that the damage is true after having detected a fault. This is established using the choice of the significance level α in the hypothesis test. The probabilities of different types of errors in hypothesis testing are well established in literature. The error of rejecting a correct null hypothesis is known as Type-I error, while the error of not rejecting a false null hypothesis is known as Type-II error. The probability of Type-I error is equal to α and the probability of Type-II error is denoted by β . This information can be written as:

$$P(H_0 \text{ is decision} | H_0 \text{ is true}) = 1 - \alpha \quad (3)$$

$$P(H_1 \text{ is decision} | H_0 \text{ is true}) = \alpha \quad (4)$$

$$P(H_0 \text{ is decision} | H_1 \text{ is true}) = \beta \quad (5)$$

$$P(H_1 \text{ is decision} | H_1 \text{ is true}) = 1 - \beta \quad (6)$$

Suppose that the residuals calculated from the system have been subjected to statistical hypothesis testing at significance level α and damage has

been detected, i.e., in other words, the decision is H_1 and the hypothesis H_0 has been rejected. The confidence in damage detection can be calculated as the probability that the truth is H_1 , subject to having rejected the hypothesis H_0 , i.e., $P(H_1 \text{ is true} | H_1 \text{ is decision})$. Let P_d denote this probability and this can be calculated using Bayes' theorem as:

$$P_d = \frac{P(H_1 \text{ is decision} | H_1 \text{ is true}) \times P(H_1 \text{ is true})}{P(H_1 \text{ is decision} | H_1 \text{ is true}) \times P(H_1 \text{ is true}) + P(H_1 \text{ is decision} | H_0 \text{ is true}) \times P(H_0 \text{ is true})} \quad (7)$$

In the context of damage detection, equal probabilities may be assigned to the events corresponding to " H_0 is true" and " H_1 is true." Therefore, $P(H_0 \text{ is true})$ and $P(H_1 \text{ is true})$ are both equal to 0.5, and hence:

$$P_d = \frac{1 - \beta}{1 + \alpha - \beta} \quad (8)$$

Bayesian Statistics-Based Approach

In this method, residuals are assumed to be normally distributed, i.e., $r \sim N(\mu, \sigma^2)$, and the probability distribution of the mean μ is continuously updated with measurements. Let the prior distribution be $N(\rho, \tau^2)$. If no additional information is available, Migon and Gamerman (Gamerman and Migon 1999) suggest $\rho = 0$ and $\tau^2 = \sigma^2$. Then, using the observed residual values ($r_1, r_2, \dots, r_n$, calculated using the available data D), the posterior distribution of μ can be calculated to be normal with mean and variance as follows:

$$\text{Posterior mean of } \mu = \frac{\frac{\rho}{\tau^2} + \frac{r_1 + r_2 + \dots + r_n}{\sigma^2}}{\frac{1}{\tau^2} + \frac{n}{\sigma^2}} \quad (9)$$

$$\text{Posterior variance of } \mu = \left(\frac{1}{\tau^2} + \frac{n}{\sigma^2} \right)^{-1} \quad (10)$$

Damage detection can be achieved through the use of Bayes' factor (B) which is defined as the

ratio of likelihood (Jeffreys 1998) of the two scenarios: "damage" and "no damage" as follows:

$$B = \frac{P(D|H_1)}{P(D|H_0)} \quad (11)$$

Jiang and Mahadevan (Jiang and Mahadevan 2008) derived the expression for the natural logarithm of the Bayes' factor, as:

$$\log(B) = -\frac{1}{2} \log(n+1) + \frac{(n \times \mu_r)^2}{2(n+1)\sigma^2} \quad (12)$$

In Eq. 12, μ_r refers to the mean of the observed residuals ($r_1, r_2, \dots, r_n$). If the Bayes' factor B is greater than 1, it implies that the data favors the hypothesis H_1 and hence suggests that there is damage. The confidence in damage detection, i.e., the probability that there is true damage, can be calculated as $P(H_1|D)$. If the prior probabilities $P(H_0)$ and $P(H_1)$ are chosen to be equal (implying that there is equal knowledge whether damage is present or not), then,

$$P(H_1|D) = \frac{B}{B+1} \quad (13)$$

This metric gives a direct measure of the probability of damage and hence is easy to compute and interpret in comparison with the classical statistics-based metric. Further, the probabilities

$P(H_0|D)$ and $P(H_1|D)$ can be updated continuously with measurements and thereby helps in tracking the uncertainty with acquisition of more measurements.

Uncertainty in Damage Localization

Damage localization is based on the comparison between damage signatures calculated from the system model and the symbols calculated from the system measurements. First, the system model is used to derive cause-effect relationships between the model parameters (that correspond to damage parameters) and model outputs (that correspond to system measurements). These cause-effect relationships, collectively called as the damage signatures, describe the qualitative changes in the zeroth and first derivatives of a system output as a result of a change in a system parameter. Sometimes, advanced modeling techniques such as bond graphs and temporal causal graphs have been used to generate such signatures (Sankararaman and Mahadevan 2011; Moustafa et al. 2010). Alternatively, these signatures may also be generated through simpler finite differencing approaches using the model, as a means of approximating derivatives that are equivalent to fault signatures (Sankararaman and Mahadevan 2013).

However, practical engineering systems usually have a large number of parameters that could become faulty, but only a small set of measurements. It may be difficult to exclusively isolate one particular damage parameter if several candidates have the same set of damage signatures. Instead, a set of prospective candidate damage parameters, $\Theta_i (i = 1 \text{ to } m)$, may be suggested by the isolation procedure. This section associates a measure of uncertainty to each of the candidate damage parameters. Recall that only one of these parameters is the true damage parameter because of the assumption that multiple damages do not occur concurrently. Further, after the damage has occurred, the value of the damage parameter Θ_i has changed to a new unknown value that is denoted by θ_i .

In order to assess the uncertainty in damage localization, measurements of the system are necessary after damage has been detected. Let t_f denote the time at which damage was detected. Let N denote the number of measurements available post-damage detection. Now it is necessary to consider all output quantities at once, as a vector. While y denotes the measurements, $y_m(\theta_i)$ denotes the model prediction available from time t_f until time $t_f + N$. Hereon, the model prediction needs to be considered as a function of the damage parameter because the value of the damage parameter has changed.

Classical Statistics-Based Approach

The uncertainty in damage localization is calculated using a heuristic least square-based metric. Assuming that Θ_i is the correct damage parameter, all the other damage parameters are assumed to be healthy (and their values are chosen to be nominal), and the least square estimate of θ_i can be calculated by minimizing Eq. 14.

$$S(\theta_i) = \sum_{t=t_f}^{t_f+N} (y_m(\theta_i) - y)^T (y_m(\theta_i) - y) \quad (14)$$

Let the least square estimate be $\hat{\theta}_i$ and $S(\hat{\theta}_i)$ the corresponding least square value. Then the probability that Θ_i is the true damage parameter can be heuristically said to be inversely proportional to $S(\hat{\theta}_i)$, and the constant of proportionality can be evaluated by considering all prospective damage parameters and equating the total probability to unity. Thus, the uncertainty in localizing the damage to the damage parameter Θ_i can be expressed mathematically as:

$$P_{\Theta_i} = P(\Theta_i \text{ is the damage parameter}) \propto \frac{1}{S(\hat{\theta}_i)} \quad (15)$$

and the constant of proportionality can be evaluated by imposing the condition:

$$\sum_{i=1}^{i=m} P_{\Theta_i} = 1 \quad (16)$$

Bayesian Statistics-Based Approach

The Bayesian approach directly calculates the probability that a given damage parameter is faulty and provides an exact measure of uncertainty as against a heuristic measure provided by the classical statistics-based approach. Let A denote the event that Θ_i is the true damage parameter. The Bayesian

approach calculates the probability of event A after collecting measurements from time t_f until time $t_f + N$. A prior probability P'_{Θ_i} is first assumed for each damage parameter to be the true damage parameter. A suitable assumption for the prior probability P'_{Θ_i} would be equal to $1/m$ since any of the candidate damage parameters is equally likely to be the true damage parameter. Then, this prior probability is updated using Bayes' theorem to calculate a posterior probability P''_{Θ_i} based on the following likelihood function:

$$P(D/A) = P(D|\Theta_i \text{ is the true damage parameter}) = L(\Theta_i) \quad (17)$$

This probability is the likelihood of event A , denoted by $L(\Theta_i)$. The calculation of this probability is done in two steps.

Let B denote the event that θ_i is the new value of the damage parameter Θ_i , i.e., after damage has occurred. Then the likelihood function corresponding to the event $A \cap B$ (the probability of observing the data conditioned on (i) event A , i.e., Θ_i is the true damage parameter, and (ii) event B , i.e., the true damaged value is θ_i), can be calculated using the probability distribution of residuals. In the context of statistical parameter estimation, it is common to assume a joint Gaussian probability distribution for the residuals (with zero mean and Σ covariance). Therefore, the likelihood can be written as (Pawitan 2001):

$$P(D|A \cap B) = L(\Theta_i, \theta_i) \propto \prod_{t=t_f}^{t_f+N} \exp\left(-(\mathbf{y}_m(\theta_i) - \mathbf{y})^T \Sigma (\mathbf{y}_m(\theta_i) - \mathbf{y})\right) \quad (18)$$

Note that $\mathbf{y}_m(\theta_i)$ and $\mathbf{y}$ are column vectors whose length is equal to number of output quantities. The covariance matrix Σ is a square matrix whose size is equal to the number of output quantities. Hence, the right hand side of Eq. 18 is a scalar.

This likelihood function $L(\Theta_i, \theta_i)$ is then used to calculate $L(\Theta_i)$, which, in turn, can be used to

update P'_{Θ_i} . Let $f'(\theta_i|\Theta_i)$ denote the probability density function of the damage value conditioned on the event that Θ_i is the damage parameter. The key is to calculate the posterior probabilities P'_{Θ_i} and $f''(\theta_i|\Theta_i)$ using Bayes' theorem. While the former indicates the uncertainty in damage localization, the latter indicates the uncertainty in damage quantification. Section “[Uncertainty in Damage Estimation](#)” focuses on the latter topic, i.e., estimation of $f''(\theta_i|\Theta_i)$, while the present section deals with the estimation of P'_{Θ_i} . It can be easily proved that (Sankararaman and Mahadevan 2013):

$$P''_{\Theta_i} \propto P'_{\Theta_i} \times P(D|A) \\ \propto P'_{\Theta_i} \times \int L(\Theta_i, \theta_i) f'(\theta_i|\Theta_i) d\theta_i \quad (19)$$

Note that there is a proportionality constant in Eq. 19. This constant can be evaluated by imposing the constraint that the sum of the values of P''_{Θ_i} corresponding to the m different damage parameters should be equal to unity. This condition is similar to that in Eq. 16, with the difference being that now the posterior probabilities need to be normalized. Note that the notion of posterior probabilities was absent while Eq. 16 was presented in the classical statistics-based method. Therefore, the advantage of the Bayesian approach is that such posterior probabilities can

be updated continuously with the availability of measurements, and therefore, the uncertainty in damage localization can be tracked continuously as a function of time.

Uncertainty in Damage Estimation

This section discusses the calculation of the uncertainty in the damage quantification stage, by estimating the uncertainty in the value of damage parameter. The classical statistics-based approach calculates statistical confidence intervals on the value of damage parameter, while the Bayesian statistics-based approach directly calculates the probability distribution of the value of the damage parameter.

Classical Statistics-Based Approach

Recall that the least square estimate of the damaged value of the damage parameter Θ_i was obtained by minimizing the sum of squares in Eq. 14. The least square estimate was denoted by $\hat{\theta}_i$ and the corresponding value of least squares was denoted by $S(\hat{\theta}_i)$. Using this information, it is possible to compute confidence bounds on the θ_i . The values of θ_i that satisfy the inequality in Eq. 20 belong to the α -level confidence bounds of θ_i . In several problems, there is an interval $([\theta_{i\alpha, \min}, \theta_{i\alpha, \max}])$ within which all values of θ_i satisfy this inequality, and therefore, this interval is referred to as the α -level confidence interval.

$$S(\theta_i) \leq S_\alpha = S(\hat{\theta}_i) \left(1 + \frac{p}{n-p} F_{p, N-p}^\alpha \right) \quad (20)$$

In Eq. 20, N denotes the number of observations over which the sum of square error was estimated and p denotes the length of the θ_i . In this case, only one parameter is assumed to be damaged at any given instant, and therefore, $p = 1$. Further, $F_{(p, N-p)}^\alpha$ with estimation (numerator) degrees of freedom p and residual (denominator) degrees of freedom $(N - p)$ at significance level α (Seber and Wild 1989).

Uncertainty Quantification in Structural Health Monitoring, Fig. 2 Confidence bounds in damage estimation

The confidence bounds of θ_i can be graphically illustrated using Fig. 2. The minimum $(\theta_{i\alpha, \min})$ and maximum $(\theta_{i\alpha, \max})$ values that satisfy Eq. 20 are also indicated in this figure, and they can be solved using optimization techniques (Sankararaman and Mahadevan 2011).

The minimum value $(\theta_{i\alpha, \min})$ can be estimated by minimizing the expression $(S(\theta_i) - S_\alpha)^2$ by considering values of θ_i that are strictly smaller than $\hat{\theta}_i$, i.e., $\theta_i < \hat{\theta}_i$. Similarly, the maximum value $(\theta_{i\alpha, \max})$ can be estimated by minimizing the expression $(S(\theta_i) - S_\alpha)^2$ by considering values of θ_i that are strictly larger than $\hat{\theta}_i$, i.e., $\theta_i > \hat{\theta}_i$.

The α -level confidence interval on θ_i , i.e., $[\theta_{i\alpha, \min}, \theta_{i\alpha, \max}]$, needs to be interpreted carefully. It acknowledges that the true value of the damage parameter Θ_i is unknown but deterministic; there is a $(1 - \alpha)\%$ probability that this interval will contain the true value of the damage parameter. This confidence interval can be calculated at multiple levels of α , but this is not equivalent to estimating the probability distribution of θ_i . In fact, in the classical statistics approach, θ_i is an unknown but deterministic quantity and hence cannot be assigned a probability distribution. However, with the availability of more data, the confidence interval can be reconstructed, and its

width may decrease with more acquisition of data, if the correct damage parameter is being estimated.

Bayesian Statistics-Based Approach

The Bayesian approach can assign probability distributions even to deterministic quantities (Calvetti and Somersalo 2007) since it assigns probabilities based on the extent of belief. Therefore, it calculates the entire probability distribution of θ_i , the value of the damage parameter Θ_i . The likelihood function $L(\Theta_i, \theta_i)$ earlier defined in Eq. 18 can be used in Bayes' theorem (Leonard and Hsu 1999) and the posterior probability distribution of θ_i can be calculated as:

$$f''(\theta_i|\Theta_i) = \frac{L(\Theta_i, \theta_i)f'(\theta_i|\Theta_i)}{\int L(\Theta_i, \theta_i)f'(\theta_i|\Theta_i)d\theta_i} \quad (21)$$

As explained earlier, $f'(\theta_i|\Theta_i)$ is the prior density function and represents the knowledge about the value of the damage parameter Θ_i before performing damage quantification. It is likely that there is no such "prior" knowledge, and a uniform distribution may be assumed, to begin with. Then, this distribution can be updated continuously with acquisition of more measurements. While Markov Chain Monte Carlo methods are commonly used to solve Eq. 21, advanced numerical integration techniques (Sankararaman and Mahadevan 2011; McKeeman 1962) may be used to provide quicker results. Such numerical techniques are particularly useful since there is only one damage parameter that is being estimated.

The probability distribution of the value θ_i of the damage parameter Θ_i can be calculated and updated continuously with acquisition of more measurements. For example, a first set of measurements can be used to update the uniform prior distribution to the corresponding posterior distribution. Then, this posterior distribution is used as a prior while updating using the second set of measurements. This procedure can be continued until a desired confidence level in damage quantification is attained. This convenience of continuously updating the uncertainty is a unique

feature of the Bayesian method and is not applicable when classical statistics-based techniques are used.

Overall Uncertainty in Diagnosis

Having estimated the uncertainty in each of the individual steps of damage diagnosis, i.e., detection, localization, and quantification, respectively, it is important to aggregate these three results to compute the overall uncertainty in damage diagnosis. In order to address this issue, consider the uncertainty estimated in the damage quantification step. The probability distribution of θ_i is, in fact, conditioned on two events: damage detection being correct and damage localization being correct. The goal in this section is to estimate the probability distribution of θ_i by accounting for the uncertainty in damage detection and damage localization, and the resultant distribution will be reflective of the overall uncertainty in diagnosis.

Recall that P_d denotes the confidence in damage detection, and P_{Θ_i} denotes the confidence in damage localization. While the former refers to the probability that the damage is true, the latter refers to the probability that Θ_i is the true damage parameter. The unconditional distribution of θ_i can be estimated by considering three events:

1. There is no damage, and hence, the structural health monitoring system triggered a false alarm. This event has a probability $(1 - P_d)$.
2. There is damage, but Θ_i is not the correct damage parameter. The probability for this event is equal to $P_d \times (1 - P_{\Theta_i})$.
3. There is damage and Θ_i is the correct damage parameter. The probability for this event is equal to $P_d \times P_{\Theta_i}$.

In the first two cases, the probability distribution of θ_i is still nominal (i.e., no damage). Let $f(\theta_i|\text{healthy})$ denote this probability distribution. In the third case, the probability distribution of θ_i corresponds to the distribution estimated in section "Uncertainty in Damage Estimation."

Using the tools of total probability, the unconditional distribution of θ_i can be calculated as:

$$\begin{aligned} f(\theta_i) = & (1 - P_d) \times f(\theta_i|\text{healthy}) + P_d \times (1 - P_i) \\ & \times f(\theta_i|\text{healthy}) + P_d \times P_i \times f''(\theta_i|\Theta_i) \end{aligned}$$

(22)

Since the above unconditional distribution accounts for the uncertainty in damage detection, damage localization, and damage quantification, it is indicative of the overall uncertainty in diagnosis. This distribution also can be continuously estimated in time, with the acquisition of measurements. If the true damage parameter is being correctly estimated, then it is expected that the variance of this distribution will decrease with acquisition of measurements, thus indicating increasing confidence in diagnosis.

Illustration: Structural Frame

Consider a simple two-storied structural frame, as shown in Fig. 3. This section illustrates the various methods for uncertainty quantification in structural health monitoring using this structural frame as a numerical example.

Description of the Structural Frame

This system has six parameters, m_1, m_2, k_1, k_2, D_1 , and D_2 , that represent the masses, stiffness, and damping parameters of the two stories of the structural frame. The inputs to the system are forces at the two levels and the measured outputs

are the accelerations at the two levels. The nominal values of these quantities are provided in Table 1.

The masses of the first and second floors are assumed not to change. Hence, there are only four parameters that could be affected by damage. Using the damage signatures (cause-effect relationships between the model parameters and measurements), it is possible to qualitatively identify the story (floor) that is damaged, and hence the prospective damage parameters are the stiffness and damping of that particular story (floor).

Damage Simulation

In order to verify the effectiveness of the methodology, it is assumed that a known amount of damage is introduced during the normal operation of the structure. For the example of illustration, consider that the value of k_1 is reduced to 80 % of its nominal value at a particular time instant. The goal is to make use of the methods described in this chapter and diagnose this

Uncertainty Quantification in Structural Health Monitoring, Table 1 Two-story frame: numerical values

Parameter	Value	Unit
k_1	30,700	N/m
k_2	44,300	N/m
D_1	307	Ns/m
D_2	443	Ns/m
m_1	136	Ns ² /m
m_2	66	Ns ² /m
$F_1(t)$	75 sin(9 t)	N
$F_2(t)$	100 sin(9 t)	N

Uncertainty Quantification in Structural Health Monitoring, Fig. 3 (a) Structural frame, (b) mechanical model

damage. For this purpose, sensors are used to measure the accelerations of both the stories. The sensors are not accurate and the measurement noise of the sensors is accounted for, through inclusion in the tracking method.

Damage detection is done through hypothesis testing, as explained in section “[Uncertainty in Damage Detection](#).” Residuals are computed by differencing the observed sensor measurements and the output of tracking system. A moving window is used to calculate the mean of the residuals, and this mean is subjected to hypothesis testing to detect damage. The classical statistics-based hypothesis testing detects damage with 95 % confidence. Since the values of Type-I and Type-II errors in classical hypothesis testing do not change, the confidence in detection also does not change. In contrast, the Bayesian method facilitates quantification and updating of uncertainty from a 61 % confidence at 5 s to 99.98 % confidence at 5.05 s.

Without loss of generality, the time at which damage is detected is denoted as $t = 0$ s. Once damage has been detected, tracking is not used. The measurements and model predictions are directly used for the purpose of quantifying the uncertainty in damage localization and damage quantification. For this purpose, three sets of data are considered, with each set consisting of 10 s of acceleration data. The first set of data consists of measurements from $t = 0$ s until $t = 10$ s. The second set of data consists of measurements from $t = 10$ s until $t = 20$ s. Finally, the third set of data consists of measurements from $t = 20$ s until $t = 30$ s. Note that continuous updating of uncertainty through these three sets of data is possible only using the Bayesian method. Therefore, continuous updating results are provided below, only for the Bayesian method. On the other hand, the results using classical statistics-based method are provided by considering all the available data as a single set.

Damage localization, as explained in section “[Uncertainty in Damage Localization](#),” is performed in two steps. First, qualitative damage signatures are used to identify a list of candidate damage parameters. In this example, as stated earlier, it is possible to uniquely identify which

story (floor) is faulty. Therefore, the candidate damage parameters are k_1 and D_1 , respectively. The heuristic measures of uncertainty using classical statistics-based methods yield 98 % and 2 % probabilities for k_1 and D_1 to be the damage parameters, respectively. On the other hand, the uncertainty in localization of k_1 , using the Bayesian method, is calculated for the first data set as 99 % and updated using Bayes’ theorem for the following two sets to 100 % and 100 %.

Damage quantification using the classical statistics procedure yields a 90 % confidence interval of (24,509 N/m, 24,612 N/m). The Bayesian approach directly calculates the probability distribution of k_1 as explained in section “[Uncertainty in Damage Estimation](#).” The overall uncertainty in diagnosis can be calculated as in section “[Overall Uncertainty in Diagnosis](#),” and the corresponding probability density function is shown in Fig. 4. From Fig. 4, it can be seen that (i) the maximum likelihood estimate (MLE) of k_1 matches closely with the true damage value, and (ii) the uncertainty in the estimate of k_1 decreases with acquisition of more measurements.

The above diagnosis procedure was also extended to five-story frames, where qualitative localization is able to isolate to the floor of damage accurately. Different damage scenarios were considered for the five-story frame, and these were detected and isolated (localized) satisfactorily with the proposed method. The damage was quantified with high accuracy. Uncertainty quantification associated with each of these three processes was also successful, and both classical statistics-based and Bayesian methods were investigated. The easy extension to multistory frames clearly indicates that this diagnosis methodology is applicable to practical structures.

Summary

This chapter presented computational methods to quantify the uncertainty in structural health monitoring, by considering the three steps of damage diagnosis, i.e., damage detection, damage localization, and damage quantification. Classical statistics-based methods and Bayesian methods

Uncertainty Quantification in Structural Health Monitoring, Fig. 4 Continuous uncertainty quantification in structural health monitoring

were investigated for this purpose. Damage detection was based on statistical hypothesis testing. While the classical hypothesis testing procedure calculated the uncertainty in detection based on the significance level of testing, the Bayesian hypothesis testing procedure calculated the likelihood of “no-damage” scenario to “damage” scenario, thereby providing a robust Bayesian metric to assess the confidence in detection. The uncertainty in localization was quantified using heuristic measures in the classical statistics-based approach, while the Bayesian method directly quantified the probability that a given parameter is the true damage parameter. The uncertainty in damage quantification was expressed in statistical confidence intervals in the classical statistics-based approach, while the Bayesian method gives the entire probability distribution of the damage parameter. Finally, the uncertainties in the three different steps were combined using the principle of total probability to provide an estimate of the overall uncertainty in diagnosis. The classical statistics-based method and Bayesian method are fundamentally different in interpretation and implementation. However, it can not only be seen that the results from Bayesian method is easy to implement and interpret but also that the Bayesian method also facilitates easy updating of uncertainty with acquisition of measurements.

It must be noted that this chapter discussed practical situations where only one damage parameter is present at any given instant of time. In some cases, it may be necessary to consider multiple, concurrent damage parameters during structural health monitoring. Ongoing research is addressing such challenges and also studying the application of structural health monitoring methods to composites in detail.

Introduction

Uncertainty is associated with many aspects of earthquake engineering. Considerable uncertainty resides in the prediction of earthquake occurrence, prediction of seismic forces, estimated capacity of a structural system to withstand such forces, and consequences associated with seismic events. This challenging problem lends itself to information/partial knowledge and uncertainty in many forms.

Traditionally, probabilistic methods have often been employed to systematically treat the inherent uncertainty in earthquake engineering applications. Notably, probability theory is used in seismic hazard analysis first outlined by Cornell (1968). Probabilistic methods also underlie load and resistance criteria for structural design. A probabilistic design methodology is based on initial work from Cornell (1969) and Ravindra and Galambos (1978) among others. These efforts form the basis of codified design of structural systems that are founded on structural reliability concepts (Ellingwood et al. 1980). Probabilistic concepts have long been utilized for loss estimation of potential earthquake events. Early studies by Whitman (1973) and Whitman et al. (1973) developed damage probability matrices that aim to characterize the effect of varying

levels of earthquake intensities. These matrices express the probability that a particular level of building damage will result from various seismic intensities. Other significant efforts that conceptualize loss estimates within a probabilistic framework include ATC-13 (1985) and HAZUS (NBIS 1997). In recent decades, beginning with FEMA 273 (1997) and FEMA 356 (2000) and more comprehensively in the Performance Based Earthquake Engineering (PBEE) approach outlined by the Pacific Earthquake Engineering Research Center (PEER) (Cornell and Krawinkler 2000; Porter 2003), performance-based measures include probabilistic concepts as a methodology that incorporates uncertainty associated with seismic hazard, vulnerabilities, and consequences related to the performance of structural systems. The PEER framework is presented in Eq. 1:

$$p(DV) = \int \int \int p(DV|DM)p(DM|EDP) \\ p(EDP|IM)p(IM)dIMdEDPdDM \quad (1)$$

Where DV is a decision variable, DM is a damage measure, EDP is an engineering demand parameter, and IM is an intensity measure. The notation $p(x)$ here represents the probability distribution function of x (and $p(x|y)$ the conditional probability distribution of x given a particular value for the variable y) and will be discussed in more detail in a later section.

This equation illustrates the types of terms that are involved in assessing the decision process in seismic design. The intensity measure (IM) consists of various characteristics of an earthquake, such as peak ground acceleration, maximum energy release, duration, etc. Each of these is dependent on the shaking mechanism at the epicenter and the geophysical conditions through which the seismic waves travel. As can be surmised, these factors are likely to exhibit different types of uncertainty, some of which include experience and expert judgment, while in current approaches, all are generally modeled

probabilistically. The engineering demand parameter (EDP) reflects the response quantities of a structure that are important to its ability to perform during the earthquake. Such quantities are typically taken as the maximum inter-story drift, the maximum displacement, or the maximum acceleration. The damage measure (DM) may include multiple failure modes of beams, columns, and floor slabs, as well as losses to nonstructural elements. As with the intensity measures, some of these quantities might involve expert judgment. Finally, the decision variable (DV) may reflect such issues as economic and social as well as structural loss to a community. Therefore, design decisions often incorporate the combination of physical and societal factors, for which the uncertainties exhibit very different characteristics of sources of knowledge and uncertainty.

Uncertainty can assume different forms and can arise from different sources. Uncertainty may arise from expert opinions/judgments, qualitative assessments (Vick 2002), measurement error (or measurement uncertainty), and/or the reliability of the source of information (Klir 2006). For example, probabilistic seismic hazard analysis combines information from geologic evidence and identification of fault locations with data from previous seismic events (Cornell 1968; Vick 2002). In loss estimations, expert opinions are often integrated with knowledge of previous earthquake events for the prediction of damage and losses of seismic scenarios that may contain little or no data (ATC 1985). This is particularly the case for large (high intensity), rare earthquake events.

Although probabilistic methods offer several tools for manipulating uncertainty and partial information, methods outside of classical probability theory, under the umbrella of *Generalized Information Theory* (GIT), help to mathematically expand information theory beyond traditional probability (Klir 2006). Prominent uncertainty theories include probability theory, possibility theory, and evidence theory. The following presents a historical perspective and mathematical overview of these uncertainty theories.

Probability Theory

Probability Theory: Historical Perspective

Probability theory initially emerged as a means of enhancing the treatment of uncertainty in the face of what is unknown or uncertain. Its inception, credited to Blaise Pascal and Pierre de Fermat in 1654, originated from games of chance (Hacking 2006). A probability came to be defined as the ratio of a particular outcome of interest to the total number of possible outcomes (Dubois and Prade 1988; Vick 2002). Characterized as a “calculus of chances,” this conception formed the frequency interpretation of probability (Dubois and Prade 1988, p. 4). This interpretation views probabilities as limits of observed frequencies of repeatable events (i.e., placing repeated bets), each event characterized by an uncertain but observable outcome. As the theory evolved, it became apparent that probabilities could assume more than one interpretation. The “subjectivists” offered another interpretation of probabilities as a “degree of belief” or commonly termed *Bayesian degrees of belief*. This class of probabilities originated from the work of Thomas Bayes, an English mathematician who established the well-known Bayes’ theorem. This interpretation views probabilities of uncertain events as a measure of one’s belief about its occurrence (Benjamin and Cornell 1970; Dubois and Prade 1988; Vick 2002).

Although a straightforward interpretation of probabilities has eluded the field since its beginnings, the relative frequency and subjective degree of belief are prominently recognized in applying probabilistic concepts (Hacking 2006; Vick 2002).

Probability Theory: Mathematical Overview

In probability theory, uncertainty is expressed in the form of a *probability distribution function* by

$$p : x \rightarrow [0, 1] \quad (2)$$

A variable, whose distribution is defined by $p(x)$, is usually referred to as a *random variable* (Ang and Tang 2007). Given a probability distribution function p , an event in the space of possibilities

can be specified by a range of values in the universe X (commonly termed the *sample space* in the context of probability theory) as a unique value. This value is termed a *probability measure*, here denoted $\text{Pro}(A)$, where A denotes an event within the sample space (S) of all possible events. A probability measure is defined by Eq. 3 (Klir 2006).

$$\text{Pro}(A) = \sum_{x \in A} p(x) \quad (3)$$

Equation 3 can be interpreted as “the probability of A .” This probability must conform to certain mathematical properties or *axioms*. Probability theory is based on the following axioms (Benjamin and Cornell 1970):

$$\begin{aligned} (\text{Pro1}) \quad & 0 \leq \text{Pro}(A) \leq 1 \\ (\text{Pro2}) \quad & \text{Pro}(S) = 1, \text{ where } S \text{ is the sample space} \\ & \text{(or set of all sample points)} \\ (\text{Pro3}) \quad & \text{Pro}(A \cap B) = \text{Pro}(A) + \text{Pro}(B) \\ & \text{when sets } A \text{ and } B \text{ are disjoint;} \\ & A \cap B = \emptyset \end{aligned} \quad (4)$$

Equation 4 indicates that probability measures are positive numbers, and as indicated by the third axiom (Pro3), a basic property of probability measures is that they are additive. This requirement is commonly referred to as the *additivity requirement*. This requirement ensures the sum of probabilities over any collectively exhaustive, mutually exclusive set of events is equal to 1 (unity). Considering a single event A , and its complement denoted $\bar{A}$, from (Eq. 4) it can be shown that

$$P(\bar{A}) = 1 - P(A) \quad (5)$$

For the special case when the probability of an event depends on the outcome (occurrence or nonoccurrence) of another event, such a probability is a *conditional probability* given by

$$\text{Pro}(A|B) = \frac{\text{Pro}(A \cap B)}{\text{Pro}(B)} \quad (6)$$

where the numerator, $\text{Pro}(A \cap B)$, is the probability of the *joint event* or the probability of the intersection of events A and B (i.e., $A \cap B$). Equation 6 can be interpreted as the probability of event A given that event B has occurred. Rearranging Eq. 6, the probability of the joint event $\text{Pro}(A \cap B)$ can be written as

$$\text{Pro}(A \cap B) = \text{Pro}(A|B)\text{Pro}(B) \quad (7)$$

Or equivalently,

$$\text{Pro}(A \cap B) = \text{Pro}(B|A)\text{Pro}(A) \quad (8)$$

From this, the “inverse” probability can be obtained by substituting the numerator in Eq. 6 with Eq. 8.

$$\text{Pro}(A|B) = \frac{\text{Pro}(B|A)\text{Pro}(A)}{\text{Pro}(B)} \quad (9)$$

Equation 9 is known as Bayes’ theorem or Bayes’ rule. Using the theorem of total probability given by

$$\text{Pro}(B) = \sum_{i=1}^n \text{Pro}(B|A_i)\text{Pro}(A_i) \quad (10)$$

where $i = 1, 2, \dots, n$, denote a set of mutually exclusive collectively exhaustive events $A_1, A_2, \dots, A_n$. Bayes’ theorem can be expanded such that

$$\text{Pro}(A_j|B) = \frac{\text{Pro}(B|A_j)\text{Pro}(A_j)}{\sum_{i=1}^n \text{Pro}(B|A_i)\text{Pro}(A_i)} \quad (11)$$

where (Eq. 11) is the conditional probability of A_j given that event B has occurred. The theorem of total probability given in Eq. 10 simply expresses the probability of B, $\text{Pro}(B)$, in terms of its conditional probabilities.

Equation 11 (Bayes’ theorem) provides a means for incorporating new information by updating *prior probabilities* or previous information expressed in the form of a probability (Benjamin and Cornell 1970). These updated

probabilities, or so-called *posterior probabilities*, lead to new numerical probabilistic values of the event of interest by considering additional knowledge about the relative likelihood of a particular event. Thus, probability theory provides a logical basis for manipulation of data in the form of relative frequencies and a mathematically permissible method for the continuous updating probabilistic values as a function of the current state of knowledge through the use of Bayes’ theorem.

Probability Theory: Interpretations

It is well established that probabilistic values can be characterized by two general classes of interpretation: relative frequencies of an observed outcome and Bayesian probabilities (or so-called subjective probabilities). The class of subjective probabilities allows for a broader context of probability theory. This interpretation proposes that probability can be justified not necessarily by the objective or frequentist basis (a frequency of occurrence among “trials”) but to single occurrence events in the form of a measure of one’s uncertainty about a particular event (Dubois and Prade 1988; Vick 2002). From this, Bayes’ theorem serves as a mathematical basis for manipulating relationships between prior and new probabilistic information. As such, the axioms of probability theory serve as a foundation for expressing uncertainty in multiple contexts.

Possibility Theory

Possibility Theory: Historical Perspective

Possibility theory gained much attention in the latter half of the twentieth century through the work of Zadeh (1978), which linked the concepts of fuzzy sets to the notions of possibilities. Possibility theory differs from probability theory in that it explicitly recognizes the case when evidence or judgments support the possibility of one event, but does not necessarily implicate evidence for the contrary event (Dubois and Prade 1988). In probability theory, uncertainty is represented by a single probability measure.

If either the probability of an event or the probability of its negation (or complement) is known, the additivity requirement guarantees that the probabilities of both are known. In possibility theory, by comparison, uncertainty is represented by dual measures, termed *possibility* and *necessity measures* (Dubois and Prade 1988; Klir 2006). These measures are founded on the basic concepts of *possibility theory*.

Possibility Theory: Mathematical Overview

Consider a set of mutually exclusive alternatives X , of which some alternatives may or may not be possible (Klir 2006). To determine truth (i.e., the correct alternative), suppose that relevant information is obtained through experimentation, testing, or observation. Presumably, this new knowledge will determine that some of the alternatives are supported by the new knowledge (or evidence E) while other alternatives are deemed impossible. The alternatives supported by the new evidence form the subset E of X . The basis of possibility theory builds on those alternatives contained in E , the subset of the remaining possible alternatives. Mathematically, this is expressed by a *basic possibility function* r_E , defined by

$$r_E(x) = \begin{cases} 1, & \text{when } x \in E \\ 0, & \text{when } x \notin E \end{cases} \quad (12)$$

Equation 12 states that alternatives supported by evidence are possible and functionally equal to one. Conversely, zero is assigned to those alternatives that are impossible.

As an extension to differentiating between possibility and impossibility in the binary sense, a generalization of classical possibility theory, a *theory of graded possibilities*, distinguishes grades (or degrees) of possibilities (Klir 2006). Instead of designating alternatives as possible (1) or impossible (0) in accordance with the characteristic possibility function in Eq. 12, alternatives are assigned a value on $[0, 1]$. Defined in Eq. 13, a graded possibility function maps the individual elements x in the universe X to the unit interval (Klir 2006):

$$r : X \rightarrow [0, 1] \quad (13)$$

Binary possibilities can be viewed as a special class of graded possibilities (i.e., when a particular alternative is fully possible $r_E(x) = 1$ or impossible $r_E(x) = 0$). For this reason, the term *graded* and subscript E can be omitted in the generalized possibilistic mappings. Thus, these functions are referred to as *basic possibility functions*, denoted $r(x)$ (Klir 2006).

In probability theory, probability measures (Pro) are determined by the values expressed in a probability distribution function $p(x)$. Similarly, in possibility theory, a basic possibility function $r(x)$ contains a description for each *singleton* (or individual element) that expresses the *possibility measure*, here denoted $\text{Pos}(A)$. A possibility measure is determined for a given event A by the following formula (Klir and Yuan 1995):

$$\text{Pos}(A) = \max_{x \in A} [r(x)] \quad (14)$$

where $A \in P(X)$, and $P(X)$ denotes the power set of X (the collection or group of all possible subsets).

Possibility theory assumes a reordering of the subsets of a possibility function such that the evidence is decreasing. This is expressed symbolically as $r(x_i) \geq r(x_{i+1})$. Reordered singletons can be aggregated into subsets A_n as follows:

A_1	x_1
A_2	$x_1 \cup x_2$
A_3	$x_1 \cup x_2 \cup x_3$
A_4	$x_1 \cup x_2 \cup x_3 \cup x_4$
$\vdots$	$\vdots$
A_n	$x_1 \cup x_2 \cup x_3 \cup x_4 \dots x_n$

Thus, the evidence from this reordering is such that $A_1 \subset A_2 \subset A_3 \subset \dots \subset A_n$. With this property, the sets are such that they are *nested* (Klir 2006). In the case of nested evidence, possibility measures are said to be *consonant*.

The preceding description introduces the concepts of possibility functions and possibility measures. These topics provide the foundation of a more complete measurement of evidence in

the form of dual measures of possibility and necessity.

In the context of a possibility measure, the alternatives not possible in the negation of the complement of A define a *necessity measure* $Nec(A)$. This is expressed by Eq. 15 (Klir and Yuan 1995).

$$Nec(A) = 1 - Pos(\overline{A}) \quad (15)$$

Thus, in comparison to probability theory, two measures of possibility and necessity fully characterize the uncertainty of an event A.

Similarly, possibility measures can be defined from necessity measures by Eq. 16 (Klir and Yuan 1995):

$$Pos(A) = 1 - Nec(\overline{A}) \quad (16)$$

Demonstrated in Eqs. 15 and 16, both possibility and necessity measures of A can be derived if one knows the complete possibility function (also termed a *possibility profile*).

Recall from Eq. 14, possibility measures can be determined from possibility values represented by a basic possibility function. Necessity measures do not share this property (Klir 2006). Therefore, much of the possibility calculus is defined in terms of possibility measures.

Possibility theory is based on the following mathematical properties or axioms:

$$\begin{aligned} (Pos1) \quad Pos(\emptyset) &= 0 \\ (Pos2) \quad Pos(X) &= 1 \\ (Pos3) \quad Pos(A \cup B) &= \max[Pos(A), Pos(B)] \\ &\text{for any sets } A, B \in P(X) \end{aligned} \quad (17)$$

Relating Eq. 14 and (Pos2) yields

$$Pos(X) = \max_{x \in X} [r(x)] = 1 \quad (18)$$

The relationship expressed in Eq. 18 guarantees that at least one alternative in the universe is fully possible (Klir 2006). From this, the second axiom (Pos2),

and the reordering property of elements, it is known that the first element in any ordered possibility function is always equal to unity or, mathematically, $r_1 = r(x_1) = 1$. This is the property of *possibilistic normalization* (Klir 2006).

Possibility theory is distinguished from probability theory by the third axiom (Pos3), the max-min requirement. Dubois and Prade (1988) suggest that the interpretation of the third axiom follows an intuitive notion of possibility. Achieving what is possible in $A \cup B$ realizes the lesser of what is possible for either A or B.

From (Eq. 17), it can be shown that possibility and necessity measures satisfy the following inequalities (Klir 2006):

$$\begin{aligned} Pos(A) + Pos(\overline{A}) &\geq 1 \\ Nec(A) + Nec(\overline{A}) &\leq 1 \end{aligned} \quad (19)$$

From Eqs. 19 and 15, it can be further shown that (Klir 2006)

$$Nec(A) \leq Pos(A) \quad (20)$$

Equation 20 states that events cannot be necessary unless they are possible (Dubois and Prade 1988). Stated another way by Zadeh (1986), necessity implies possibility.

Possibility Theory: Interpretations

There are two main perceptions of possibility theory. One view assumes an interpretation first introduced by Zadeh (1978), the *fuzzy set interpretation of possibility theory*. This interpretation will be discussed in the following section. The other interpretation sees possibility theory as a special case of evidence theory. In the latter case, possibility theory is obtained when a body of evidence in the context of evidence theory is nested (Shafer 1987). This interpretation will be discussed in more detail in section “Evidence Theory.”

As discussed by Dubois and Prade (1988), the fuzzy set interpretation of possibility theory associates a degree of possibility with how well an object corresponds to a category into which it may be placed. From this perspective, the

“categories” are crisp sets, and the associated degree of measure of a particular element expresses how well it more or less relates to a particular set of interest. Within the context of this interpretation, a possibility function (or possibility profile) is developed from information expressed in the form of a fuzzy set. This idea is represented mathematically by

$$r(x) = \mu_{\underline{A}}(x) \quad (21)$$

In this expression, $\underline{A}$ is a fuzzy set on a universe X , and the membership function $\mu_{\underline{A}}(x)$ (interpreted as the degree of membership of an element x in the fuzzy set $\underline{A}$) assigns a grade or degree of “possibility,” $r(x)$, that the element x is $\underline{A}$. Thus, the fuzzy set interpretation of possibility theory provides a mathematical framework linking the concepts of fuzzy sets with formal possibility measures.

Evidence Theory

Evidence Theory: Historical Perspective

In the mid-1960s Dempster introduced work in the area of statistical inference founded on the idea of upper and lower probabilities (Dempster 1967; Shafer 1976). Roughly a decade later, Shafer related Dempster’s work to the uncertain expressions of judgments and introduced his own developments (Shafer 1976). In his work, Shafer presented a *theory of evidence* in which *belief functions* could be formalized, arising not necessarily from bounded probabilities, but from a degree of belief based on available evidence (Shafer 1976). Shafer retitled Dempster’s original notions of upper and lower probabilities *beliefs* and *plausibilities* (Yager and Liu 2008). As the works became known to the artificial intelligence community, the theory fell under the name of the Dempster-Shafer Theory (DST) of evidence or, commonly, *evidence theory* (Shafer 2012).

Evidence theory is based on a measure of degree of belief, called a *belief measure* (Shafer 1976).

Belief measures (also commonly referred to as belief functions) aim to generalize the well-known interpretation of subjective probability theory – i.e., the Bayesian probability for a subjective measure of uncertainty – to a broader concept of “evidence.” Like possibility and necessity measures, evidence theory is developed from dual measures of belief and plausibility (Klir and Yuan 1995). These measures express “beliefs” or judgments formulated by available evidence (Yager and Liu 2008). Although Dempster’s original works were closely linked to classical probability theory, there are some significant distinctions between classical probability theory and evidence theory.

Importantly, evidence theory differentiates between lack of belief or evidence and disbelief (Shafer 1987). That is, evidence theory explicitly recognizes ignorance. Secondly, partial information in evidence theory can be expressed on sets, rather than information defined on single elements (i.e., singletons) (Yager and Liu 2008). In this case, evidence can be allocated to a set of “events,” without specifying how the evidence is distributed to the individual elements themselves (Dubois and Prade 1988). These concepts present a versatile framework for treating uncertainty within the realm of evidence theory.

Evidence Theory: Mathematical Overview

Belief Measures

A belief measure, denoted $\text{Bel}(A)$, expresses the degree of support or evidence (i.e., a degree of belief) that a particular element belongs to the set A (Klir and Yuan 1995). Formally, a belief measure is a function defined by

$$\text{Bel} : P(X) \rightarrow [0, 1] \quad (22)$$

In the context of evidence theory, the universal set X is commonly referred to as a *frame of discernment* or more simply as a *frame* (Shafer 1976).

Belief functions are based on the following axioms (Klir 2006):

$$(Bel1) \text{ Bel}(\emptyset) = 0$$

$$(Bel2) \text{ Bel}(X) = 1$$

$$(Bel3) \text{ Bel}(A_1 \cup A_2 \cup \dots \cup A_n) \geq \sum_i \text{ Bel}(A_i) - \sum_{i < j} \text{ Bel}(A_i \cap A_j) + \dots + (-1)^{n+1} \text{ Bel}(A_1 \cap A_2 \cap \dots \cap A_n) \quad (23)$$

for all integers, n , and all possible subsets $A_1, A_2, \dots, A_n$, of x .

Like possibility theory, belief measures replace additivity with a weaker requirement. The inequality in Eq. 23, (Bel3), requires that the union of the sets be greater than or equal to the sum of the degrees of belief of each individual set (Klir 2006). When $A_1, A_2, \dots, A_n$ are pairwise disjoint, ($A_i \cap A_j = \emptyset$) and (Bel3) becomes

$$(Bel3) \text{ Bel}(A_1 \cup A_2 \cup \dots \cup A_n) \geq \text{ Bel}(A_1) + \text{ Bel}(A_2) + \dots \text{ Bel}(A_n) \quad (24)$$

Rewritten for two sets, A and B , where $A \cap B = \emptyset$:

$$(Bel3) \text{ Bel}(A \cup B) \geq \text{ Bel}(A) + \text{ Bel}(B) \quad (25)$$

The axioms in Eq. 23 are motivated by the rule for combining evidence in evidence theory, referred to as *Dempster's rule of combination* (Shafer 1976). This rule is formally introduced later in section “[Dempster's Rule of Combination](#).”

Plausibility Measures

As mentioned previously, evidence theory is based on dual pairs of belief and plausibility measures. Plausibility measures can be defined through evidence expressed in the form of a belief measure or they can be defined independently. Defined in the context of a belief measure, plausibility measures, denoted $Pl(A)$, express the amount of belief not committed to $\bar{A}$ (Yager and Liu 2008):

$$Pl(A) = 1 - \text{ Bel}(\bar{A}) \quad (26)$$

Equation 26 can be understood as follows: for beliefs not committed to $\bar{A}$ (the contrary of A), evidence theory does not automatically commit evidence to A . It recognizes, however, that A may be more plausible from this evidence (Yager and Liu 2008). Summarized by Shafer (1987), the quantities denoted by $\text{ Bel}(A)$ and $Pl(A)$ express respectively, “our judgment of the extent to which the evidence we are considering supports A and our judgment of the extent to which this evidence falls short of refuting A ” (Shafer 1987, p. 62). Similar to Eq. 26, as dual measures, belief measures can be related to plausibility measures via the following equation (Klir 2006):

$$\text{ Bel}(A) = 1 - Pl(\bar{A}) \quad (27)$$

Alternatively, a plausibility measure can be defined independent of one's belief by a functional mapping on the unit interval given by

$$Pl : P(X) \rightarrow [0, 1] \quad (28)$$

The value assigned to $Pl(A)$ characterizes total evidence that is possible or “plausible.” Notice in Eqs. 22 and 28 that belief and plausibility measures are defined on the power set $P(X)$. They therefore can represent evidence for a collection of elements.

Due to the inequality of the third axiom (Bel3), it can be shown that possibility and necessity measures are characterized by (Klir 2006)

$$\begin{aligned} \text{ Bel}(A) + \text{ Bel}(\bar{A}) &\leq 1 \\ Pl(A) + Pl(\bar{A}) &\geq 1 \end{aligned} \quad (29)$$

Equation 29 describes the possibility that the belief measure for some set A combined with the belief measure of $\bar{A}$ may be less than 1 (unity). Conversely, plausibility measures are characterized by evidence for A and $\bar{A}$ which, when combined, may be greater than 1(unity).

Equations 26 and 29 yield the following relationship between beliefs and plausibilities (Klir and Yuan 1995):

$$Pl(A) \geq Bel(A) \quad (30)$$

This relationship expresses the idea that a measure of plausibility for the set A is at least as great as the belief committed to the set (Ross 2010). Mathematically, the plausibility measure $Pl(A)$ represents not only the evidence represented by the belief $Bel(A)$ but also the evidence associated with any sets that overlap with A . Hence, at a minimum, the plausibility will be as strong as indicated by a belief (Yager and Liu 2008).

As demonstrated by Eq. 27, a degree of belief in or evidential support of A , $Bel(A)$, does not implicate disbelief of A – expressed by $Bel(\bar{A})$ (Shafer 1976). Conversely, Eq. 26 shows that a positive value of $Pl(A)$ does not necessarily imply the belief that there is evidence in support of A . For this reason, evidence theory differs from classical probability theory in that it provides a natural framework for modeling ignorance (Shafer 1976).

If there is limited evidence available for A and no evidence available for $\bar{A}$, then the amount of ignorance is large (Ross 2010). Total ignorance, the special case where $Bel(A) = 0$ and $Pl(A) = 1$, is characterized by evidence that neither supports nor refutes A (Shafer 1987). *Vacuous belief functions* are those belief functions defined by complete ignorance (Shafer 1976). Conversely, in the special case of complete evidence (zero ignorance) such that the sum of the belief and the complement of the belief equal unity, the belief measure is a probability measure.

Basic Evidence Assignments

Information within the context of evidence theory is often expressed in terms of a *basic evidence assignment*, denoted by $m(A)$ (Ross 2010). Other literature have used the terms basic probability assignments (Klir 2006), basic probability numbers (or probability masses) (Shafer 1976; Yager and Liu 2008), or basic belief assignments (or basic belief masses) (Smets 1994). The quantity, $m(A)$, represents the degree of belief that a particular element x of the universe X belongs to the set A , but does not include any evidence assigned to the subsets of A (Ross 2010). In other words, the basic evidence assignment, $m(A)$,

expresses a degree of evidence in support of exactly A . Every set in which $m(A) > 0$, where $A \in P(X)$, is called a *focal element*, so named because the evidence focuses on these sets or the elements contained within them (Klir and Yuan 1995). In other words, any element of $P(X)$ supported by evidence is a focal element. If there is evidence that the element belongs to a subset of A , say B (i.e., $B \subset A$), this belief must be represented by another quantity $m(B)$ (Klir 2006).

Evidence expressed in the form of basic evidence assignments can be combined to form belief and plausibility measures using the following respective formulas (Klir and Yuan 1995):

$$Bel(A) = \sum_{B \subseteq A} m(B) \quad (31)$$

$$Pl(A) = \sum_{B \cap A \neq \emptyset} m(B) \quad (32)$$

Equations 31 and 32 effectively aggregate individual “pieces” of evidence expressed in terms of basic evidence assignments (Klir 2006). $m(A)$ and $Bel(A)$ in Eq. 31 may be related as follows: $m(A)$ expresses the amount of evidence which supports the proposition that the element in question belongs to the set A alone. A belief measure, $Bel(A)$, meanwhile is an expression of the evidence that supports A or any of the subsets of A (Klir and Yuan 1995). The quantity $Pl(A)$ is the degree of evidence that the element in question belongs to the set A , to any subset of A , or to any set that overlaps (or intersects) with A (Klir and Yuan 1995).

Dempster's Rule of Combination

Another facet of evidence theory is the ability to combine information from multiple sources (Yager and Liu 2008). The standard method for combining information from independent sources (i.e., independent bodies of evidence) in evidence theory is given by (Shafer 1976)

$$m_{1,2}(A) = \frac{\sum_{B \cap C = A} m_1(B) \cdot m_2(C)}{1 - K} \quad (33)$$

where

$$K = \sum_{B \cap C \neq \emptyset} m_1(B) \cdot m_2(C) \quad (34)$$

Equation 33 is most commonly referred to as *Dempster's rule of combination*. In this expression, A is a focal element, and m_1 and m_2 represent independent bodies of evidence in the form of basic evidence assignments. The value $m_{1,2}$ can be thought of as a joint message or a *joint evidence assignment* of the two pieces of evidence (Shafer 1987; Klir and Yuan 1995).

Dempster's rule of combination can be conceptualized as a ratio of two quantities of evidence. In the numerator, it is the evidence that supports or is in agreement with the hypothesis A. In the denominator, it is the total evidence that does not conflict among the sets, where conflict is quantified by null intersections of A and B (i.e., disjoint focal elements). As suggested by Shafer (1976), empty intersections can be thought of as information that has no commonality or is conflicting (Shafer 1976).

Special Cases of Evidence Theory

At a fundamental level, belief functions are expressions of subjective degrees of belief (Shafer 1976). In this regard, subjective probabilities can be viewed as a special case of belief measures defined on singletons. When all available evidence is defined only on individual elements, belief and plausibility measures become probability measures (proof in Klir 2006). The evidence may therefore be described probabilistically (Ross 2010). Shafer (1976) refers to this special class of belief functions as *Bayesian Belief Functions*.

In the context of possibility theory, when a body of evidence is nested, that is, a body of evidence is defined by $A_1 \subset A_2 \subset A_3 \subset \dots \subset A_n$, belief and plausibility measures become necessity and possibility measures (Klir 2006). Accordingly, possibility measures are consonant plausibility functions, a special case of belief and plausibility measures (Shafer 1987). For nested bodies of evidence, it can be shown that

plausibilities reduce to the axioms of possibility measures (Klir and Yuan 1995):

$$Pl(A \cup B) = \max[Pl(A), Pl(B)] \text{ for all } A, B \in P(X) \quad (35)$$

Equation 35 shows the close connections between belief functions and possibility measures (Shafer 1987).

Evidence Theory: Interpretations

Evidence theory allows for the imprecise representation of data. Evidence can be assigned to a set of alternatives without specifying how the evidence is distributed to individual elements. This introduces a mathematical alternative for manipulating subjective information that can distinguish between lack of belief and disbelief (Shafer 1976). Unlike probability theory, evidence theory does not presuppose beliefs about the negation of an event through beliefs assigned to a given proposition. Hence, evidence theory can capture ignorance explicitly (Ross 2010). Shafer (1976) suggests this is of particular importance in the case of a set of possibilities that contains several events. As shown, special cases of belief and plausibility measures become probability and possibility/necessity measures. Evidence theory, however, is also applicable independent of other theories (Smets 1994; Yager and Liu 2008).

Within evidence theory, Dempster's rule of combination presents a unique mathematical framework for combining evidence from distinct sources (Smets 1994). Dempster's rule of combination intuitively combines evidence so that the combination of two beliefs – both supporting A – yields more support than either piece of evidence alone (Shafer 1987).

Types of Uncertainty

Sections “Probability Theory,” “Possibility Theory,” and “Evidence Theory” demonstrate that the formulations of other uncertainty theories were motivated by acknowledgment of different

forms of uncertainty. From these theories, distinct types of uncertainty commonly termed *conflict* and *nonspecificity* are identified (Klir and Yuan 1995).

Conflict is a form of uncertainty associated with classical probability theory. Probability theory expresses evidence in the form of a probability distribution, which distributes evidential assignments over multiple values. The probability assigned to any given element, however, is evidence that “conflicts” with the evidence assigned to other elements contained in the distribution (Klir and Smith 2001). In other words, evidence defined for some element x_i in the form of a probability distribution conflicts with evidence that supports other elements, the probabilities assigned to other elements, such as x_j and x_k . Similarly, the probability in support of the elements x_j and x_k indicates less support for the element x_i . These elements are in competition with one another so to speak, and hence, the form of uncertainty characterized by classical probability theory is commonly referred to as *conflict* (Klir and Smith 2001).

Possibility theory possesses a type of uncertainty called *nonspecificity* (Klir and Smith 2001). This uncertainty is concerned with information contained in sets of possible alternatives (predictions, diagnoses, etc.), “unspecific” to any particular alternative. In this regard, large sets are less specific (greater nonspecificity), while small sets are more specific (less nonspecificity). Because evidence is nested in possibility theory, it does not conflict (Klir and Smith 2001; Klir 2006). Possibility theory is therefore free of conflict, while probability theory is free of nonspecificity. As discussed in Section “Evidence Theory,” evidence theory has direct mathematical connections to both probability theory and possibility theory. As such, evidence theory can express both types of uncertainty (Klir and Smith 2001).

Summary

Broadly, different uncertainty theories expand the mathematical framework of conventional

methods and tools characterized by probability theory. There are mathematical and interpretational connections among the theories, but each theory differs fundamentally in its modeling of uncertain situations. Each theory is distinguished by its mathematical properties or axioms. From this basis, different uncertainty theories offer varying mathematical properties in the treatment of uncertainty, including (i) information at the set and subset levels, and (ii) incorporation of the other notions of uncertainty (e.g., ignorance) (Klir 2006).

There are multiple well-established interpretations of the various uncertainty theories. Instinctively, dual pairs of possibility/necessity and belief/plausibility measures are a mechanism for representing imprecise probabilities. This may be well suited for uncertainty that arises from partial “evidence” or a lack of information. This is separate from the uncertainty that may result from a random process or information modeled as purely probabilistic in nature (Smets 1994).

Building; Change detection; Multi-temporal images; Remote sensing; SAR; Satellite; Urban area

Introduction

Urban areas grow and change rapidly in various parts of the world, and hence, monitoring and modeling of urban areas have become increasingly important. Regular and up-to-date information on urban changes is required for city planning, disaster management, environmental impact assessment, and appropriate allocation of services and infrastructures. Current approaches to urban monitoring generally include field surveys and interpretation of aerial photographs. Moreover, the recent advancements in remote sensing technology have made satellite imagery an efficient tool for collecting urban area's information. Compared with optical sensors, synthetic aperture radar (SAR) does not suffer from the limitation of sunlight and weather conditions. In addition, side-looking observation scheme of SAR is useful to assess the heights and exterior walls conditions of buildings and other structures. SAR images obtained from very-high-resolution (VHR) satellites, e.g., TerraSAR-X and COSMO-SkyMed, are especially useful for urban modeling and change detection as well as for damage mapping after disasters. These VHR SAR satellites are only recent vintages, but the imagery acquired has been used in various fields. In this entry, a basic method of urban change monitoring using multi-temporal SAR imagery data is introduced and several examples are presented.

Method of Change Detection from Multi-temporal SAR Intensity Images

SAR is one of the most powerful tools for monitoring changes in the earth's surface. SAR systems are capable of recording both the amplitude and phase of backscattering echoes from the objects on the earth's surface. SAR interferometric analyses using phase information successfully provided relative ground displacements due to earthquakes (Massonnet et al. 1993) and due to land subsidence in normal time (Bayuaji et al. 2010). Although SAR interferometry has

high sensitivity for gradual changes such as land subsidence and volcano's inflation, it is difficult to apply to sudden changes in urban areas such as new construction and demolition of buildings. Thus, SAR intensity (amplitude) data are often used to assess changes in urban built environment with low coherence (Yonezawa and Takeuchi 2001; Matsuoka and Yamazaki 2004).

SAR intensity data acquired and processed in digital number (DN) are often converted to a physical quantity called the backscattering coefficient (σ_0) measured in decibel (dB) units. After this conversion, an adaptive filter (e.g., Lee 1980) is usually applied to original SAR images to reduce speckle noise, which makes the radiometric and textural aspects less efficient, and to improve the correlation coefficient between the two images.

Figure 1 shows an example of two-temporal TerraSAR-X backscattering coefficient images covering Tokyo, Japan. Both images were taken by HH polarization and from the descending path with 42.82° incidence angle at the center. Since they were taken in the stripmap mode, the azimuth resolution was about 3.3 m and the ground range resolution was about 1.2 m. After the enhanced ellipsoid correction (EEC), the two images were transformed into 1.25 m/pixel.

If two-temporal SAR intensity images for the same location in the same radar incidence conditions exist, the simplest comparison is the color composite of the two images. The color composite approach can be used for up to three-temporal images by assigning red (R), green (G), and blue (B) colors for the three images, respectively. If the color composite shows a gray color (between white and black), it means no change in backscatter among them. On the contrary, if the color composite exhibits a dominant color, it indicates a stronger backscatter for that colored SAR image. By this method, changes in buildings and structures in urban areas can be visually observed.

Figure 2 shows a close-up of the TerraSAR-X images of Toyosu district, shown in the upper square in Fig. 1. In the figure, cyan (blue + green)

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 1 Two-temporal TerraSAR-X backscattering coefficient images acquired on (a) 24 May 2008 and (b) 24 November 2009, covering Tokyo, Japan. They were taken by HH polarization in stripmap mode, from the descending path

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 2 Close-up of two TerraSAR-X images for Toyosu district in Fig. 1 and their color composite. Red color is assigned for the image (a) 24 May 2008 and

blue and green colors for the image (b) 24 November 2009 in the color composite image (c). Cyan (blue + green) color in (c) shows new structures and red demolished ones during this period

color shows new structures, such as bridges and buildings, and red color shows demolished ones during the 1.5 years period.

The change detection from two-temporal SAR intensity images can be evaluated

quantitatively by their difference value, d , and the correlation coefficient, r , by the following equations:

$$d = \bar{I}a_i - \bar{I}b_i \quad (1)$$

$$r = \frac{N \sum_{i=1}^N I a_i I b_i - \sum_{i=1}^N I a_i \sum_{i=1}^N I b_i}{\sqrt{\left(N \sum_{i=1}^N I a_i^2 - \left(\sum_{i=1}^N I a_i \right)^2 \right) \cdot \left(N \sum_{i=1}^N I b_i^2 - \left(\sum_{i=1}^N I b_i \right)^2 \right)}} \quad (2)$$

where i is the pixel number, $I a_i$ and $I b_i$ are the backscattering coefficient of the second and first images, and $\bar{I a}_i$ and $\bar{I b}_i$ are the corresponding averaged values over the $N (=k \times k)$ pixels window surrounding the i -th pixel. The window size, N , may be assigned by considering the spatial resolution of the SAR images and the size of target objects to extract.

Figure 3 plots the difference and correlation coefficient images corresponding to the SAR data in Fig. 2. Change detection in a period is usually carried out using one of these two indices or using a combined index of the two. For example, Matsuoka and Yamazaki (2004, 2010) proposed a linear combination of the two indices as an empirical discriminant formula between change and no change. A similar combined index, z , was also proposed by Liu and Yamazaki (2011) as

$$z = \frac{|d|}{\max(|d|)} - c r \quad (3)$$

where $\max(|d|)$ is the maximum absolute value in the difference and c is a weighting constant of the two indices. The correlation coefficient is generally sensitive to subtle changes, and thus, it shows a low value even for a small change. On the contrary, the normalized absolute value of difference is relatively stable. Hence, in this example, the weight for difference was set as four times of that for correlation. An example of the combined index is shown in Fig. 3c. Using this plot, the threshold value for judging change or no change can be determined by comparing with optical satellite or airborne images or GIS data.

By setting the threshold as $z > \mu + 2\sigma$, with the mean value μ and standard deviation σ , Fig. 4

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 3 Difference (a) and correlation coefficient (b) images corresponding to the SAR images in Fig. 2. The window size of 9×9 was used in calculation.

Combined index, z , in (c) was calculated by setting $c = 1/4$, and thus, it has the range between -0.25 to 1.25 . Possible changed areas are shown in red color (c), indicating new construction or demolition

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 4 The extracted changed areas overlapping on the QuickBird true-color image on 20 May 2008 (a), showing new construction (*positive change*) and

demolition (*negative change*). Comparison of false-color QuickBird image on 20 May 2008 (b) and WorldView-2 image on 11 May 2010 (c) for the *yellow square* in (a)

shows the extracted changed areas overlapping on a QuickBird true-color image, where new construction (positive change of d) and demolition (negative change of d) are highlighted in cyan and red colors. Comparing with close-up high-resolution optical images of similar acquisition dates, newly constructed bridges and buildings can be confirmed. However, negative changes of backscatter were observed not only for demolished building areas but also for areas which were casted by radar shadow of new buildings. Hence, the extraction of change in SAR backscatter in dense urban areas is rather complex. For more accurate evaluation of radar shadow and layover, a 3D GIS urban model is necessary.

Example for Airport Runway Construction

As another example of urban change monitoring, the progress of the expansion construction in the

Tokyo Haneda International Airport, Japan, is considered. To satisfy increasing demand of domestic and international passengers, the fourth runway, named the D-runway, was constructed in the Haneda Airport on the Tokyo Bay. Figure 5 shows aerial photographs of the D-runway's construction site, showing the stage of construction. The new D-runway is composed of two parts: floating steel-jacket platforms (lower left in each photo) and land reclamation (lower right in each photo).

Three-temporal TerraSAR-X images taken in different dates in 2008 and 2009 are shown in Fig. 6 to monitor the D-runway's construction stage in the Haneda Airport. In these images, the construction stages of the new runway by combining steel-jacket platforms and land reclamation can be clearly observed. The color composite of the three SAR images highlights new constructions, such as the D-runway, the connection bridge, and the new international terminal building. Since the new runway was built on the

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 5 Aerial photographs of the D-runway's construction site in the Tokyo Haneda International airport. In the photos of four dates, the lower left is floating steel-jacket platforms and the lower right is reclaimed

land. These two parts constitute the new D-runway. This new runway is connected to the existing part of the airport by the connection bridge (Haneda Airport Construction Office 2010)

Tokyo Bay, boats used for construction are seen in different locations for each image.

At the right upper part of the three TSX images, a shape that is similar to the steel-jacket platforms, a part of the D-runway, could be seen. This phenomenon, known as “ambiguity,” appears as the ground objects duplication on image along range or azimuth direction (Li and Johnson 1983). Such phenomena often appear and are caused by overlapping return signals from one main pulse with multiple Doppler frequencies. Similar azimuth ambiguities were presented by Brusch et al. (2011) in automatic ship detection using TerraSAR-X images.

The difference between the first (24 May 2008) and second (11 October 2008) images and their correlation coefficient were calculated as shown in Fig. 7. The change factor, z , defined

above was also calculated and shown in the figure. Using the histogram of the factor z , the positive and negative changed areas were extracted. Compared with the aerial photographs, the extracted results were found to be reasonable.

Example for Tsunami Damage to Building Exterior Walls

The Mw 9.0 Tohoku earthquake occurred on 11 March 2011, off the Pacific coast of northeastern (Tohoku) Japan, caused gigantic tsunamis, resulting in widespread devastation. Typical building damage in the 2011 Tohoku earthquake tsunami is shown in Fig. 8. It is noted that damage is concentrated to building exterior walls or lower parts, which is not the same with damage caused

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 6 Three-temporal TerraSAR-X images of construction site in the Tokyo Haneda airport. Color composite image (d) highlights the stage of new constructions.

Azimuth ambiguities, which duplicate the real steel-jacket platforms, can be observed in the *blue square* of each image in the sea

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 7 Difference (a) and correlation coefficient (b) images corresponding to the first (24 May 2008) and second (11 October 2008) SAR images in Fig. 6.

Combined index z was calculated in (c), where high z values correspond to the new runway under construction and ships

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 8 Typical tsunami damage to reinforced concrete building (*left*) and steel-frame building (*right*)

observed in the 2011 Tohoku, Japan, earthquake. Damage is concentrated to the exterior walls and lower stories of buildings (Yamazaki et al. 2013)

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 9 The pre-event TSX image taken on 21 October 2010 (a), the post-event images taken on 13 March 2011 (b) and on 4 April 2011 (c), and the

TerraSAR-X's imaging area along the Pacific coast of Tohoku, Japan, including the Sendai-Shiogama Port area (d)

by strong earthquake shaking. This kind of damage to building exterior walls can be extracted with the aid of side-looking nature of SAR. The strong backscattering echoes from exterior walls and double bounce with the ground are often reduced after this type of structural damage.

SAR Data and Preprocessing

Three-temporal TerraSAR-X images taken before and after the earthquake are shown in Fig. 9. The pre-event image was taken on 21 October 2010 (local time) while the post-event ones were taken on 13 March 2011 (2 days after the

earthquake) and on 4 April 2011. The incident angle was 37.31° at the center of the images. The three images were captured with HH polarization from a descending path. The images were acquired in the stripmap mode with azimuth resolution about 3.3 m and ground range resolution about 1.2 m. The images were orthorectified multi-look corrected products (EEC) where the image distortion caused by variable terrain height was compensated by using a globally available DEM (SRTM). They have been resampled and projected to a WGS84 reference ellipsoid with a square pixel size of 1.25 m.

Two preprocessing were applied to the images. First, the three images were transformed

Urban Change Monitoring:
Multi-temporal SAR Images,

Fig. 10 Schematic figure of SAR observation for an ideal tall flat-roof building (Yamazaki et al. 2013). 3D layout (a), an actual TerraSAR-X intensity image for the central Tokyo (b), the amplitude of backscatter from an intact building (c), and the amplitude of backscatter from a damaged building due to tsunami (d)

to the backscattering coefficient (σ_0), which represents the radar reflectivity per unit area in the ground range. After the transformation, the values range between -30 and 30 dB. An enhanced Lee filter (Lopes et al. 1990) was then applied to the original SAR images to reduce the speckle noise. To minimize any loss of information included in the intensity images, the window size of the filter was set to 3×3 pixels.

It is known that large crustal movements (coseismic and post-seismic displacements) occurred in this area due to the Mw 9.0 event (Ozawa et al. 2011). The shift when the post-event TerraSAR-X images were taken compared with the pre-event one was estimated 3.11 m to the east and 0.55 m to the south in the Sendai area (Liu and Yamazaki 2013). Thus, the pre-event SAR image was manually shifted 2 pixels (2.5 m) to the east in order to match with the post-event SAR images.

SAR Backscatter Characteristics of Buildings

Backscattering echoes from buildings in VHR SAR images include the information on the three-dimensional shapes of buildings. Reconstruction of buildings from VHR SAR images were carried out by several researchers (e.g., Brunner et al. 2011). Due to the side-looking geometry of SAR sensors, the backscattering echoes of VHR SAR from a stand-alone building can be shown schematically in Fig. 10.

If a building stands alone on a flat ground, the backscatter from the building shows layover on the ground range. In a usual case, the fringe of the rooftop exhibits strong backscatter (blue arrow **d** in Fig. 10a, c) and it leans toward the direction of SAR illumination. The foot fringe of a building also exhibits strong backscatter (blue arrow **b**) due to the double bounce of radar from

the ground and the building's exterior wall. The backscatter from the building exterior wall (blue arrow **c**) together with the double-bounce component, the layover area corresponding to the building's exterior wall, is generally distinguishable in a ground range SAR intensity image. Thus, the height of the building, H , can be calculated from the length of layover area, L , as

$$H = L \tan \theta \quad (4)$$

where θ is the incidence angle of SAR. A similar geometrical relationship is obtained for a radar shadow area (area **f** behind the building corresponding to $L' + B$ with B = the building width). If the radar shadow is clearly observed as in Fig. 10b, the building height is also estimated by the length of radar shadow, L' , as

$$H = L' / \tan \theta. \quad (5)$$

In other words, if the height of a building is known, the areas of layover and radar shadow can be estimated on the ground range SAR intensity image. If the lower part of the building's exterior wall is damaged as represented in Fig. 10d, the area of layover due the exterior wall (**a** + **c**) will be reduced or the backscatter intensity of the area will get smaller. The area of radar shadow (**f**) will also become small for a damaged building.

Case Study for Sendai-Shiogama Port

The Sendai-Shiogama Port, which was severely hit by the 2011 Tohoku earthquake tsunami, was selected as a case study site of building damage detection from SAR images since there were many large buildings and warehouses damaged by the tsunami attack. Figure 11 shows aerial images of the Sendai-Shiogama Port and its surroundings after the tsunami attack. Area **A** was located within the tsunami inundation zone and area **B** outside of the zone. Thirteen (13) damaged buildings were extracted from

area **A** and thirteen non-damaged ones were selected from area **B**.

In the study, building footprints were drawn manually using the optical images. Then the layover areas were determined by shifting the rooftop frames manually. In this stage, the building heights were estimated from the buildings' cast shadow lengths (Iwasaki and Yamazaki 2011) and the ground photos in Google Street View. The backscattering coefficients within the estimated layover area for each building were extracted for the pre- and post-event SAR images, and their values were used in change detection due to the tsunami attack.

The average value of the backscattering coefficient within the layover area was calculated for the 13 damaged and 13 non-damaged buildings for the three time instants. The difference of the average values of the backscattering coefficients within the layover area of each building before and after the tsunami attack is plotted in Fig. 12 for the 13 damaged buildings (a–m) in area **A** and 13 non-damaged buildings (n–z) in area **B**. It is observed that for the damaged buildings, the average backscattering coefficient within the layover area tends to be reduced in the post-tsunami SAR images while the average value is almost unchanged for the non-damaged buildings. The 13 March 2011 image was captured only two days after the tsunami attack, and hence, the effect of debris spread on the ground might raise the backscatter there and then canceled out the effect of exterior wall damage. In the 04 April 2011 image, some debris had been cleared, but vehicles and some other objects might exist in the layover area. Due to these possibilities, the difference values are not the same for the two time intervals.

Figure 13 compares the close-up of the TerraSAR-X images and the optical images of similar acquisition dates for a damaged building c. Building c suffered from severe tsunami attack on its exterior wall and the wall was lost almost completely. Due to this damage situation, the backscatter from the exterior wall as well as the double-bounce component reduced

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 11 Aerial images of Sendai-Shiogama Port and its surroundings after the 2011 tsunami attack.

Area A within the tsunami inundation zone was severely affected and area B was located outside of the zone

significantly. From the detailed observation of damaged and non-damaged buildings at their SAR reflection side faces, the backscatter coefficient in the layover area is considered to be a good indicator to judge the damage status of building exterior walls.

Summary

The use of multi-temporal synthetic aperture radar (SAR) imagery for urban change

monitoring is presented. Basically SAR does not suffer from the limitation of sunlight and weather conditions, and thus, it has wider acquisition opportunities than optical sensors. In addition, side-looking observation scheme of SAR is useful to acquire 3D configuration of buildings and other structures. In this entry, recent applications of very-high-resolution (VHR) SAR in urban change detection and damage assessment after natural disasters were presented. To access changes in urban areas, at least two SAR images from the same acquisition conditions are

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 12 The difference of the average values of the backscattering coefficients within the layover area of each building before and after the tsunami attack for the 13 damaged buildings in area A and 13 non-damaged buildings in area B

Urban Change Monitoring: Multi-temporal SAR Images, Fig. 13 Close-up of the TerraSAR-X images at the three acquisition dates and the optical images of

similar acquisition times for damaged building c. The ground photo of SAR reflection side of the building extracted from Google Street View is also shown

necessary. The difference and correlation coefficient of the backscattering coefficients from multi-temporal SAR data are considered to be good indicators to extract changes on the earth

surface. The side-looking scheme of SAR is also useful in assessing the condition of the building's exterior wall, by comparing layover and radar shadow of multi-temporal images.

Very-Long-Period Seismicity at Active Volcanoes: Source Mechanisms

Gregory P. Waite
Department of Geological and Mining
Engineering and Sciences, Michigan
Technological University, Houghton, MI, USA

Synonyms

Very low-frequency seismicity; VLP events; VLPs

Introduction

Deformation at active volcanoes spans a wide range of frequencies, from permanent changes up to cycles of 100s of Hz. Scattering and anelasticity attenuate the high-frequency signals rapidly, making their detection difficult. The dominant range of frequencies observed with seismological methods, between about 0.5 and 5 Hz, has been well recorded for many decades, beginning with analog recordings. Studies of discrete events and longer-duration tremor in this so-called long-period (LP) band have led to significant advances in understanding of volcanological processes, but studies of events with lower frequencies have only been possible since

the use of instruments that can record them has become widespread.

Very-long-period (VLP) seismicity with frequencies below the LP band has been observed at nearly every type of active volcano, including those with activity limited to hydrothermal systems. As with LP seismicity, VLP seismicity includes both discrete events and tremor. Because VLP events involve source mechanisms that are different from those of earthquakes that occur along tectonic faults, they are referred to as VLP events, rather than VLP earthquakes. Studies of VLP events have only been possible since permanent and temporary networks of broadband seismic recording stations at active volcanoes began in the 1990s. In this comparatively short amount of time, detailed investigations of VLP events have led to great advances in understanding of the geometries of shallow magma conduits, how magma moves through these systems, and how magma and magmatic gases interact with host rocks. These interactions are manifested as deformations, which result in elastic wave propagation. When these processes have timescales of 10s of seconds to minutes, VLP seismicity can result. Because of their lower frequency nature, VLP seismicity typically represents somewhat different fluid processes than those responsible for LP events. This entry describes the observations and principal models for VLP events. It begins with a brief discussion of the instrumentation used to record VLP seismicity, with a

particular emphasis on the limitations and complications that can arise. A summary of VLP observations leads to a detailed section on modeling and interpretation.

Instrumentation

Observations of VLP events require broadband seismometers installed in quiet locations. The use of active force feedback technology in sensors allows for recordings at low frequencies without requiring an unreasonably large mass ([► Principles of Broadband Seismometry](#)). Broadband sensors in use on volcanoes have a flat response to a wide range of periods, or frequencies, typically from about 120 to 0.02 s period (0.0083–50 Hz), although the lower limit on many of these sensors is a 60 or 30 s period. These narrower band sensors are sometimes called intermediate band rather than broadband sensors. This distinction is important, as the band of the instruments used limits observations of VLP events. The lower bound of the VLP band varies therefore, depending on the capability of the recording systems.

Below the low-frequency corner of the broadband seismometer, the response typically falls off at 40 dB per decade, but strong signals with frequencies below the corner can be recovered. However, at these lower frequencies, the signals are more likely to include both ground rotation (tilt) and translation. The horizontal components of broadband seismometers are sensitive to tilt through changes in gravitational acceleration (Rodgers 1968). In fact, the broadband signal is more susceptible to tilt with increasing period so that tilt dominates translation at periods below the sensor corner if the seismometer experiences substantial rotation. Because VLP recordings are typically made in the near field, the influence of tilt at frequencies below the corner cannot be ignored. Because tilt does not affect the vertical component to a measurable degree, it can be used to help discriminate between translational and rotational motion. Recent studies have taken advantage of the tilt response to incorporate it

into modeling of VLP band volcanic signals (Chouet and Dawson 2013; Maeda et al. 2011).

The tilt-dominated signals at frequencies below the instrument corner are in what is known as the ultra-long-period or ULP band (Johnson et al. 2009). Because of the importance of the instrument on the nature of the signal (i.e., rotation versus translation), the period that separates the VLP band from the ULP band might best be defined as the low corner of the seismometer used in the recording of the signals and therefore might vary from 30 to 120 s.

At the upper end of the VLP band from about 8 to 3 s period, the ubiquitous oceanic microseismic signal typically dominates. This signal, which is primarily due to interactions between ocean waves and the near-shore ocean floor, is observed everywhere on Earth but is particularly strong at ocean islands. Therefore the upper end of the observable VLP band is, in most cases, about 8 s.

Observations of VLP Seismicity

Unlike LP events, which typically have a long-duration, narrow-band coda of 10s of seconds that includes dozens of cycles, VLP events most often include only one cycle. Notable exceptions include events recorded at Mt. Erebus (Aster et al. 2008; Rowe et al. 1998) and Kilauea (Chouet and Dawson 2013; Chouet et al. 2010). VLP event locations are difficult to determine with respect to higher-frequency events, as discussed below. Where they have been determined, depths are usually within 1 km of the surface.

Although less common, VLP seismicity can also be found in the form of long-duration tremor. As with volcanic tremor in the LP band, VLP tremor signals may last for many minutes to days. Changes in tremor amplitude have been correlated with changes in surface activity (Kaneshima et al. 1996).

While some VLP seismicity can be clearly seen on broadband recordings, the amplitudes are typically much lower than those of any associated higher-frequency signal, including the

Very-Long-Period Seismicity at Active Volcanoes: Source Mechanisms, Fig. 1 Example VLP waveforms from four volcanoes with well-studied VLP seismicity.

All data were band-pass filtered between 60 and 12 s period, except Erebus which was filtered from 30 to 15 s period

ocean microseism, so seismograms must be filtered before the VLPs are visible. Figure 1 shows examples of VLP events from four different volcanoes.

VLP events may be associated with phreatic eruptions (Kawakatsu et al. 2000), strombolian eruptions (Chouet et al. 2008), vulcanian eruptions (Chouet et al. 2005), passive effusion (Waite et al. 2008), or without any surface expression at all (Hill et al. 2002).

VLP events have been observed at volcanoes ranging from low-viscosity, low-silica systems such as Stromboli and Kilauea to intermediate composition systems such as Augustine and Popocatepetl and to more viscous, silica-rich systems, such as Mount St. Helens. Chouet and Matoza (2013) have compiled a list of studies published since 1992, to which the reader is referred for a comprehensive review.

Modeling

For typical earthquakes, the most basic type of information determined includes the time of occurrence, the location, and the size of the event. VLP events do not lend themselves to simple location and magnitude determinations, so other techniques have been developed. The key challenge involves the uncertainty in the first arrival time. Because VLP events do not have a clear, impulsive onset, the uncertainty in choosing the onset of the event may be many seconds. Since seismic waves propagate on the order of several km per second, this translates into an unacceptably large uncertainty in the location and time of the origin. Furthermore, the magnitudes determined for typical tectonic earthquakes are based on the assumption that seismicity is generated by shear on a near-planar fault.

In the case of volcanic VLP events, this is almost certainly never the case.

Fortunately, because of the low frequency of VLP events, the wavelengths are 10s to 100s of km, which simplifies the modeling of wave field propagation. The waveforms are not distorted by shallow heterogeneities between the source and recording station, although topography does have an important affect (Neuberg and Pointer 2000).

Particle Motion Methods

The simplest techniques for modeling the source location of VLP events use the mapped particle motions. Assuming that most of the motion is in the radial-vertical plane, seismic recordings made on stations surrounding the surface projection of a VLP source can be used to identify that point. This first-order approach can also be used to estimate the VLP event depth but is complicated by surface topography that can significantly distort the particle motion.

A method based on the assumption of radial particle motions, called radial semblance, involves solving for the model that minimizes particle motion out of the radial-vertical plane (Kawakatsu et al. 2000). The method requires that the seismic velocity of the medium is known, but the choice of velocity does not greatly affect the location. A more important potential problem with the method is that it assumes an isotropic source. Because VLP recordings are typically made in the near field, they can have significant components of motion out of the radial plane for source geometries such as dikes or sills.

Full-Waveform Modeling

Most studies of VLPs in recent years have employed full-waveform modeling, as long as enough seismic stations are available to constrain the source mechanism. In these studies, a point source is typically chosen, and the wave field is modeled using a finite-difference approximation approach. For VLP events, the long wavelengths simplify the modeling in two important ways. First, the structural model used for the wave field modeling can be fairly simple. Variations in the elastic parameters of rocks on the order of km can be ignored for stations within a few km of

the source and wavelengths of 10s to 100s of km. This means the velocity-density structure can be assumed to be homogeneous. Choosing the wrong velocity will introduce some error in the source location but will not significantly alter the source mechanism.

The second way in which modeling of VLP data is simplified by the long wavelengths is that source finiteness can be ignored. In studies where the wavelength is on the order of the size of the source, for example, for a 100-m-long section of the conduit, the source dimensions affect the predicted waveforms at stations in the near field. However, the wavelength of VLP events is orders of magnitude larger than the source dimension, meaning a point source approximation is appropriate.

Moment Tensor Inversion

Waveform modeling approaches rely on source representation theory; that is, that there exists a set of equivalent forces that can represent those that caused the event (“► [Long-Period Moment-Tensor Inversion: The Global CMT Project](#)”, and “► [Non-Double-Couple Earthquakes](#)”). In modeling of tectonic earthquakes, the representative forces can be described by the symmetric second-order moment tensor, which has six independent components (Fig. 2). The components of the moment tensor are nine force couples, which represent either dipole or shear couples. A purely isotropic source would involve volume change, but not shear, and could be represented by a tensor with nonzero values for the dipole components on the diagonal and a nonzero trace. The off-diagonal terms describe torque and are nonzero when there is shear. Tectonic earthquakes, which involve slip on a near-planar fault, can adequately be described with shear and no volume change (the trace of the tensor is zero as in Fig. 3). On the other hand, VLP events may involve volume changes and no shear. Figure 4 provides an example of a source commonly found in VLP inversions, that of a tensile crack, with a nonzero trace.

Advective net mass transfer gives rise to single forces in addition to the moment components. Single forces are insignificant in tectonic

Very-Long-Period Seismicity at Active Volcanoes: Source Mechanisms,

Fig. 2 Force couples representing the full moment tensor. Dipole components are on the diagonal. The off-diagonal components represent shearing force couples

Very-Long-Period Seismicity at Active Volcanoes: Source Mechanisms, Fig. 3 Example of force couples representative of slip on a fault. For simplicity, the third dimension is not shown. For x and y in the horizontal plane, this would represent a vertical strike-slip fault. Right-lateral slip on the fault normal to the y direction,

represented by (a), or left-lateral slip on the fault normal to the x direction, represented by (b), would both be represented by the pair of force couples shown in (c) and (d), which is why this is called a double-couple solution. The dimensionless symmetric moment tensor for this set of force couples is also shown in (e)

Very-Long-Period Seismicity at Active Volcanoes: Source Mechanisms,

Fig. 4 Example of force couples representative of opening of a tensile crack lying in the x - y plane and opening in the z direction. Note that this can be represented with positive dipole components

earthquake modeling but may become important for VLP events associated with eruption or transfer of a large mass of material. Large landslides and glacier movements can also produce signals that are well modeled with single force solutions. In these cases, as the mass accelerates along the surface of the Earth, the response is a single force in the direction opposite the motion of the mass movement. Later, when the mass begins to slow, the reaction force is parallel to the direction of the slide. Similarly, the reaction force to a volcanic eruption is opposite the direction of motion of the erupted mass. Single forces can arise within the Earth as well. If the center of mass of a magma volume accelerates, the force can be observed seismically as long as there is a means for it to couple to the solid earth. Specific models are addressed below.

In order to model the source mechanism, Green functions that describe the response at one location (the station) to an impulse at another (the source) are computed. The displacement field $u_n(\vec{r}, t)$, generated by a source, may be written as:

$$u_n(\vec{r}, t) = F_p(t) * G_{np}(\vec{r}, t) + M_{pq}(t) * G_{np,q}(\vec{r}, t), \quad p, q = x, y, z, \quad (1)$$

where $u_n(\vec{r}, t)$ is the n -component of the displacement at time t and receiver position $\vec{r}$, $F_p(t)$ is the time history of the force applied in the p -direction, $M_{pq}(t)$ is the time history of the

pq -component of the moment tensor, and $G_{np}(\vec{r}, t)$ is the tensor of Green functions that relates the n -component of displacement at the receiver position, $\vec{r}$, with the p -component of impulsive force at the source position. Although it is not specified in Eq. 1, $G_{np}(\vec{r}, t)$ depends on the source position as well. The q notation indicates spatial differentiation with respect to the q -coordinate, and the symbol $*$ denotes convolution. Summation over repeated indices is implied.

With the matrix of Green functions, $\mathbf{G}$, the linear inverse problem, $\mathbf{d} = \mathbf{G}\mathbf{m}$, is solved where $\mathbf{d}$ is the data vector and $\mathbf{m}$ is the model vector, which consists of moment tensor components and single forces. Each model parameter has a time history. In the most general case, the inversion is allowed to vary freely so that a new model vector is computed for each corresponding time in the data vector. An analogous approach is to compute the inversions in the frequency domain, so that one frequency at a time is solved for each moment component. Other approaches to solving the inverse problem have also been used.

Because the number of model and data parameters involved in the inversions is small, the process is computationally inexpensive. This approach does not require that the ratio of the moment components is constant throughout the source time history, but in most cases the resulting ratios are stable for most of the source time history of the event.

Although the inversion can be constrained in various ways, for example, to force the trace of

the tensor to be zero in the case of tectonic earthquakes, unconstrained inversions for VLP sources are preferred. VLP source inversions are typically dominated by the isotropic components, suggesting volume changes in conduits as the primary source of deformation. Single forces are included in inversions to account for advection-related forces. By repeating the inversion over a large volume of points (Green functions) in a grid, the preferred source centroid location is chosen as that with the lowest misfit to the data.

Typical VLP Source Models

The time history of the moment tensor and single forces representing the VLP source must be interpreted in terms of a physical model. Although the modeling assumes a point source, which represents the centroid location of moment and force, the characteristics of the moment and force components have implications for the orientation of the source components. If the ratios of the moment components are stable for the duration of the event, the eigenvectors and eigenvalues (principal components) can easily be obtained and compared with simplified geometries. Assuming the host rock surrounding the source can be represented with as a homogeneous elastic material with elastic Lamé parameters λ and μ and the volume change is ΔV , a tensile crack can be represented with dipole components having magnitudes equal to $\Delta V\lambda$ for the in-plane components and $\Delta V(\lambda + 2\mu)$ for the component that is normal to the crack plane. For igneous rocks, possibly at high temperatures given their proximity to magmatic fluids, values of λ and μ may vary over several orders of magnitude. The ratio between them, however, is limited; λ ranges from 1 to 2 times μ . The ratios of the eigenvalues of a tension crack are then between 1:1:2 and 1:1:3. For a pipe, the dipole components are $\Delta V\lambda$ for the component parallel to the pipe and $\Delta V(\lambda + \mu)$ for those perpendicular to it leading to ratios of 1:2:2 to 2:3:3. For a purely spherical source volume change, the components are equal.

In some cases the moment tensor looks very much like one of these end member physical

models. In these cases, the source can be interpreted as volume change related to inflation and/or deflation of a portion of the conduit. In other cases, the interpretation is not straightforward but may involve a combination of sources. For example, for magma flowing from a sill into a dike, one would expect the total moment to be close to the combined volume decrease in the sill $-\Delta V\lambda[1:1:(1+2\mu/\lambda)]$ and increase in the dike, which might be $\Delta V\lambda[1:(1+2\mu/\lambda):1]$.

Single forces arise from net mass advection. Acceleration of the center of mass of a fluid will produce a reaction force in the Earth. The nature of the reaction force is related to the coupling, which can be separated into shearing and normal forces. Shearing forces along the conduit walls in a direction antiparallel to the flow direction couple as frictional forces. The efficiency of this mechanism is strongly related to the magma fluid viscosity. Normal forces couple to conduit geometrical features where there is a change in the shape or orientation of the conduit. Numerical and analog laboratory experiments demonstrate the efficacy of the coupling of single forces through this mechanism. A change in conduit geometry, for example, from a sill to a dike as above, can provide a location for the coupling of pressure changes resulting from mass movements to occur. It is important to recognize that steady flow, without acceleration, will not produce observable single forces.

VLP Events and Magma Type

VLP events have been identified and modeled at volcanoes with nearly all magma types. Styles of VLP event tend to be related to the fluid viscosity, which depends on magma composition and temperature. In general, low-silica magmas, such as basalts, have low viscosity, and high-silica magmas, such as rhyolite, have higher viscosity. In addition to the temperature, the presence of dissolved volatiles and the crystal content influence viscosity as well. Because of the importance of viscosity on interpreting the source mechanisms, the description of types of VLP sources is organized by fluid type.

VLP Events at Low-Viscosity Volcanoes

The nature of eruptions at low-viscosity volcanoes is linked to the movement of exsolved gas. Because gas bubbles can ascend buoyantly through the higher-density magma relatively easily, eruptions tend to be less explosive than at volcanoes with magmas that are capable of trapping bubbles under higher pressures. Typical eruptions include bursting of bubbles at the top of the magma column, although more explosive eruptions are possible.

Bubbles grow through diffusion of volatiles out of solution and through coalescence of smaller bubbles. Bubbles also grow as they ascend due to the lower magma pressures at shallow depths. Under favorable conditions bubbles can grow to a diameter as large as the conduit, and if the gas volume is large enough, the bubble will occupy an elongated region within the conduit. As this gas slug ascends, magma must descend around it through a relatively thin film. An abrupt acceleration of the center of mass occurs where the conduit changes shape, either by changing diameter or orientation. VLP seismicity can result from these accelerations, which produce the equivalent of single forces and moments.

A well-studied laboratory analog model involves the ascent of a gas slug in a cylindrical conduit that has an abrupt change from a smaller to larger diameter (James et al. 2006). The slug accelerates slowly as it ascends through the lower portion of the conduit due to the gradual decrease in pressure of the overlying fluid. When the slug enters the upper portion of the conduit, it expands and accelerates rapidly. The mass of the gas is low so that the acceleration of the slug does not impart a significant force, but the acceleration of the gas requires a downward acceleration of the fluid. The fluid is massive enough to produce an observable force which couples to the conduit at the point where it enlarges and, to a lesser degree, through the frictional forces along the conduit wall. This model provides context for interpreting VLP events in low-viscosity magmas where gas slug ascent is common.

VLP events from Mount Erebus, Etna, Kilauea, and Stromboli are among the best-studied examples from low-viscosity volcanoes. In each case, the migrations of gas slugs have been interpreted as the source of at least some of the VLP events. In most cases the VLP events are temporally linked to explosive eruptions. At Stromboli, for example, moment tensor inversions point to the inflation and deflation of crack-like portions of the conduit to accommodate the movement of gas slugs that lead to strombolian-style eruptions (Chouet et al. 2008). VLP events associated with eruptions for separate, closely spaced vents have distinct waveform characteristics, and the source mechanisms are consistent with changes in the conduit geometry leading to each of the vents.

At Kilauea, there are also multiple styles of VLP events, all of which are associated with differential motions of gas and magma. Again, the best coupling of the forces within the magma to the solid conduit occurs at places in the conduit where the geometry changes. One feature that emerges from the modeling is the transition from a near-horizontal crack to a pipe that leads to the surface (Chouet et al. 2010). This corner is at a depth of about 1 km below the surface, about two or three times deeper than the main VLP source centroid at Stromboli. At Erebus, similar types of eruptions are associated with the ascent of a gas slug from a position 400 hundred meters below and a several hundred meters to the northwest of the active lava lake (Aster et al. 2008).

VLP Events at High-Viscosity Volcanoes

In contrast to VLP seismicity at low-viscosity volcanoes, which tend to be associated with small-scale strombolian explosions, at higher-viscosity systems, VLP events are most commonly associated with more explosive vulcanian-style eruptions. These higher-viscosity volcanoes are typically andesitic and dacitic in composition, but less silicic magmas can have high viscosities in the shallow subsurface if their crystal content is high. These larger

eruptions may eject significant masses of rock, meaning the vertical reaction force is the dominant component of the VLP source mechanism (Ohminato et al. 2006).

In other cases, the source mechanisms of VLP events associated with vulcanian-style eruptions are dominated by crack-like mechanisms associated with changes in conduit geometry or shallow (1–2 km) magma reservoirs (Chouet et al. 2005). Inflation or deflation mechanisms are not likely to involve gas slugs in these cases, since the magmas are too viscous to allow slug ascent. Instead, deflation may follow the explosion and be related to the eruption of material from the conduit. Re-inflation of the conduit can be the result of a combination of the influx of new magma and pressurization associated with rapid gas exsolution (Nishimura 2004).

VLP events in silicic systems may also be associated with the passive extrusion of magma, as in the case of Mount St. Helens (Waite et al. 2008). The VLP events were the result of unsteady flow as the magma moved from a vertical to horizontal portion of the conduit just below the surface. The mechanism included inflation and deflation of cracks and also nearly horizontal single forces. The single forces were associated with acceleration and deceleration of magma as it moved through this portion of the conduit.

VLP Events at Hydrothermal Systems

Hydrothermal cracks, filled with water, steam, or a combination of nonmagmatic fluids, may also be the source of VLP events. Unsteady flow of pressurized hydrothermal fluids through cracks (Nakamichi et al. 2009; Ohminato 2006) can produce VLP events that are very similar to those produced in magmatic systems. The low viscosity of water and steam relative to magma inhibits measureable flow-related frictional single forces, so mechanisms tend to be dominated by volume changes in cracks. At Aso volcano, nearly continuous VLP tremor is attributed to resonance in a horizontal crack (Kaneshima et al. 1996).

Long-Duration VLPs and VLP Tremor

VLP events tend to have short duration with respect to the period, having only one or two cycles. However, VLP events may have long durations indicative of a resonant source mechanism (Chouet et al. 2010; Kumagai et al. 2003; Rowe et al. 1998). Nearly continuous VLP tremor, with intermittent higher amplitudes, was recorded at Usu, but unlike Kilauea and Erebus, this signal was not associated with any observable surface activity (Yamamoto et al. 2002). In these low-viscosity systems, the ringing of the signal may be attributed to the oscillations of pressure waves, which are induced by the initial mass advection-related mechanism. At Usu, it was most likely related to unsteady flow of magma through a constricted portion of the conduit. Although VLP tremor is uncommon, it can be useful for constraining the extent of magma conduit components, as resonant properties of the signal depend on both the fluid and host rock properties and the size and shape of the resonator.

Relationship Between VLP Events and Gas Emissions

At Erebus, Kilauea, and Stromboli, VLP events are temporally linked to visual observations of explosions; the correlation is consistent with models for the VLP that involve ascent of a gas slug through the conduit to the surface. In a few cases, VLP events have been recorded coincident with high-resolution gas emission measurements. These cases provide a means for quantitative estimates of the relationship between outgassing and VLP events. At Asama (Kazahaya et al. 2011) and for certain types of VLP events at Fuego (Waite et al. 2013), the VLP event amplitudes correlate with the mass of SO₂ measured for each discrete gas emission (Fig. 5). The correlation is less clear at Etna but is present under certain conditions (Zuccarello et al. 2013). These correlations demonstrate the influence of unsteady gas flow on deformation in the shallow conduit. They can be used to infer the role of gases for VLP events even when quantitative measurements are not available.

Very-Long-Period Seismicity at Active Volcanoes: Source Mechanisms, Fig. 5 (a) Temporal correlation between VLP events (*solid line*) and SO₂ emission rate (*dots*) plotted for about 90 min on 15 January 2008 from Fuego. Masses computed for each of the six events are

listed above the SO₂ data. The *dashed line* is a weighted 50-point moving average of the SO₂ emission data. The linear regressions of SO₂ mass against seismic moment (b) show a positive correlation.

Summary

Very-long-period seismicity is usually the result of fluid transport processes in magmatic or hydrothermal systems. VLP events are most often related to inflation and deflation of elements of a conduit system, such as dikes, sills, and pipes; they tend to be dominated by isotropic elements of the moment tensor. Forces associated with mass advection can give rise to single force source components which are not found in models for typical earthquake sources. VLP events have been found in nearly every type of volcano yet they are not ubiquitous. If fluid flow is steady, there will not be large pressure fluctuations necessary to cause VLP seismicity. While their existence has only been known since the early 1990s, interpretations of VLP events have led to a far greater understanding of geometry and dynamics of fluids in shallow magmatic and hydrothermal systems.

Introduction

Structural health monitoring (SHM) relies on the repeated observation of features that are each sensitive to a certain type of structural damage. Among the many possible features, dynamic characteristics, in particular natural frequencies, are often selected as they depend on the global and the local stiffness of the structure of interest as well as its boundary conditions.

Monitoring the evolution of the features over time allows, in principle, to detect structural damage. In practice, however, this needs to be applied with care because of two reasons. Firstly, many features cannot be measured directly, but they have to be estimated from measured data using system identification techniques. Modal characteristics, for instance, can be estimated from vibration response data such as accelerations or strains, but this introduces estimation errors (Reynders et al. (2008); Reynders 2012). Secondly, nearly all features are not only sensitive to structural damage but also to changes in temperature, relative humidity, wind speed, operational loading, etc. This means that both the accuracy of the estimated features and the environmental and operational influences should be accounted for.

This entry presents a case study, where a full-sized structure has been monitored for almost a year before introducing realistic damage in a controlled way. The aim of the long-term continuous monitoring test was to quantify the environmental variability of the bridge dynamics, while the aim of the subsequent short-term progressive damage test was to investigate experimentally whether realistic damage has a measurable influence on the bridge's dynamic behavior. The combination of a long-term continuous monitoring test with realistic short-term progressive damage tests resulted in a unique data set that has aided many researchers in benchmarking new methods for system identification, operational modal analysis, damage identification, and structural health monitoring (Maeck and De Roeck 2003; Reynders and De Roeck 2009). In the next sections, the bridge and the performed tests are first described in more detail. Subsequently, the

identified modal characteristics are presented as well as their evolution during the monitoring period. Finally, results on structural health monitoring and damage identification are presented.

Description of the Structure and the Dynamic Tests

The Z24 bridge was located in the canton Bern near Solothurn, Switzerland. It was part of the road connection between the villages of Koppigen and Utzenstorf, overpassing the A1 highway between Bern and Zürich. It was a classical post-tensioned concrete two-cell box-girder bridge with a main span of 30 m and two side spans of 14 m (Fig. 1). The bridge was built as a freestanding frame with the approaches backfilled later. Both abutments consisted of triple concrete columns connected with concrete hinges to the girder. Both intermediate supports were concrete piers clamped into the girder. An extension of the bridge girder at the approaches provided a sliding slab. All supports were rotated with respect to the longitudinal axis, which yielded a skew bridge. The bridge, which dated from 1963, was demolished at the end of 1998, because a new railway adjacent to the highway required a new bridge with a larger side span.

To monitor the bridge dynamics over a 1-year time span, 16 accelerations were measured on the bridge at different points and in different directions. Every hour, a sequence of 65,536 acceleration samples, taken at the 16 sensors, was collected and stored to a hard disk after compression. The construction works at the new bridge that replaced the Z24 caused damage to one accelerometer. Although the type of accelerometer was specially designed for long-term use, some showed a considerable drift and a few of them failed during operation. Since the aim of the long-term monitoring test was to quantify the environmental variability of the bridge dynamics, all environmental variables that were considered of possible importance for the bridge dynamics have been monitored. Sensors to measure air temperature, air humidity, rain true or false, wind speed, and wind direction were installed at

the bridge, resulting in five sensors for the atmospheric conditions. A sensor consisting of two inductive loops was installed to detect the presence of vehicles on the bridge. Since temperature was known to have a key influence on the dynamics of civil engineering structures, the bridge's thermal state was monitored in detail. At the middle of the three spans, the temperature was measured at eight positions on the girder. The girder was a continuous beam with the intermediate piers clamped into it, and therefore the angular deflection of the girder at these piers and the elongation of the middle span were also measured. The soil temperature near each of the concrete columns at the approaches was monitored, as well as that near the north, central, and south parts of the intermediate piers (12 sensors in total). Finally, the temperature of the pavement was also measured at the middle of the three spans, since the drilling of the access holes for the installation of the temperature sensors on the girder revealed that the asphalt cover had a

thickness of 16–18 cm instead of the 5 cm as indicated on the blueprints.

In order for the subsequent progressive damage tests to be significant, it was made sure that they were relevant for the safety of the bridge and that the simulated damage occurred frequently, a condition that was checked in the literature and by questioning Swiss bridge owners. Since the A1 highway was never closed to traffic, some damage scenarios that meet these criteria could not be applied without reducing the safety of the traffic, which was considered of paramount importance. The traffic on the Z24 bridge was diverted to the A36 highway. Table 1 gives a complete overview of all progressive damage tests that were performed. Some of them are illustrated in Fig. 2. Before and after each applied damage scenario, the bridge was subjected to a forced and an ambient operational vibration test. With a measurement grid consisting of a regular 3×45 grid on top of the bridge deck and a 2×8 grid on each of the two pillars,

291 degrees of freedom have been measured: all displacements on the pillars and mainly vertical and lateral displacements on the bridge deck. Because the number of degrees of freedom to be measured exceeded the number of available accelerometers and acquisition channels, the data were collected in nine setups using five

Date (1998)	Scenario
4 August	Undamaged condition
9 August	Installation of pier settlement system
10 August	Lowering of pier, 20 mm
12 August	Lowering of pier, 40 mm
17 August	Lowering of pier, 80 mm
18 August	Lowering of pier, 95 mm
19 August	Lifting of pier, tilt of foundation
20 August	New reference condition
25 August	Spalling of concrete at soffit, 12 m ²
26 August	Spalling of concrete at soffit, 24 m ²
27 August	Landslide of 1 m at abutment
31 August	Failure of concrete hinge
2 September	Failure of 2 anchor heads
3 September	Failure of 4 anchor heads
7 September	Rupture of 2 out of 16 tendons
8 September	Rupture of 4 out of 16 tendons
9 September	Rupture of 6 out of 16 tendons

reference channels. The forced excitation was applied by two vertical shakers, placed on the bridge deck. A 1-kN shaker was placed on the middle span and a 0.5-kN shaker was placed at the Koppigen side span. The shaker input signals were generated using an inverse fast Fourier transform (FFT) algorithm, resulting in a fairly flat force spectrum between 3 and 30 Hz. After scenario 8, a drop weight test was also performed, using a device that allowed to drop a mass of up to 120 kg from a height of up to 1 m in a controlled way (Reynders et al. 2010). The applied shaker and drop weight forces were periodic with eight periods. A total of 65,536 samples were collected at a sampling rate of 100 Hz, using an antialiasing filter with a 30-Hz cutoff frequency.

Identification of Modal Characteristics

The ambient, shaker, and drop weight data from scenario 8 of the progressive damage test have been employed as benchmark data for system identification methods for operational modal analysis. Peeters and Ventura (2003) compare the modal parameter estimates obtained by seven different research teams in the framework of this benchmark. In addition, new modal parameter estimation techniques have been validated on the benchmark data. The best reported result was obtained by applying a subspace identification algorithm (Reynders and De Roeck 2008) and a maximum likelihood algorithm

subspace identification (Reproduced with permission from: E. Reynders et al. Fully automated (operational) modal analysis, *Mechanical Systems and Signal Processing*, 29:228–250, 2012)

(Parloo, Guillaume, and Cauberghe 2003) to the shaker data. In this way, 10 modes could be determined.

From the ambient vibration data, 6 modes can be determined with good quality (see Fig. 3). These modes are also predominantly present in the long-term monitoring data. Modes 1, 5, and 6 are vertical bending modes, while mode 2 is a lateral mode. Modes 3 and 4 are modes that show combined bending and torsion, which is caused by the skewness of the pillars with respect to the bridge deck. They have close natural frequencies and their mode shapes look similar, but in fact they show a low degree of correlation.

Peeters and De Roeck (2001) also identified the modal characteristics of the first four modes (see Fig. 3) for each of the 5,652 sets of hourly acceleration data, recorded during the continuous monitoring test. For these data, detailed mode shapes are not available due to the small number of accelerometers employed during the monitoring period. The evolution of the natural frequencies over time is plotted in Fig. 4. It can be noted in this figure that the monitoring system failed (was not active) during short periods of time.

Of all environmental variables that had been recorded, the temperature was found to have the largest influence on the modal characteristics. A plot of the natural frequencies as a static function of the temperature of the surface asphalt

layer (Fig. 4) reveals the high influence of the temperature on the bridge dynamics, as well as its nonlinear nature. The most probable explanation lies in the large temperature dependency of the Young's modulus of the asphalt layer (Peeters and De Roeck 2001).

Structural Health Monitoring by Natural Frequency Tracking

As was observed in Fig. 4, the natural frequency variations due to regular environmental and operational variability may mask the influence of even severe damage completely. Therefore, when performing damage detection by monitoring natural frequencies, it is necessary to filter out the regular environmental variability.

This can be achieved by system identification. In this approach, a mathematical model that describes the relationship between regular environmental variations and variations in natural frequencies is fitted to training data that have been collected on the undamaged structure. Afterwards, in the monitoring phase, the mathematical model is employed for predicting the natural frequencies. When the differences between these predicted values and the observed ones grow large, the structure behaves differently as during the training phase. These differences are then most probably caused by damage,

monitoring data in damaged condition (Reproduced with permission from: E. Reynders, G. Wursten, and G. De Roeck. Output-only structural health monitoring in changing environmental conditions by means of nonlinear system identification. *Structural Health Monitoring*, 13(1):82–93, 2014)

because the regular environmental variations are accounted for by the model.

Several system identification techniques have been proposed in this context (Xia et al. 2012). One of the most promising approaches is based on improved kernel principal component analysis or kPCA (Reynders et al. 2014). This approach has the advantages of (1) identifying a very general nonlinear model in a computationally cheap and robust way and (2) being output only, i.e., not requiring the measurement of the environmental and operational quantities that cause the regular variations in the modal characteristics. Figure 5 illustrates that kPCA can effectively predict the onset of damage (installation of the pier settlement system, see Table 1) by natural frequency monitoring. The predictions are better when more training data samples are used, because in this

way, the nonlinear model covers a larger portion of the regular environmental and operational variations of the natural frequencies. Alternative approaches that do need the environmental data as inputs also perform well on the present data set (see, e.g., Spiridonakos and Chatzi 2014), since a large amount of environmental variables was measured.

Damage Localization and Quantification

Modal characteristics cannot only be used for monitoring and damage detection but also for damage localization and quantification. The progressive damage test data from the Z24 bridge have served as benchmark data in this context, and Reynders and De Roeck (2009) present a

Vibration-Based Damage Identification: The Z24 Bridge Benchmark, Fig. 5 Evolution of the misfit of a nonlinear output-only model that predicts the evolution of the first four natural frequencies of the Z24 bridge. *Left*: misfit of a model trained with 3,000 data samples. *Right*: misfit of a model trained with 4,000 data samples. *Blue dots*, training data; *green triangles*, monitoring data in

undamaged condition; *red crosses*, monitoring data in damaged condition (Reproduced with permission from: E. Reynders, G. Wursten, and G. De Roeck. Vibration-Based Damage Identification: The Z24 Bridge Benchmark, Fig. 6 Relative difference in bending stiffness of the Z24 bridge deck between damage scenarios 4–6 and damage scenario 2. *Left*, local flexibility (LF) method; *right*, direct stiffness calculation (DSC) and

finite element model updating (FEMU) (Reproduced with permission from: E. Reynders and G. De Roeck. A local flexibility method for vibration-based damage localization and quantification. *Journal of Sound and Vibration*, 329(12):2367–2383, 2010)

literature review of the benchmark results reported up to 2009.

Two major approaches for damage localization and quantification can be discriminated: model based and non-model based, also called parametric and nonparametric, respectively. Parametric methods are based on a (finite element) model of the structure, some parameters of which are adjusted using vibration measurements, by minimizing the difference between

the modal characteristics computed with the model and the ones that are identified from measurements. Nonparametric methods do not need a detailed model of the structure, but most of them are based on ad hoc damage indicators with a rather limited range of application; exceptions are the damage-locating vector method of Bernal (2002) and the local flexibility method of Reynders and De Roeck (2010).

For the Z24 bridge, the linear bending and torsion stiffness of the bridge deck have been most often employed for damage localization and quantification. The pier settlement of the bridge (damage scenarios 3–6 from Table 1) is the damage case that has the largest influence on these quantities. Figure 6 shows the estimated ratio between the bending stiffness in damaged and undamaged condition, as obtained from three different damage identification methods: one non-parametric (Reynders and De Roeck 2010) and two parametric methods (Maeck et al. 2001; Teughels and De Roeck 2004). All three methods yield qualitatively similar results: a large reduction in bending stiffness around the settled pier, which is in agreement with observed crack patterns in the bridge deck. Quantitative differences are probably related to the fact that the three methods use different assumptions and strategies to aggregate the local damage over a certain zone of the structure.

Summary

Structural health monitoring (SHM) relies on the repeated observation of features that are each sensitive to a certain type of structural damage. Among the many possible features, dynamic characteristics, in particular natural frequencies, are often selected as they depend on the global and the local stiffness of the structure of interest as well as its boundary conditions. This entry presents a case study, where a full-sized structure has been monitored for almost a year before introducing realistic damage in a controlled way. The combination of a long-term continuous monitoring test with realistic short-term progressive damage tests resulted in a unique data set that has aided many researchers in benchmarking new methods for system identification, operational modal analysis, damage identification, and structural health monitoring. The bridge and the performed tests are first described in detail. Subsequently, the identified modal characteristics are presented along with their evolution during the monitoring period. Finally, recent results on structural health monitoring and damage identification, obtained with the Z24 data, are presented.

Vibrations of Beams for Seismic Response Estimation

Vittorio Gusella and Federico Cluni
Department of Civil and Environmental
Engineering, University of Perugia, Perugia, Italy

Introduction

The last decades have seen a growing interest for design and construction of tall buildings. In order to accurately estimate the dynamic response to environmental loads of such complex constructions, structural models are usually characterized by a large number of degrees of freedom; as a consequence, structural optimization algorithms, used to reduce the cost and the energy required to construct such buildings while maintaining appropriate safety levels, might be time consuming and even not feasible given the large dimension of the problem. As far as the global response is concerned, it is of interest to develop reduced models that are capable of giving approximate optimal solutions by significantly reducing the computation time. Therefore, a reduced model based on a Timoshenko beam will be presented in this paper which can be used to estimate the

response of tall buildings subjected to environmental loads, such those induced by earthquakes.

Flexural Beam Models

In the present section, the main beam models are recalled, focusing mainly on the Timoshenko model, which is able to describe the flexural behavior of the beam taking into account, besides the flexural stiffness and inertia due to deflections, also the shear deformability and the rotational inertia. Nevertheless, before introducing the Timoshenko beam model, the two models that can be considered to be the ones on which it is based, the Euler-Bernoulli and the simple shear models, will be briefly recalled.

The Cartesian reference system consists of the principal axes of the section, x and y , and the axis of the beam (the line where centroids of the sections lie), z . The beam is loaded with a distributed load $q(z)$, acting in the direction y , and a distributed moment $m(z)$ whose axis is in x direction (see Fig. 1). The analysis is limited to the plane y - z , and the only displacements of interest are those in y direction, the deflection $v(z)$. In the following, since the dependence on z is obvious, it will be dropped.

In what follows, the balance equations, which relate the loads q and m to the bending moment M and shear force V , will be used:

$$\frac{dM}{dz} = V - m \quad (1)$$

$$\frac{dV}{dz} = -q \quad (2)$$

The Euler-Bernoulli Beam

It is assumed that the deflection of the beam is due to the moment only, and therefore this behavior is known as “pure bending.” The constitutive equation which relate the bending moment M to the slope of deflection curve is

$$M = EI \frac{d\theta}{dz} \quad \text{with} \quad \theta = -\frac{dv}{dz} \quad (3)$$

Vibrations of Beams for Seismic Response Estimation, Fig. 1 Reference system of the beam model

where EI is the bending stiffness, the product of the Elastic (Young's) modulus, E , and the second moment of area (or moment of inertia) for rotation around x , I . The previous relation takes into account the fact that the sections of the beam remain plane in the deformed configuration and normal to the axis.

Using Eqs. 3 and 1, the following equation is obtained:

$$EI \frac{d^2 \theta}{dz^2} = V - m \Rightarrow -EI \frac{d^3 v}{dz^3} = V - m$$

Assuming $m = 0$, differentiating again, and using Eq. 2, the Euler-Bernoulli equation for the beam is obtained:

$$\frac{d^4 v}{dz^4} = \frac{q}{EI}$$

Moreover, the following are also valid:

$$M = -EI \frac{d^2 v}{dz^2}$$

$$V = -EI \frac{d^3 v}{dz^3}$$

The Euler-Bernoulli model can be extended to the dynamic case using the D'Alembert principle and adding to the external load q the load equivalent to inertia forces associated with deflections, q_i :

$$q_i = -\rho A \frac{\partial^2 v}{\partial t^2}$$

where ρ is the density of mass and A is the area of the section. Assuming ρ and A constant along the axis, the equation that rules the problem is

$$EI \frac{\partial^4 v}{\partial z^4} + \rho A \frac{\partial^2 v}{\partial t^2} = q$$

The free motion equation is

$$\frac{\partial^4 v}{\partial z^4} + \frac{\rho A}{EI} \frac{\partial^2 v}{\partial t^2} = 0$$

with solution that can be written through separation of variables as

$$v(z, t) = \tilde{v}(z) \cos(\omega t + \phi) \quad (4)$$

where

$$\tilde{v}(z) = D_1 \cos(kz) + D_2 \sin(kz) + D_3 \cosh(kz) + D_4 \sinh(kz)$$

and

$$k = \sqrt[4]{\frac{\omega^2 \rho A}{EI}}$$

The parameters D_1 , D_2 , D_3 , and D_4 can be obtained using the boundary conditions and determining ω to avoid the trivial solution. For example, in the case of cantilever beam clamped at $z = 0$ and free at $z = L$, the following boundary conditions hold

$$v(0,t) = 0, \quad \theta(0,t) = 0, \quad M(L,t) = 0, \quad V(L,t) = 0$$

and the values of ω are given by the following

$$\cos \sqrt[4]{\frac{\omega^2 \rho A}{EI}} L \cosh \sqrt[4]{\frac{\omega^2 \rho A}{EI}} L + 1 = 0$$

which has solutions

$$\omega_j = (a_j L)^2 \frac{1}{L^2} \sqrt{\frac{EI}{\rho A}}$$

with

$$a_1 L = 1.875, \quad a_2 L = 4.694, \quad a_3 L = 7.855, \\ a_j L \approx a_3 L + (j-3)2\pi \quad \text{for } j = 4, 5, \dots$$

The Simple Shear Beam

The simple shear beam model is based on the assumption that the beam undergoes only shear deformation. In this case, the constitutive equation which relates V to the slope of deflection curve is

$$V = GK\gamma \quad \text{with} \quad \gamma = \frac{dv}{dz} \quad (5)$$

where GK is the shear stiffness, the product of the tangential modulus, G , and shear area K . Moreover, the shear area is related to A by means of a *shear factor* κ , $K = \kappa A$, which depends on the shape of the section and is determined by means of energetic equivalence.

Using the preceding and Eq. 2, the following equation is obtained:

$$\frac{d^2 v}{dz^2} = -\frac{q}{GK}$$

In dynamics, by means of D'Alembert principle, the following equation of motion is obtained:

$$GK \frac{\partial^2 v}{\partial z^2} - \rho A \frac{\partial^2 v}{\partial t^2} = -q$$

and in free motion

$$\frac{\partial^2 v}{\partial z^2} - \frac{\rho}{GK} \frac{\partial^2 v}{\partial t^2} = 0$$

Adopting the separation of variables Eq. 4, the following expression for deflection is obtained:

$$\tilde{v}(z) = D_1 \cos(kz) + D_2 \sin(kz)$$

and

$$k = \sqrt{\frac{\omega^2 \rho}{GK}}$$

The parameters D_1 , D_2 can be obtained using the boundary conditions and determining ω to avoid the trivial solution. For example, in the case of cantilever beam clamped at $z = 0$ and free at $z = L$, the boundary conditions are

$$v(0,t) = 0, \quad V(L,t) = 0$$

and therefore

$$\omega_j = (2j-1) \frac{\pi}{2L} \sqrt{\frac{GK}{\rho}} \quad \text{for } j = 1, 2, \dots$$

The Timoshenko Beam Model

In the Timoshenko beam model (Timoshenko 1921, 1922), it is assumed that the slope of the deflection curve is the sum of those due to bending moment and those given by shear deformation, each one assumed to act alone

$$\frac{dv}{dz} = \gamma - \theta \quad (6)$$

The first part of both Eqs. 3 and 5 is unchanged, while the second parts are modified according to Eq. 6, and therefore

$$V = GK\gamma = GK \left(\frac{dv}{dz} + \theta \right), \quad M = EI \frac{d\theta}{dz}$$

Assuming EI and GK constant along the axis, the following equations are obtained:

$$\begin{cases} \text{GK} \left(\frac{d^2 v}{dz^2} + \frac{d\theta}{dz} \right) = -q \\ \text{EI} \frac{d^2 \theta}{dz^2} - \text{GK} \left(\frac{dv}{dz} + \theta \right) = -m \end{cases} \quad \begin{cases} \text{GK} \left(\frac{\partial^2 v}{\partial z^2} + \frac{\partial \theta}{\partial z} \right) - \rho A \frac{\partial^2 v}{\partial t^2} = 0 \\ \text{EI} \frac{\partial^2 \theta}{\partial z^2} - \text{GK} \left(\frac{\partial v}{\partial z} + \theta \right) - \rho I \frac{\partial^2 \theta}{\partial t^2} = 0 \end{cases}$$

In dynamics the D'Alembert principle is used again. Moreover, in the Timoshenko beam model, the inertial forces associated to rotations θ are also taken into account

$$m_i = -\rho I \frac{\partial^2 \theta}{\partial t^2}$$

and the equations of motion are therefore

$$\begin{cases} \text{GK} \left(\frac{\partial^2 v}{\partial z^2} + \frac{\partial \theta}{\partial z} \right) - \rho A \frac{\partial^2 v}{\partial t^2} = -q \\ \text{EI} \frac{\partial^2 \theta}{\partial z^2} - \text{GK} \left(\frac{\partial v}{\partial z} + \theta \right) - \rho I \frac{\partial^2 \theta}{\partial t^2} = -m \end{cases} \quad (7)$$

In free motion the following equations hold:

and considering that

$$\begin{aligned} \theta &= \gamma - \frac{\partial v}{\partial z} \Rightarrow \frac{\partial \theta}{\partial z} = \frac{\partial \gamma}{\partial z} - \frac{\partial^2 v}{\partial z^2} = \frac{1}{\text{GK}} \frac{\partial V}{\partial z} - \frac{\partial^2 v}{\partial z^2} \\ &= -\frac{\rho}{\text{GK}} \frac{\partial^2 v}{\partial t^2} - \frac{\partial^2 v}{\partial z^2} \end{aligned}$$

the following equation can be obtained:

$$\text{EI} \frac{\partial^4 v}{\partial z^4} + \rho A \frac{\partial^2 v}{\partial t^2} - \rho I \left(1 + \frac{E}{\text{GK}} \right) \frac{\partial^4 v}{\partial z^2 \partial t^2} + \frac{\rho^2 I}{\text{GK}} \frac{\partial^4 v}{\partial t^4} = 0$$

The solution is given by

$$v(z, t) = \tilde{v}(z) \cos(\omega t + \phi)$$

where

$$\tilde{v}(z) = \begin{cases} D_1 \cos(k_1 z) + D_2 \sin(k_1 z) + D_3 \cos h(k_2 z) + D_4 \sin h(k_2 z) & \omega < \omega_c \\ D_1 \cos(k_1 z) + D_2 \sin(k_1 z) + D_3 \cos(k_2 z) + D_4 \sin(k_2 z) & \omega > \omega_c \end{cases} \quad (8)$$

where ω_c is a cut-off frequency given by

$$\omega_c = \frac{\text{GK}A}{\rho I}$$

As usual, ω is found by imposing the suitable boundary conditions.

It can be interesting to plot the values of ω in terms of variation of slenderness $\lambda = L/r$ where $r = \sqrt{I/A}$, as in Fig. 2 (the values have

Vibrations of Beams for Seismic Response Estimation,

Fig. 2 Pulsations of the first (blue), second (red), and third (green) mode of cantilever beam with $\kappa = 0.85$ and $E/G = 2.6$: (—) Timoshenko beam model, (— —) Euler-Bernoulli beam model, (— · —) simple shear model

been obtained assuming $\kappa = 0.85$ and $E/G = 2.6$). It can be noted that as λ increases, the values ω of the Euler-Bernoulli model are achieved

$$\frac{\omega_j L}{\sqrt{\frac{E}{\rho \lambda^2}}} = (a_j L)^2$$

while as λ decreases the values of the simple shear model are recovered

$$\frac{\omega_j L}{\sqrt{\frac{E}{\rho \lambda^2}}} = (2j - 1) \frac{\pi}{2} \sqrt{\frac{G}{E}} \kappa \cdot \lambda$$

It is worth noting that the convergence to the Euler-Bernoulli or simple shear beam tends to slow down as mode number increases. For intermediate values of slenderness, the natural frequencies ω depend on both the bending stiffness EI and the shear stiffness GK .

Example The case of a cantilever beam with the following characteristics:

$$\begin{array}{lll} A = 0.120 \text{ mm}^2, & I = 1.60 \cdot 10^{-3} \text{ mm}^4 & K = 0.102 \text{ mm}^2 \\ E = 30,000 \text{ N/mm}^2, & G = 11,538 \text{ N/mm}^2 & \\ \rho = 2,500 \text{ kg/m}^3 & L = 2.0 \text{ m} & \omega_c = 542.43 \text{ rad/s} \end{array}$$

is considered in what follows.

The first 12 modal shapes are shown in Fig. 3, and the parameters of Eq. 8 are shown in Tables 1 and 2. In the tables also the phase velocity, defined as the ratio between the angular frequency, ω , and the wavenumber, k_1 , is reported: as well known, the phase velocity is unbounded for the Euler-Bernoulli beam, while in the case of Timoshenko beam the two different families of waves present when $\omega > \omega_c$, with wavenumbers k_1 and k_2 , tend to the following values (Hagedorn and DasGupta 2007):

$$\begin{aligned} \lim_{j \rightarrow +\infty} \frac{\omega_j}{k_1} &= \sqrt{\frac{G\kappa}{\rho}} = 62.63 \text{ rad/s} \\ \lim_{j \rightarrow +\infty} \frac{\omega_j}{k_2} &= \sqrt{\frac{E}{\rho}} = 109.54 \text{ rad/s} \end{aligned}$$

where j is the mode number.

Deterministic Excitation-Response Relations

The unit impulse applied at the section $z = z_0$ at the instant $t = t_0$ is considered:

$$f(z, t) = \delta(z - z_0) \delta(t - t_0)$$

Assuming that prior of the unit impulse application the beam is at rest with zero displacement, the response can be expressed by (Robson et al. 1971; Crandal 1979; Lin 1967; Elishakoff 1988)

$$v(z, t) = h(z, t - t_0; z_0)$$

where $h(z, t - t_0; z_0)$ is the *impulse response function* or *Green's function*. A $f(z, t)$ arbitrary space-time action can be regarded as a superposition of unit impulses at the time τ in generic section $0 \leq \xi \leq L$

$$f(z, t) = \int_{-\infty}^{+\infty} d\tau \int_0^L f(\xi, t - \tau) \delta(z - \xi) \delta(\tau) d\xi$$

If the impulse response function is known, then the response at the time t in the generic section $0 \leq \xi \leq L$ can be obtained by the following convolution integral or superposition integral:

Vibrations of Beams for Seismic Response Estimation, Fig. 3 First 12 modal shapes of the Euler-Bernoulli beam (dashed red) and Timoshenko beam (solid blue)

$$v(z,t) = \int_{-\infty}^{+\infty} d\tau \int_0^L f(\xi,t-\tau)h(z,\tau;\xi)d\xi$$

The unit complex sinusoidal action with the fixed frequency ω applied at the section $z = z_o$ is

$$f(z,t) = \delta(z-z_o)e^{i\omega t}$$

Given the *complex frequency response function* $H(z,\omega;z_o)$, the response is given by

$$v(z,t) = H(z,\omega;z_o)e^{i\omega t}$$

Let $F(z, \omega)$ be the Fourier transform of the action $f(z, t)$ which is assumed to be an integrable function, so that

$$F(z, \omega) = \int_{-\infty}^{+\infty} f(z, t) e^{-i\omega t} dt$$

and

$$f(z, t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} F(z, \omega) e^{+i\omega t} d\omega$$

The complex frequency response function is the Fourier transform of the impulse response function and

$$H(z, \omega; z_0) = \int_{-\infty}^{+\infty} h(z, \tau; z_0) e^{-i\omega \tau} d\tau$$

$$h(z, \tau; z_0) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} H(z, \omega; z_0) e^{i\omega \tau} d\omega$$

Introduced the Fourier transform of the response

$$V(z, \omega) = \int_{-\infty}^{+\infty} v(z, t) e^{-i\omega t} dt$$

$$v(z, t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} V(z, \omega) e^{+i\omega t} d\omega$$

the excitation-response relation for Fourier transform is

$$V(z, \omega) = \int_0^L H(z, \omega; \xi) F(\xi, \omega) d\xi$$

so that

$$v(z, t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} e^{i\omega t} d\omega \int_0^L H(z, \omega; \xi) d\xi \int_{-\infty}^{+\infty} f(\xi, \tau) e^{-i\omega \tau} d\tau$$

and

$$V(z, \omega) = \int_{-\infty}^{+\infty} e^{-i\omega \tau} d\tau \int_0^L h(z, \tau; \xi) d\xi \frac{1}{2\pi} \int_{-\infty}^{+\infty} F(\xi, \omega) e^{+i\omega \tau} d\omega$$

Statistical Characteristics of the Excitation

Let $f(z, t)$ be a random space-time processes. In order to describe this processes, it is introduced the *ensemble average* or *expected value*

$$E[f(z, t)] = m_f(z, t)$$

the *space-time correlation*

$$E[f(z_1, t_1) f(z_2, t_2)] = R_f(z_1, z_2, t_1, t_2)$$

and the *space-time covariance*

$$\begin{aligned} E[(f(z_1, t_1) - m_f(z_1, t_1)) (f(z_2, t_2) - m_f(z_2, t_2))] \\ = \Gamma_f(z_1, z_2, t_1, t_2) \end{aligned}$$

It is assumed that the previous characteristics are sufficient to describe the excitation.

Considering the case of weak stationary process, the mean is independent on t , and

the space-time correlation depends on $\tau = t_2 - t_1$ so that

$$\begin{aligned} E[f(z, t)] &= m_f(z) \\ E[f(z_1, t) f(z_2, t + \tau)] &= R_f(z_1, z_2, \tau) \\ E[(f(z_1, t) - m_f(z_1)) (f(z_2, t + \tau) - m_f(z_2))] &= \\ = \Gamma_f(z_1, z_2, \tau) &= R_f(z_1, z_2, \tau) - m_f(z_1) m_f(z_2) \end{aligned}$$

If $z_1 = z_2 = z$, the *autocovariance function* is obtained

$$\Gamma_f(z, \tau) = R_f(z, \tau) - m_f^2(z)$$

that for $\tau = 0$ reduces to the *variance*

$$\sigma_f^2(x) = E[f^2(z)] - m_f^2(z)$$

where $R_f(z, \tau)|_{\tau=0} = E[f^2(z)]$ is the *mean-square value*.

Let $S_f(z_1, z_2, \omega)$ be the *space-time cross-spectral density function*; this function is connected to the cross-correlation function by the *Wiener-Khintchine relations*:

$$\begin{aligned} S_f(z_1, z_2, \omega) &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} R_f(z_1, z_2, \tau) e^{-i\omega \tau} d\tau \\ R_f(z_1, z_2, \tau) &= \int_{-\infty}^{+\infty} S_f(z_1, z_2, \omega) e^{i\omega \tau} d\omega \end{aligned}$$

If $z_1 = z_2 = z$ and $\tau = 0$, the mean-square value can be expressed by the cross-spectral density function

$$E[f^2(z)] = \int_{-\infty}^{+\infty} S_f(z, z, \omega) d\omega$$

and for excitation with zero mean

$$\sigma_f^2(x) = \int_{-\infty}^{+\infty} S_f(z, z, \omega) d\omega$$

It is worth noting that earthquake-induced base accelerations are samples of non-stationary random process. Anyway, there is an interval,

called *strong motion phase*, where the base accelerations can be considered samples of stationary random process. The length of strong motion phase is T_S . It is commonly assumed that, if T_S is much greater than the period of the elementary oscillator, both the base accelerations and the response can be considered samples of stationary random process with zero mean.

Statistical Characteristics of the Response

The statistical characteristics of the response can be obtained from corresponding characteristics of the excitation by taking the averages of the previously introduced relations. The expected value of the response can be obtained by equation

$$E[v(z, t)] = E \left[\int_{-\infty}^{+\infty} d\tau \int_0^L f(\xi, t - \tau) h(z, \tau; \xi) d\xi \right]$$

and interchanging the integral operators and mean operator, the following equation is obtained:

$$E[v(z, t)] = \int_{-\infty}^{+\infty} d\tau \int_0^L E[f(\xi, t - \tau)] h(z, \tau; \xi) d\xi$$

where $E[f(z, t)]$ is the mean of the excitation. If the excitation is a stationary processes, its mean value is constant, $E[f(z, t)] = m_f(z)$, and also the mean value of the response is constant, $E[v(z, t)] = m_v(z)$, where

$$m_v(z) = \int_{-\infty}^{+\infty} d\tau \int_0^L m_f(\xi) h(z, \tau; \xi) d\xi$$

If in addition $m_f(z) = 0$, as for the seismic excitation, then $m_v(z) = 0$.

The space-time correlation function of the response is obtained by average of the product of $v(z_1, t)$ and $v(z_2, t + \tau)$, which are given by the impulse response function

$$E[v(z_1, t), v(z_2, t + \tau)] = E \left[\int_{-\infty}^{+\infty} d\theta_1 \int_0^L f(\xi_1, t - \theta_1) h(z_1, \theta_1; \xi_1) d\xi_1 \times \int_{-\infty}^{+\infty} d\theta_2 \int_0^L f(\xi_2, t + \tau - \theta_2) h(z_2, \theta_2; \xi_2) d\xi_2 \right]$$

and interchanging the integral operators and mean operator

$$E[v(z_1, t), v(z_2, t + \tau)] = \int_{-\infty}^{+\infty} d\theta_1 \int_{-\infty}^{+\infty} d\theta_2 \int_0^L d\xi_1 \times \int_0^L E[f(\xi_1, t - \theta_1) f(\xi_2, t + \tau - \theta_2)] h(z_1, \theta_1; \xi_1) h(z_2, \theta_2; \xi_2) d\xi_2$$

If the excitation is stationary, then its space-time correlation is independent of t and so is the response space-time correlation

$$R_v(z_1, z_2, \tau) = \int_{-\infty}^{+\infty} d\theta_1 \int_{-\infty}^{+\infty} d\theta_2 \int_0^L d\xi_1 \times \int_0^L R_f(\xi_1, \xi_2, \tau + \theta_1 - \theta_2) h(z_1, \theta_1; \xi_1) h(z_2, \theta_2; \xi_2) d\xi_2$$

Applying the Wiener-Khintchine relations, the space-time cross-spectral density of the response can be obtained by the following:

$$S_v(z_1, z_2, \omega) = \int_0^L d\xi_1 \int_0^L d\xi_2 \int_{-\infty}^{+\infty} h(z_1, \theta_1; \xi_1) d\theta_1 \int_{-\infty}^{+\infty} h(z_2, \theta_2; \xi_2) d\theta_2 \times \frac{1}{2\pi} \int_{-\infty}^{+\infty} R_f[\xi_1, \xi_2, \tau + \theta_1 - \theta_2] e^{-i\omega\tau} d\tau$$

Introducing in the previous integrals the unity products $e^{-i\omega\theta_1} e^{i\omega\theta_1}$ and $e^{-i\omega\theta_2} e^{i\omega\theta_2}$, by the frequency response function

$$H(z_1, -\omega; \xi_1) = \int_{-\infty}^{+\infty} h(z_1, \theta_1; \xi_1) e^{i\omega\theta_1} d\theta_1$$

$$H(z_2, \omega; \xi_2) = \int_{-\infty}^{+\infty} h(z_2, \theta_2; \xi_2) e^{-i\omega\theta_2} d\theta_2$$

and introducing the space-time cross-spectral density of the excitation,

$$S_f(\xi_1, \xi_2, \omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} R_f[\xi_1, \xi_2, \tau + \theta_1 - \theta_2] e^{-i\omega(\tau + \theta_1 - \theta_2)} d(\tau + \theta_1 - \theta_2)$$

the following expression to determine $S_v(z_1, z_2, \omega)$ is obtained:

$$S_v(z_1, z_2, \omega) = \int_0^L \int_0^L H(z_1, -\omega, \xi_1) S_f[\xi_1, \xi_2, \omega] H(z_2, \omega, \xi_2) d\xi_1 d\xi_2$$

Natural Modes and Frequencies

The dynamic proprieties of the systems can be described in terms of *natural modes*, $\tilde{v}$, and corresponding *natural frequencies*, ω . In what follows, the natural modes will be expressed in terms of both deflection, $v_j(z) = \tilde{v}(z)$, and rotation, $\theta_j(z)$, where j is the mode number. Once the natural modes have been found, the equations of motion Eq. 7 can be reduced to

$$m_j \frac{d^2 g_j}{dt^2} + k_j g_j = f_j$$

where m_j , k_j , and f_j are, respectively, the generalized mass, stiffness, and force corresponding to mode j , given by

$$\begin{cases} m_j = \int_0^L (\rho A v_j^2 + \rho I \theta_j^2) dz \\ k_j = \int_0^L \left(-EI \left(\frac{d\theta_j}{dz} \right)^2 + GK \left(\frac{d\gamma_j}{dz} \right)^2 \right) dz, \quad \text{with } k_j = \omega_j^2 m_j \\ f_j = \int_0^L (q v_j + m \theta_j) dz \end{cases} \quad (9)$$

and g_j is the j th principal coordinate. In the preceding, the following orthogonality properties of

the modes have been used (Bishop and Price 1977):

$$\begin{cases} \int_0^L (\rho A v_j v_k + \rho I \theta_j \theta_k) dz = a_{kj} \delta_{kj} \\ \int_0^L \left(-EI \frac{d\theta_j}{dz} \frac{d\theta_k}{dz} + GK \frac{d\gamma_j}{dz} \frac{d\gamma_k}{dz} \right) dz = a_{kj} \omega_k^2 \delta_{kj}, \quad \text{with } \delta_{kj} = \begin{cases} 1 & \text{if } k = j \\ 0 & \text{if } k \neq j \end{cases} \end{cases}$$

Once the g_j are known, the values of displacements are given by

$$h_j(t) = \begin{cases} 0 & t \leq 0 \\ \frac{1}{m\omega_j\sqrt{1-v_j^2}} e^{-v_j\omega_j t} \sin(\omega_j\sqrt{1-v_j^2} t) & t > 0 \end{cases}$$

$$v(z, t) = \sum_{j=1}^{\infty} v_j(z) g_j(t), \quad \theta(z, t) = \sum_{j=1}^{\infty} \theta_j(z) g_j(t) \quad \text{so that}$$

If a modal damping v_j is assumed, the equations of motion are

$$h(z, t; z_0) = \sum_{j=1}^{\infty} v_j(z) v_j(z_0) h_j(t)$$

$$m_j \frac{d^2 g_j}{dt^2} + 2v_j \sqrt{k_j m_j} \frac{dg_j}{dt} + k_j g_j = f_j$$

and using the Fourier transform relation, the complex frequency response is

that can also be written as

$$H(z, \omega; z_0) = \sum_{j=1}^{\infty} v_j(z) v_j(z_0) H_j(\omega)$$

$$\frac{d^2 g_j}{dt^2} + 2v_j \omega_j \frac{dg_j}{dt} + \omega_j^2 g_j = \frac{1}{m_j} f_j$$

where the single degree of freedom unit complex frequency response function is given by

Let $h_j(t)$ be the single degree of freedom unit impulse response function. With initial conditions $g_i = 0$ and $dg_j/dt = 0$, and assuming distributed load $q = \delta(z - z_0) \delta(t)$ and distributed moments $m = 0$, the solution is

$$H_j(\omega) = \frac{1}{m(\omega_j^2 - \omega^2 + 2v_j \omega_j \omega i)}$$

$$g_j(t; z_0) = h_j(t) v_j(z_0)$$

Inserting in the previous equations, the following expressions for space-time correlation and space-time cross-spectral density are obtained:

where

$$R_v(z_1, z_2, \tau) = \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} v_j(z_1) v_k(z_2) \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} h_j(\theta_1) h_k(\theta_2) d\theta_1 d\theta_2 \times \int_0^L \int_0^L v_j(\xi_1) v_k(\xi_2) R_f[\xi_1, \xi_2, \tau + \theta_1 - \theta_2] d\xi_1 d\xi_2 \quad (10)$$

$$S_v(z_1, z_2, \omega) = \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} v_j(z_1) v_k(z_2) H_j(-\omega) H_k(+\omega) \times \int_0^L \int_0^L v_j(\xi_1) v_k(\xi_2) S_f[\xi_1, \xi_2, \omega] d\xi_1 d\xi_2 \quad (11)$$

Application to the Beam Under Seismic Load

The concepts illustrated in the previous sections are applied to the case of the cantilever beam seen previously in the example, subjected to a seismic

load. The seismic load is modeled by means of an elastic response spectrum according to the European standard for seismic actions (Eurocode 8 2004). It has been assumed a type 1 elastic response spectrum with a ground type C, with parameters:

Vibrations of Beams for Seismic Response Estimation, Fig. 4 Elastic response spectrum according to Eurocode 8 and corresponding power spectral density function

$$\begin{aligned} a_g &= 0.355 \text{ g (Peak ground acceleration)}, & S &= 1.15 \text{ (Soil factor)} \\ T_B &= 0.20 \text{ s}, & T_C &= 0.60 \text{ s}, & T_D &= 2.00 \text{ s} \end{aligned}$$

A 5 % damping, $\nu = 0.05$, was adopted. The response spectrum in terms of pseudo-accelerations (RSA) is shown in Fig. 4a.

In order to apply what presented in previous sections, the power spectral density function, $G_{\ddot{u}_g}$, corresponding to the assumed response spectrum is needed. The method proposed in (Cacciola et al. 2004) is used. The time observing window (coincident with the strong motion phase) T_S has been set to 10s, while the cut-off frequency is $\omega_u = 150 \text{ rad/s}$ and the frequency step is $\Delta\omega = 2\pi/T_S = 0.63 \text{ rad/s}$. An iterative scheme has been used as suggested in (Cacciola 2010), and the power spectral density function obtained is shown in Fig. 4b.

The generation of a time history of base acceleration is achieved by means of superposition of N_a harmonics with random phases Φ_i as follows:

$$\ddot{u}_g(t) = \varphi(t) \sum_{i=1}^{N_a} \sqrt{2G_{\ddot{u}_g(i\Delta\omega)}\Delta\omega} \cos(i\Delta\omega t + \Phi_i)$$

where $\varphi(t)$ is the modulating function (which changes the total energy but not its distribution among the frequencies; see Fig. 4b) (Cacciola 2010):

$$\varphi(t) = \begin{cases} \left(\frac{t}{t_1}\right)^2 & \text{for } t \leq t_1 \\ 1 & \text{for } t_1 < t \leq t_2 \\ e^{-\beta(t-t_2)} & \text{for } t > t_2 \end{cases}$$

with $t_2 = t_1 + T_S$. In the present case, it was assumed $t_1 = 10\text{s}$ and $\beta = 0.3 \text{ s}^{-1}$. An example of the generated $\ddot{u}_g(t)$ is shown in Fig. 5.

The problem of the beam subjected to the base acceleration given by $\ddot{u}_g(t)$ can be solved by means of modal analysis, as formulated in Eq. 9.

In the case of seismic action represented by base accelerations $\ddot{u}_g(t)$, the external loads are

$$\begin{cases} q = -\rho A \ddot{u}_g(t) \\ m = 0 \end{cases}$$

and therefore:

$$\begin{aligned} f_j &= -\int_0^L \rho A \ddot{u}_g(t) v_j dz = -\Gamma_j \ddot{u}_g(t), \text{ with} \\ \Gamma_j &= \int_0^L \rho A v_j dz \end{aligned}$$

Once the time histories of g_j have been determined, the solution is given by

Vibrations of Beams for Seismic Response Estimation,

Fig. 5 Example of a time history of acceleration compatible to power spectral density function $G_{\ddot{u}_g}$

Vibrations of Beams for Seismic Response Estimation,

Fig. 6 Displacement at free end for base accelerations of Fig. 5

Vibrations of Beams for Seismic Response Estimation, Fig. 7 Power spectral density function of free end displacement by means of modal analysis with generated

spectrum compatible accelerograms and by means of stochastic analysis

$$v(z, t) = \sum_{j=1}^{N_p} v_j(z) g_j(t), \quad \theta(z, t) = \sum_{j=1}^{N_p} \theta_j(z) g_j(t)$$

where N_p is the number of modes considered in the solution. For example, the displacement at the free end, $v(L)$, for the base acceleration shown in Fig. 5 and assuming $N_p = 10$ (the modal contribution tends to be negligible quite rapidly) is shown in Fig. 6.

The power spectral density function of the displacement at free end, $S_v(L, L, \omega)$ is shown in Fig. 7, compared to that evaluated by mean of Eq. 11. As can be appreciated, the same results are obtained using both procedures.

Introduction

One of the primary goals of volcanology is to develop methods to forecast future eruptive activity. Good forecasts have the potential to increase the effectiveness of hazard mitigation plans, allowing well-timed evacuations or improved management of a return to exclusion zones. Volcanic earthquakes and seismicity are key datasets that form the basis for eruption forecasts. Seismometers are amongst most widely installed volcano monitoring equipment. Increased seismicity is a primary indicator of volcanic unrest, and eruptions are frequently preceded by changes in the rate, location, magnitude, and type of earthquakes. In combination with geodetic data, they can provide indications as to the volumes and locations of magma.

Earthquakes provide an insight into otherwise hidden processes occurring at volcanoes and that may have a causal link to eruptive activity, such

as edifice deformation, magma migration, and magma failure. Consequently, changes in the seismic activity at a volcano can be expected to provide information on the state of unrest, whether unrest is likely to lead to an eruption, and, if so, when. It may also in future provide information about changes in the nature of eruptive activity and the style, size, and location of impending activity.

A forecast is a probabilistic estimate of future activity based on current observations and past behavior. It needs to include aspects of timing, as well as physical attributes of the activity itself. A forecasting model quantitatively links observations to these probabilistic estimates, by applying empirical statistics or physical and theoretical considerations. But, how well do different forecasting models perform? Many evaluations of forecast performance have been undertaken retrospectively. These types of analyses are important for developing and refining methods and for identifying the action of different processes. However, the true performance of forecasts can only be fully evaluated through real-time forecasting (i.e., with forecasts issued ahead of the eruption) and rigorous testing. This approach eliminates conscious or subconscious biases due to data, model, and parameter selection.

Forecasting Eruptive Activity Using Seismicity Data

What Is a Forecast?

Although the words “forecast” and “prediction” have similar dictionary definitions, the associated connotations are different in different disciplines of geophysics. In some instances, the words are used interchangeably. For example, the US National Weather Service has a “Weather Prediction Center” which issues “Short Range Forecasts” of weather conditions (<http://www.hpc.ncep.noaa.gov/>). This topic has been heavily debated in the earthquake community. The term “prediction” has come to mean a highly specific statement about the time, location, and magnitude of a future event, generally with very narrow

confidence bounds. In contrast, a “forecast” is a more probabilistic statement, with a greater (and, perhaps, better quantified) uncertainty. It is broadly accepted that reliable and accurate earthquake “prediction” is unlikely to be a possibility, except in exceptional circumstances (Jordan et al. 2011).

In volcanology, similar distinctions have been made between more specific, shorter-term predictions and more general, longer-term forecasts (Swanson et al. 1983). In some scenarios, highly confident and precise statements about future volcanic activity may well be justifiable. However, such statements can readily be included as one end-member of a broader, probabilistic framework of eruption “forecasting” that incorporates more common, but less confident, statements (Sparks 2003). Such a probabilistic framework implies that there is an effort to more fully account for uncertainties in data, models, and system behavior, however small or large this may be. It can also accommodate and aggregate information from empirical observations, expert opinion, and physics-based models.

Eruption forecasts can be categorized on the basis of data sources and timescales (Marzocchi and Bebbington 2012). Short-term eruption forecasting is predominantly based on the observation of precursors. A precursor is an observable phenomenon that correlates with an increase in the probability of occurrence of a certain type of eruptive activity. Short-term forecasting is usually associated with timescales of hours to weeks or months before the event and is the type of information associated with evacuations. Forecasts can include aspects of timing but also eruption style, size, and location. Seismic activity is an important eruption precursor and plays a key role in short-term forecasting. Long-term forecasting uses historical and geological data to establish probability distributions for eruption frequencies, magnitudes, and styles. Although seismology may play a role, for example, in characterizing the size and location of the volcanic plumbing system, it is relatively minor compared to other considerations for long-term forecasting purposes.

Short-term forecasts use properties of monitoring data and other physical observations to determine the time-dependent probability of different types of activity. These probabilities may be based on physical models or on empirical statistics derived from observations before previous eruptions. The form in which a forecast is presented has implications for its utility and verifiability, and, as yet, there is no established standard or protocol for how a forecast is formulated. There are important differences between, for example, statements such as “the eruption will occur in x days $\pm y$ days,” which assume that current unrest will certainly lead to an eruption, and those such as “there is an $x\%$ probability of an eruption within y days,” which do not. Probabilities of different phenomena based on certain models are likely to be conditional on other imprecisely known factors, such as the probability that the volcano is currently in “unrest” or that unrest will lead to an eruption. The resulting forecasts will be associated with confidence bounds reflecting the uncertainty in the process, statistics, and underlying model. Consequently, some forecasts will be associated with narrower confidence bounds than others.

Seismic Eruption Precursors

Numerous seismic phenomena have been observed to precede eruptions and changes in eruptive activity (Chouet and Matoza 2013). These include changes in the characteristics of earthquakes and in the seismic properties of the volcanic edifice and surrounding crust (e.g., seismic velocity or anisotropy). Earthquakes can indicate deformation and failure of the volcanic edifice (produced by increased magma pressure or flank instability) and the movement of magma and other fluids in the crust. In addition, earthquakes can be generated by deformation of magma itself, providing warnings, for example, of changes in the growth and failure of lava domes. Consequently, factors including changes in the rate, location, and magnitude of earthquakes, changes in the type of earthquakes, and changes in the focal mechanisms of earthquakes might contain information about changes in probability of eruptive activity,

though it can be hard to assign a unique underlying cause.

Earthquake Types

A variety of different earthquakes are observed at volcanoes, characterized by frequency content and duration. The appearance of different types of earthquakes can be sufficient to diagnose the activation of particular physical processes.

Seismic waves from volcano-tectonic (VT) earthquakes have a sharp onset and high-frequency content and indicate brittle failure of the volcanic edifice, underlying crust, or even the magma itself (McNutt 2005). Low-frequency (LF) or long-period earthquakes have frequencies that are generally lower than for VT earthquakes, with an absence of high frequencies, and originate from the movement of magmatic or hydrothermal fluids. Volcanic tremor has frequencies similar to LF events but sustains its amplitude for longer periods of time (from minutes to days). Hybrid events have a high-frequency onset, identical to VT events, but an increased low-frequency coda more like LF events. Hybrid events have been interpreted as fluid movement following an initial brittle failure event or by the scattering of high-frequency signals during wave propagation within the edifice.

Elevated Earthquake Rates

The most common indicator of volcanic unrest is an increase in the rate of earthquakes. Volcano-tectonic earthquakes are generated by stick-slip shear motion on faults within the volcanic edifice. Each event represents an increment of brittle failure and the accumulation of damage. Increased rates of these events indicate increased rates of deformation and can result from combinations of factors including (1) an increase in the stresses driving deformation, such as increasing magma pressure or flank deformation; (2) progressive material weakening (damage) of the volcanic edifice such that deformation rates increase at a constant driving stress; (3) an increased proportion of the brittle component of deformation (i.e., the seismic to aseismic ratio); or (4) thermal activation of the hydrothermal system. Although some eruptions are preceded by years of elevated rates of seismicity, other eruptions can occur with

little or no change in seismicity. Extended periods of seismic unrest are expected in situations where there is prolonged magma accumulation, the progressive formation of a fracture pathway, or slow evolution of edificial stresses. In contrast, little seismicity is expected where a magma pathway has been preserved from a previous eruption, where magma rapidly rises from depth to the surface, or where temperature and stress conditions promote aseismic deformation. The total strain inferred from earthquakes typically represents only a very small proportion of the total deformation observed at the surface and is biased toward large, more dynamic events occurring at shallow depth. Accordingly inferences made from the earthquake seismograms or population dynamics may preserve this bias.

The simplest model for the temporal occurrence of earthquakes is a Poisson process. In this model, the average rate of earthquakes is λ , and occurrence times are random and independent. If λ is constant with time, the model is called a “homogenous Poisson process.” In the more general case that $\lambda(t)$ varies with time, the model is called a “non-homogenous Poisson process”; increases in $\lambda(t)$ for volcanic earthquakes are potential precursors to eruptive activity. For a Poisson process, the times between successive earthquakes are described by an exponential distribution, and earthquake rates (the numbers of earthquake occurring within a given time window) are described by a Poisson distribution. Aside from perhaps the very largest events, tectonic earthquake occurrence has been shown to be non-Poissonian (i.e., the variations in earthquake rate are greater than would be expected by from a Poisson process), and this is also the case for volcanic earthquakes. More realistic point process earthquake occurrence models, such as the ETAS (epidemic-type aftershock sequence) model, incorporate earthquake interaction and triggering processes on top of an underlying Poisson process. However, even outside periods of eruptive activity, volcanic seismicity is characterized by swarms and other nonstationary phenomena, resulting in variations in earthquake rate that are greater than those that can be expected from a simple earthquake triggering

model. These variations mean that it can be difficult to identify anomalous increases in the underlying earthquake rate $\lambda(t)$ especially when the background behavior is poorly characterized.

Preruptive changes in earthquake rate can take different forms. At a volcano that has been quiescent for many years, simply the occurrence of detectable earthquakes may be indicative of the resupply of magma and the approach to eruption. At volcanoes where there is ongoing seismicity, a change in the system (e.g., a switch from deformation being primarily driven by tectonic process to deformation being driven by magma pressure) may be indicated by step changes in earthquake rate. Systematic increases in earthquake rate with time are frequently reported before eruptions. Such sequences can evolve over a wide range of timescales, from hours to years, and it has been argued that they may potentially allow more direct forecasts of the timing of an eruption.

Increases in the rate of earthquakes originating within a magma body are likely to be indicative of processes including magma pressurization, increased rates of magma movement, increased flow of non-magmatic fluids or gases, or changes in the rheology of the magma. Consequently, such changes are likely to correlate with changes in the probability of an eruption or a change in eruptive behavior.

Completeness Magnitude

Identifying and quantifying changes in earthquake rates relies on accurate determination of the earthquake catalogue completeness magnitude. The completeness magnitude is a lower magnitude threshold above which all earthquakes are recorded. As the frequency-magnitude relation is exponential for small magnitudes, small changes in the completeness magnitude can lead to apparently significant changes in rate if they are unaccounted for. Changes in completeness magnitude can arise from improvements in monitoring networks, seasonal noise changes, or hypocenter migration. Completeness magnitude is also correlated with earthquake rate; at times of high earthquake rate, a greater proportion of

small magnitude earthquakes will be undetected. Correct determination of the completeness magnitude is also important before any analysis of the frequency (F) versus magnitude (m) distribution. As in the case of tectonic earthquakes, this takes the form of a Gutenberg–Richter distribution, $\log(F) = a - bm$, where a and b are model parameters related, respectively, to total event rate and the relative proportion of large and small events.

There are a range of different quantitative methods to determine the completeness magnitude for an earthquake catalogue. The three most frequently used methods are the maximum-curvature method, the goodness-of-fit test, and the b -value stability method (Mignan and Woessner 2012). These methods are all based on the assumption that the earthquake magnitudes follow a Gutenberg–Richter distribution. In scenarios where the rate (and completeness magnitude) increases with time, it is likely that these methods systematically underestimate the completeness magnitude. This results in an underestimate of the total number of events above the apparent threshold, because several small events are not detected.

Earthquake Magnitudes

Earthquake magnitude is a measure of the size of the earthquake. Magnitude is proportional to the logarithm of the amount of energy released and depends on the amount of slip and the area of the source. Larger magnitude earthquakes reflect larger amounts of energy release, greater deformation and slip, and a greater increment of brittle damage. Events of magnitude 5–6 have been recorded in volcanic areas. However, volcanic earthquake catalogues are commonly dominated by events of magnitudes 1–3. An earthquake of magnitude 2 is associated with movements of about 10 mm over a distance of 100 m (McNutt 1999). If the b -value of the frequency–magnitude distribution remains constant, increases in the maximum magnitude in a given time window reflect an increase in earthquake rate and so are a proxy measure for rate, albeit with a much greater uncertainty in $m_{\max}$ than N . A decrease in the b -value of the frequency–magnitude

distribution can also result in proportionally more large events.

The frequency–magnitude distribution of earthquakes, and in particular the seismic b -value, describes the relative proportions of large and small events. Changes in b -value have been linked to changes in stress and to changes in the populations of faults and fractures in the volcanic edifice. These observations are supported by those from laboratory experiments and the predictions of theoretical models.

Large tectonic earthquakes have also been reported as precursors to eruptions. Global studies suggest a correlation between large events and the onset of eruptions or changes in eruptive style (Schmid and Grasso 2012). Earthquakes occurring within a few fault lengths of the volcano may influence the magmatic system by a static stress transfer mechanism, directly dilating or compressing the plumbing system. These effects are also observed for “silent” earthquakes in the flanks of volcanoes such as Kilauea, Hawaii, where slip occurs too slowly to generate seismic waves but does result in a considerable static stress change. However, triggering effects have been identified over much larger distances of hundreds of kilometers. At these distances, static stress changes are small, and so any interaction is likely to be due to dynamic effects as the earthquake waves pass through the volcano. Potential mechanisms for this effect include the perturbation of the magma chamber and diffusion of pore fluids in the surrounding crust.

Hypocenter Migration

Earthquakes occur where the local deviatoric stress overcomes rock strength and friction. The stress field in a volcano is a function of tectonic and edificial stresses and magmatic and fluid-driven stresses. Consequently, earthquakes are expected to occur either where magmatic and fluid stresses are the greatest or where background stresses have already brought the edifice close to failure. In some instances, earthquake locations may be expected to indicate magma migration. There are many good examples where the location of earthquake hypocenters closely correlates with independent observations

of the location of magma, such as surface deformation signals and eruptive vents. This evidence is particularly strong at volcanoes where there is lateral migration of magma, including Krafla in Iceland and Kilauea in Hawaii. At Kilauea, the lateral migration of epicenters has been observed into one or both of the rift zones that emanate from the volcano's summit region. The most accurate locations indicate that events occur along a narrow range of depths, suggesting the unzipping of crust along a preferred stress horizon above a deeper rift-zone reservoir. In general, however, it remains unclear as to what extent earthquake hypocenters can be used to map magma migration.

Upward migration of earthquake sources might be expected to be a commonly observed precursor, mapping the movement of magma from depth to the surface. However, it is rarely reported. The absence of clear upward migrating signals may partly be explained by large uncertainties in estimates of the hypocentral location estimation, but, even in the case of well-located data, such patterns are rare. Alternatively, the breaking of the crust that occurs in the vicinity of a propagating magmatic fracture may involve fault movements that are too small to be detected at the surface; in this case, the detected volcano-tectonic seismicity may reflect how stress changes across the deforming crust and volcanic edifice induce movements of existing, larger faults. Distributed deformation is also observed on a smaller scale in laboratory tests on natural rock samples in compression, where localization on or near the final macroscopic crack that controls bulk failure or fault often occurs only at the very last minute. In the case of a volcanic eruption, the final upward migration of magma through this cloud of seismicity is often rapid and accompanied by high levels of tremor and other seismic noise. These attributes place strong constraints on the reliability, accuracy, and timeliness of any eruption forecast based on inferences of physical processes from the seismicity.

Before many eruptions, elevated rates of earthquakes occur in several discrete clusters, kilometers across, located in different parts of the edifice. This behavior has been observed at a

variety of different types of volcano including Mt Pinatubo, Mount St Helens, and Kilauea, with clusters separated by several kilometers horizontally or vertically. These different clusters may indicate distinct magma bodies, magma movement, or non-magmatic deformation processes. At volcanoes with flank instability, such as Kilauea and Mt Etna, elevated rates of earthquakes in the flank are indicative of increased rates of flank movement. These swarms can occur concurrently with seismicity associated with the magma plumbing system and have been observed to directly precede changes in eruptive activity.

Earthquake Focal Mechanisms

Earthquake focal mechanisms describe the nature of deformation at the earthquake source. Most VT earthquakes are double-couple, indicative of shear motion on a fault plane. The orientation of focal mechanism describes the stress field at the source. Rotations of the focal mechanism with time from, for example, strike-slip to reverse, have been reported before some eruptions and interpreted in terms of magma pressurization changing the orientations of the principal stresses in the vicinity of the magma body (Roman and Cashman 2006). Non-double-couple earthquakes indicate a more complex source, including tensile failure and events associated with finite volume changes, such as explosions or collapses. In Iceland, for example, such sources have been associated with tensile failure during the opening of subsurface cracks.

Factors Influencing the Characteristics of Precursory Seismicity

For magma to reach the surface along a new pathway, the magma pressure must be sufficient (1) to raise the magma to the surface against gravity, (2) to drive magma flow against the magma viscosity, and (3) to open the conduit against the crustal stress and rock strength sufficiently wide for magma flow. Patterns of precursory seismicity before any given eruption will reflect the details of the physical processes that result in that specific volcanic system satisfying these conditions. The volcanic system may

already be close to the eruptive conditions at the start of unrest, either because the system has not relaxed since the preceding eruption or because non-magmatic processes (e.g., flank movement or regional earthquakes) bring the system to this state. In this scenario, only a small amount of preeruptive magma-driven deformation may be required, with short-lived VT seismicity. After long repose times or large eruptions, or in tectonic settings that inhibit upward magma movement, greater amounts of magma-driven deformation are likely to be required before the necessary eruptive stress conditions are reached. Consequently, prolonged VT seismicity may be expected. These may be combined with changes in the statistical properties of seismicity such as changes with time in the clustering of events and their frequency–magnitude distribution.

Presence of a Preexisting Magma Pathway

Magma requires a physical through-going pathway in order to migrate from depth to the surface. The formation and opening of a pathway are generally associated with VT seismicity and so the state of any preexisting pathway influences the nature of precursory seismicity. At volcanoes where a pathway already exists, the onset of eruption, or a change in style of an ongoing eruption, may be associated with little additional deformation of the edifice. In this scenario, the deformation and seismicity that occur result from pressure changes within the magma body, leading to earthquakes in the surrounding edifice and, potentially, within the magma body itself. Depending on the rheology of the magma, these processes may be associated with seismicity resulting from brittle failure of the magma or tremor-like seismicity associated with fluid movement. Where a magma pathway does not exist before the start of unrest, the formation of a new magma pathway is expected to be associated with increased rates of VT seismicity, owing to faulting in the crust around a pressurized magma body. However, the general lack of a close correlation between the location of dikes and earthquake hypocenters suggests that the earthquakes themselves are unlikely be directly related to the formation of a magmatic pathway.

Volcanic Stress Conditions

Magma requires a sufficiently wide pathway through which to flow. For a pathway to open, magma pressure must exceed the minimum principle compressive stress. This can be achieved by an increase in magma pressure or by a reduction in the stress. Increases in magma pressure can be caused by the supply of additional magma from depth or by the vesiculation of magma, as a result of processes such as crystallization or stimulation by dynamic stress changes produced by the passage of seismic waves. Reduction in edificial stress conditions can occur by processes including flank instability, regional tectonic earthquakes, and time-dependent deformation of the edifice.

Magma Rheology

Magma composition, crystallinity, and temperature are primary factors controlling magma rheology. Magma rheology determines how readily it will flow through a pathway and how flow might generate earthquakes. Basic magma is generally hotter and less viscous than silicic magma, meaning it can flow through narrower pathways and with a lower driving pressure.

Forecasting Eruptions Using Precursory Seismic Phenomena

The previous sections have set out different types of precursory seismic phenomena and the different broad factors that influence their occurrence. However, many of these factors are poorly known at the start of unrest, and the complexity of volcanic systems mean that precursory patterns may vary considerably between eruptions. It is therefore a challenge to quantitatively link precursory behavior to probabilities of eruptive activity. Three different approaches are (1) using empirical statistics based on previous data, (2) using physics-based models, and (3) using the opinion of a group of experts. The boundaries between these approaches are indistinct, and the application of one almost certainly requires elements of the others.

Empirical Data

Probabilistic forecasts of future activity can be constructed using the empirical statistics of datasets associated with past preeruptive behavior. This methodology relies on the robust characterization and classification of precursory phenomena (both in archive datasets and in real-time monitoring data). The probability of different types of activity, within different time windows, can be determined on the basis of past correlation with one or more metrics, such as the rate of local VT earthquakes, the amplitude of tremor, or the occurrence of large magnitude regional earthquakes. The probability of an eruption can then be estimated, for example, from the number of times previous eruptions have been observed to occur when the given metrics have exceeded particular values. The confidence in the forecasts depends heavily on the quality and quantity of past data. At frequently active volcanoes with long-running monitoring programs (such as Kilauea and Mt Etna), the data are sufficient to build volcano-specific statistical models for precursory seismicity. At less frequently active volcanoes, those with less well-established monitoring programs, or those where the style of activity is changing, it is necessary to combine data with those from analogous volcanoes. This process involves a degree of subjectivity – just what are the most likely analogues, and how can the statistics be relatively weighted? Even when datasets are combined, current data archives are small and inconsistent. Regional and global initiatives to integrate monitoring datasets, and to collate historical data, will improve the basis for empirical forecasts.

Physics-Based Models

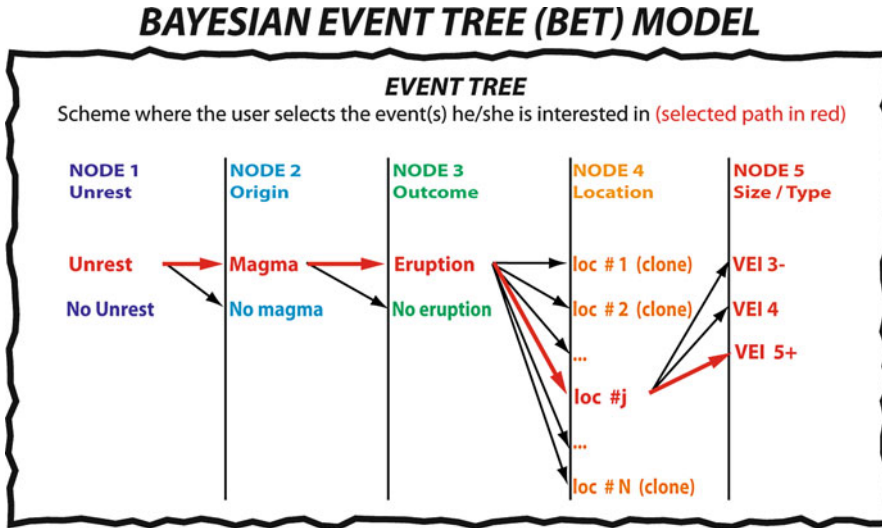

Physics-based models use an understanding of the physical process controlling the approach to eruption to quantitatively link aspects of seismic or other precursory phenomena to the properties of future eruptive activity. The biggest appeal of physics-based models is that they have the potential to be applied to eruptions at volcanoes where there is little or no archive data on which to base empirical models. The most widely applied model of this type is the material failure model,

which links rates of seismicity and deformation to the timing of eruption onset through theoretical and experimental understanding of rock mechanics, fracturing, and faulting. Additional models related to seismicity, such as earthquake focal mechanisms and the evolution and transfer of stress, also have the potential to be formulated to produce probabilistic eruption forecasts.

Expert Elicitation and Event Trees

Many monitoring datasets are too limited, and the understanding of physical processes is too incomplete, to produce completely objective eruption forecasts. In practice, the gap is bridged by expert opinion, where one or many individuals assess the likelihood of different scenarios given the empirical and physical information available. Expert elicitation can also be used to define thresholds for seismic precursor metrics that indicate likely changes in behavior (e.g., the rate of magnitude 2 and greater VT earthquakes exceeding 10 per day). Formal methodologies, such as the Delphi method, can assimilate opinions from groups of experts. These approaches may include weighting for individuals on the basis of past performance or performance on benchmark questions.

Several strategies have been developed to integrate information based on different precursory phenomena, including event trees (Sobradelo and Martí 2010; Marzocchi et al. 2008; Newhall and Hoblitt 2002) and Bayesian belief networks (Aspinall et al. 2003). Event trees provide a quantitative method to combine different forecasting approaches, including empirical statistics, the outputs of physics-based models, and expert opinion to provide probabilities of future volcanic activity. Event trees follow a hierarchical structure, with a series of increasingly specific levels mapping out all possible outcomes of unrest (Fig. 1). The probabilities at each node may be independent or may be conditional on those of preceding nodes. The probability of any given outcome can then be calculated by combining the probabilities associated with all the nodes along the path. These probabilities can be calculated using Bayesian statistics in a Bayesian framework that

Volcanic Eruptions, Real-Time Forecasting of,
Fig. 1 Bayesian event-tree scheme for forecasting volcanic eruptions (Marzocchi et al. 2008). The tree follows a

hierarchical structure, with the probability of each path being computed using the conditional probabilities of each node and, in this instance, Bayesian statistics

can account for both epistemic and aleatoric uncertainties. The event-tree approach allows many different sources of information to be combined and uncertainty to be formally quantified. It also provides a structured framework in which to consider the range of potential future activity, different eruptive scenarios, and the evidence required to distinguish between possible outcomes.

Seismic monitoring data are a primary input to event-tree forecasts. A key challenge is how to develop appropriate metrics to describe seismic characteristics and to establish the thresholds, and relative weightings, for different metrics. The record of monitoring data from volcanoes is currently too small and short to do this empirically, and instead, these values are usually provided by expert opinion.

Material Failure Models

Material failure models are physics-based forecasting methodologies that utilize the rates of preeruptive seismicity and deformation. Increasing rates of local earthquakes have been widely reported before a range of volcanic eruptions and

changes in volcanic activity. In some instances, the rate appears to increase systematically with time, leading to the development of models to describe preeruptive changes in earthquake rate and aiming to provide quantitative forecasts of the timing of eruption. In scenarios where baseline monitoring data is unavailable, or where empirical data from analogue volcanoes may not be reliable, physics-based forecasting models have the potential to provide quantitative forecasts of future activity.

The History of Material Failure Models

Several pioneering studies observed increases in rates of earthquakes and their energy release before eruptions and used these parameters to propose simple, empirical methods for forecasting the timing of eruptions. Thus, Omori (1920) and Minakami (1960) used examples from Japanese volcanoes to investigate the forecasting potential of increasing rates of occurrence of local earthquakes, or volcano-tectonic events, whereas Tokarev (1963, 1971) argued that the cumulative Benioff strain (which is proportional to the square root of the seismic energy released) followed a hyperbolic increase with time before selected andesitic eruptions in Russia and Japan.

Volcanic Eruptions, Real-Time Forecasting of,

Fig. 2 Cumulative seismic strain release rate $\dot{\Omega}$ and inverse rate $\dot{\Omega}^{-1}$ before the 12 April 1960 eruption at Bezymianny (After Voight 1988)

Voight (1988) recognized a similarity in the behavior of field precursors to eruptions and the rates of cracking monitored before the bulk failure of samples undergoing creep in the laboratory. He implicitly inferred that the similarity indicated the control of scale-independent deformation processes before larger-scale failure (from failure of a laboratory sample to breaking of the crust before an eruption) and proposed a “fundamental law for failing materials,” for which the acceleration ($\ddot{\Omega}$) and rate of change ($\dot{\Omega}$) of a precursor (Ω) are related by

$$\ddot{\Omega} = A\dot{\Omega}^\alpha$$

which describes a self-accelerating trend, such that as the rate increases, the acceleration becomes larger, increasing the rate still further; A is an empirical constant, and α , which usually lies between 1 and 2, describes the strength of the feedback relation that drives self-acceleration (Fig. 2). The limit $\alpha = 1$ corresponds to an exponential increase in rate with time,

whereas $\alpha > 1$ describes power-law increases that are faster than exponential and include a hyperbolic increase with time when $\alpha = 2$.

The power-law forms of Voight’s relation inherently define a singularity, associated with an infinite rate of occurrence of local earthquakes (and of their release of seismic energy). This singularity corresponds to an inverse-rate approaching zero and is inferred to indicate the formation of a magmatic pathway immediately before eruption. Forecasting the time of eruption therefore equates to extrapolating the precursory trend to the time at which the inverse rate becomes zero (or when the rate tends to an infinite value). In contrast, the exponential form of Voight’s relation $\alpha = 1$ does not contain a singularity and will yield the theoretical infinite rate only after an infinitely long time. In such cases, the end of the precursory sequence must be defined by an alternative threshold, such as a finite maximum rate or a maximum cumulative value for the precursor (e.g., a maximum rate or a maximum total number of local earthquakes).

Cornelius and Voight (1995) describe methods for preparing forecasts from trends with different values of α .

When first proposed, the Voight relation was presumed to apply to a range of precursors related to deformation and seismicity. The term Ω has thus been identified with ground deformation, numbers of seismic events, seismic energy release, and the amplitude of seismic signals, notably RSAM or real-time seismic amplitude measurements (Voight and Cornelius 1991). It was also assumed that accelerations in precursors followed a single trend, associated with a single value of α . However, field observations and data from rock-fracture experiments in which the applied stress increases with time (instead of the creep experiments, under constant stress, that were used to develop the original relation) show that seismic-related precursors can accelerate while the bulk deformation rate remains constant. In such cases, the Voight relation may be applicable to the seismic precursors, but not to bulk deformation. They also show that accelerations can evolve with time from exponential to faster-than-exponential trends. The selection of suitable precursors and their behavior with time may thus change according to time-dependent variations in the conditions of loading during the approach to bulk failure (Kilburn 2012).

Theoretical Underpinning of the Voight Relation: Rock Mechanics, Fracture Growth, Damage, and Lava Dome Growth/Failure

The Voight equation describes the type of self-accelerating behavior that is consistent with observations of precursors to eruptions. It also emphasizes the key role played by the rate of change a precursor, rather than the value of the precursor above a background amount. Given the strong connection of precursors to brittle failure, models to explain the Voight relation have focused on fracture or fault growth and linkage through a volcanic edifice and underlying crust. The models have adopted a broadly damage-mechanics approach and related the seismic precursors, in particular, to the behavior of a population of faults within a volume of

deforming crust that is much larger than the typical fault length (Kilburn 2003; Lengliné et al. 2008; Main 1999). Accelerating rates of earthquakes can also be interpreted in terms of rate-and-state friction acting on a population of faults (Segall 2013), and in addition, they can emerge under specific regimes within the Epidemic-Type Aftershock Sequence (ETAS) model (Amitrano and Helmstetter 2006).

All the models require the action of a time-dependent process to control rates of self-acceleration. For creep deformation under a constant applied stress, continued fracturing is associated with the weakening of rock around fracture tips. A preferred weakening mechanism is stress-enhanced chemical corrosion, in which fluids in the rock, notably water, chemically attack the silicon–oxygen bonds in the zones of high strain at the tips of fractures. For deformation under increasing stress, time dependence is provided by the bulk stress rate itself. For both loading conditions, the rate of redistribution of stress in the vicinity of growing fractures may appear as another controlling time-dependent process.

Accelerating rates of local seismicity have also been reported before changes in eruptive style at volcanoes that have already established a connection between a magma body and the surface. They are especially evident during the effusion of andesitic–dacitic lava domes, including those from Mount St Helens in the USA and Soufriere Hills on Montserrat, and appear to precede major increases in effusion rate or the sector collapse of domes. Current models suggest that the fracturing in these cases may occur as stresses increase within a feeding conduit or dike and cause cooler magma in contact with the wall rock to ascend by fracture, rather than by flow (Hammer and Neuberg 2009).

Model Application and Statistics

An important aspect of the development of forecasts on the basis of physical models is how to optimize models given observed data. Most physics-based forecasting models (including those underpinned by Voight's relation) take the

form of differential equations. Forecasts rely on estimating equation parameters and their uncertainty given some observed data and, perhaps, some prior belief. Consequently, the reliability of forecasts using this approach relies on the robustness of the methods used to estimate parameter values, as well as on the quality and quantity of the data.

Best-fit values for parameters have conventionally been estimated using least-squares regression. However, the most appropriate method for estimating parameters depends on the nature of the data and whether the data is aggregated into finite size bins. Continuous data (such as strain or tilt measurements) require different error distributions to discrete data (such as number of earthquakes per day). As a result, least-squares regression may not be a suitable method for estimating parameters. More robust estimates may instead be obtained using alternative fitting techniques, such as the generalized linear model and the maximum-likelihood method. Thus, the generalized linear model allows different error distributions to be accounted for on aggregated data and can be formulated for different simple forms of Voight's relation. In contrast, for the occurrence of discrete events (e.g., earthquake occurrence), the best model parameters can be estimated using the maximum-likelihood function (Bell et al. 2013).

Real-Time Forecasting and Testing

Neils Bohr is often quoted as saying that "prediction is difficult, especially about the future." In this context, fitting past data, i.e., with the benefit of hindsight, is always going to be much easier than fitting "future" data or indeed any data not used to formulate a hypothesis. Fitting past data is sometimes called "history matching." It is useful for developing insight into the processes at work and developing appropriate hypotheses to test, but cannot be used to assess predictability. After developing models on one dataset, the next step may be to fit a different set of past data and

see if the model still works or to break up a new dataset into two components, use the older data to forecast the younger using the same model, and then test the outcome. This is sometimes called "hind-casting" by the meteorological community. It is a step up from history matching, but it is still plagued by the fact that it is not possible to avoid biases creeping in from knowing the actual outcome, for example, retrospectively selecting a dataset containing events with a disproportional number of eventual eruptions or even in deciding what and when to publish. However hard humans try to be unbiased, it is an established fact that they cannot avoid unconscious biases of data, model, and parameter selection creeping in unconsciously. This is why medical trials are run as "double blind" tests, for which neither doctors nor patients know who is on the drug being tested and who is on the placebo. History matching and hind-casting are necessary, but not sufficient, steps in developing a forecasting model. Such testing may help rule out some models but cannot really be used to prove that a particular one will really work in true forecasting mode. The only way to test this properly is to make and test a forecast in real time, in true prospective mode, in a way that can be verified by the community. Moreover, to test a probabilistic forecast, it is also necessary to make many real-time forecasts and assess the accuracy of the outcomes for a representative statistical sample.

The Importance of Real-Time Testing: Lessons from the Earthquake and Meteorological Communities

Forecasting is used in two ways. In scientific terms, it is the "gold standard" hypothesis test and can be used to test multiple hypotheses in a manner that is as objective and unbiased a manner as possible. In practical terms, forecasting is an operational matter – when do we have enough evidence that activity is sufficient to justify some preparatory action, for example, a heightened alert or the evacuation of a vulnerable district? In the introduction, we distinguished between "forecasting" – a statement of probability – and "prediction," which has connotations with

determinism that is difficult to reconcile with what we know about the complexity, nonlinearity, and our incomplete and uncertain sampling of potential precursors to an eruption. This semantic distinction is old but important. Recently, Ken Mylne of the UK Met Office has written that “*uncertainty* is an inherent part of weather forecasting – the very word *forecast*, coined by Admiral Fitzroy, who founded the Met Office over 150 years ago, differentiates it from a *prediction* by implication of uncertainty” (our italics). This distinction has been taken up by the seismological community in the wake of the debate on earthquake predictability and was influenced by the failure of the Parkfield, California earthquake prediction experiment. Bakun et al. (2005) concluded “The 2004 Parkfield earthquake, with its lack of obvious precursors, demonstrates that reliable short-term earthquake prediction still is not achievable.”

Discussion in the earthquake seismology community has now moved on to the prospective forecasting of space, time, and magnitude-dependent probabilities for earthquake recurrence, informed by the experience in meteorology. To verify forecasting power, the forecasts are lodged in advance with, and made public by, the co-laboratory for the study of earthquake predictability (CSEP) and then tested by the community after a sufficient time has elapsed to distinguish between competing models. Models may be updated, but then they need to be re-tested by the same method. At present, this activity has concentrated on forecasting over a few months or years, where predictability is largely determined by the properties of a mixture of (spatially smoothed) random and triggered seismicity. Several hundreds of years may be needed to gauge the power of longer-term forecasts based on possible nonrandom recurrence, owing to a residual memory of past events and stress renewal. The predictability based on statistical forecasts for a potentially destructive tectonic earthquake is high in relative terms over a time-independent background rate. However, the absolute probabilities remain low at 1 % per day or less (Jordan et al. 2011). Given the much

clearer precursory signals prior to volcanic eruptions, we may expect a significantly larger predictability than this, though still well short of 100 %. At the time of writing, no similar globally coordinated forecasting experiment for testing predictability of volcanic eruptions (CSVP) has yet been constituted.

Testing Eruption Forecasting Models

The development of eruption forecasting models has usually involved retrospective application to example datasets. In many cases, these datasets have been specifically chosen to illustrate the potential viability of the model in question. However, a more systematic approach is recommended to establish the forecasting performance of a model, involving three stages of model testing and evaluation. Firstly, models are benchmarked against synthetic data. With modern computational methods, it is relatively simple to produce large numbers of realizations of synthetic earthquake or surface deformation data with some of properties that might be expected for real preeruptive sequences. For example, synthetic precursory data can be generated using the assumptions underlying the failure forecast model. The FFM can then be applied to the data as if they were real, with forecasts compared against the known input parameters. The performance of the model against these data will show a “best-case” outcome that will not be beaten in real applications. Secondly, models are validated against archive data. Datasets from past eruptions at the volcano of interest, or from analogue volcanoes, can be used for “retrospective testing.” Models are then applied as if the data were being collected in real-time, forecasts issued, and the results compared against the real observations. These tests can begin to establish true forecast uncertainty, and the extent to which the model is truly consistent with the observed data and trends. Finally, models are tested in real time on volcanic monitoring data and with forecasts issued ahead of eruptions. Such “prospective testing” establishes the true forecasting performance of different models, their relative performance, and their

performance compared to simpler null hypotheses: In this way there is no possibility for unfair selection of data or model parameters.

This approach requires formulating models to run automatically and independently, meaning that the forecasting model must be formalized and otherwise hidden sources of uncertainty are accounted for. For example, it must be determined when it is appropriate to apply any given model to data, what the model inputs and outputs are, and what are the values and uncertainties of any model constants. This approach also brings attention to questions such as: what constitutes a good forecasting performance?; and what are the most appropriate forecast metrics for both testability and utility for different potential end-users?

The Future of Eruption Forecasting

There is much that is still unknown about preeruptive processes, and so plenty of scope for improvement in eruption forecasting models. When does the inclusion of physics improve forecasting performance above simply empirical models? How can we best combine multi-parameter datasets, especially seismicity and deformation data? And can we develop reliable physical models for forecasting the style, size, and location of eruption as well as the timing? Key to answering these questions work is the establishment of consistent and well-integrated multi-parameter monitoring datasets from a wide range of volcanoes. These datasets should include information from apparently quiescent systems to establish baseline behavior; a continuous record from a single seismometer and GPS station at an otherwise unmonitored volcano would potentially provide valuable information when unrest was detected. International databases, data standards, and data sharing agreements, supported by new Informatics and computational facilities, should allow the most to be made of available data.

Forecast testing and evaluation will provide some answers to questions regarding forecast

performance and the physical processes controlling volcanic eruptions. However, these developments will also bring further challenges regarding forecast operation and outputs. It will be necessary to develop ensemble forecasting methodologies for integrating the outputs of different models and Bayesian methods for updating forecasts in real time as new data arrives. Ultimately, the aim of eruption forecasting is to help efforts to increase resilience to volcanic hazards. This will require the inclusion of potential end-users at early stages in the model development process to establish the best approach for formulating, communicating, and visualizing forecasts and their uncertainty.

Summary

Eruption forecasts are probabilistic assessments of future eruptive activity, and are important for effective mitigation of volcanic hazards. Changes in patterns of volcanic earthquakes are a key indicator of unrest, and seismic signals are one of the primary datasets used for short-term forecasting of volcanic activity. Forecasting models take information from seismic data and convert it into quantitative estimates of future activity and their uncertainty. These models can be purely empirical, based on statistics of precursory signals before previous events, or physical, based on theoretical concepts of preeruptive processes. A critical step to future improvements of forecasting methods is the development of independent real-time testing of forecasting models (i.e., before the eruption has happened).

Introduction

Introduction and Definitions

Volcano-tectonic (hereafter VT) earthquakes, sometimes also termed high-frequency (HF) earthquakes, are a category of volcanic seismic signal. They are local earthquakes that occur in a volcanic setting and possess clear impulsive *P*- and *S*-phases with energy between 1 and 20 Hz, an example of which is shown in Fig. 1.

VT earthquakes are interpreted as resulting from brittle failure or shear fracturing along a fault plane and are therefore indistinguishable from ordinary double-couple tectonic earthquakes. Since VT earthquakes possess the same characteristics as tectonic earthquakes, if they are recorded at sufficient stations, standard seismological methods and tools can be used to determine their hypocenters, magnitudes, and focal mechanisms.

The local stress field in volcanic environments is a combination of the regional tectonic stress and that produced by magmatic and hydrothermal processes. The interaction of these two components leads to the generation of VT earthquakes, which are produced by stress changes, linked to the movement of magma or other fluids.

Therefore, VT earthquakes are often linked to magmatic intrusion and are generally regarded as one of the earliest precursors to increased volcanic activity or unrest (Roman and Cashman 2006). VT earthquakes rarely follow the typical mainshock-aftershock sequence seen for tectonic earthquakes, but instead often exhibit different patterns of swarm behavior, with events clustering in time and space without a single mainshock (McNutt 2005). An increase or acceleration in the rate of VT seismicity is often associated with volcanic eruptions, and theoretical models and concepts, such as material failure, have been used to explain these trends and even to produce short-term eruption forecasts.

Magnitudes of VT earthquakes are typically small, $0 < m_b < 3$, and are rarely higher than $m_b 4.5$ (Zobin 2012), but their generally shallow depth can produce locally high intensities close to the source. The relationship between earthquake magnitude and frequency of occurrence is described by the Gutenberg-Richter frequency-magnitude relation, generally expressed by the *b*-value, where *b* is the slope of linear relationship between magnitude and number when written as $\log_{10} N = a - bM$. In tectonically active areas the *b*-value is generally close to 1.0, but in volcanic areas swarms of VT earthquakes can have much higher *b*-values, with many smaller events and fewer larger ones.

Examples

VT earthquakes can occur before and during volcanic eruptions in a variety of tectonic settings. In basaltic systems such as Piton de La Fournaise volcano, La Reunion, VT earthquakes have been used to track the migration and propagation of magma in an intruding dyke (Battaglia et al. 2005). This behavior is uncommon, however, especially at more silicic volcanoes, and VT seismicity does not usually reveal the path of magma migrating towards the surface prior to eruption. A common precursory feature appears to be the presence of distinct distal clusters of VT earthquakes away from the main volcanic vent, which often disappear with the onset of magmatic activity.

earthquake waveform showing *P*- and *S*-phases and broad amplitude spectrum. This example shows 15 s long three-component velocity seismograms from a M_L 2.8 VT

Several examples of this phenomenon have been seen preceding volcanic eruptions in recent years. Each of the last major eruptions at Augustine volcano, Alaska, was preceded by several months of increased and escalating VT seismicity. In the 8 months preceding the explosive eruption in 2006, a cluster of distal VT earthquakes occurred approximately 25 km northeast of Augustine volcano (Fisher et al. 2010). The 1990 eruption of Unzen volcano in southwest Japan was preceded by several years of VT seismicity distributed mainly more than 4 km to the west of the summit (Umakoshi et al. 2001). Two months of VT seismicity also preceded the 1991 eruption of Mount Pinatubo, Philippines. Again, the seismicity occurred in distinct clusters, at shallow depths below the summit and slightly deeper around 5 km to the northwest, with the rate of seismicity accelerating in the days before 7 June eruption. During the early stages of the eruption of Soufrière Hills volcano, Montserrat, in 1995, two main distal clusters of VT earthquakes several km northeast and northwest of the vent were also observed (Aspinall et al. 1998). These are discussed in more detail in the section “[Pre-1995 and Phase 1 VT Seismicity](#).”

Outline

This contribution comprises of a roughly chronological review of VT seismicity at Soufrière Hills volcano (hereafter SHV), Montserrat, chosen because the well-monitored and well-studied ongoing eruption of SHV offers an unparalleled example of the evolution of VT earthquakes during a long-lived multiphase dome-building volcanic eruption.

Section “[Soufrière Hills Volcano](#)” provides some background to the current eruption of SHV, before the VT seismicity is discussed in detail in the following sections. Section “[Pre-1995 and Phase 1 VT Seismicity](#)” discusses the preeruption and early-eruption seismicity, while the relationship between VT seismicity, stress changes, and magmatic intrusion throughout the eruption is examined in the section “[VT Earthquakes and Stress](#).” Some of the more recent VT seismicity at SHV is described in the section

“[Recent VT Seismicity at SHV](#),” primarily the short spasmodic bursts or swarms of VT seismicity that have been termed VT “strings.”

Soufrière Hills Volcano

Geological Background and Eruptive History

Soufrière Hills volcano is an andesitic volcano occupying the southern portion of the island of Montserrat. The 16 × 10 km island is located in the northern part of the 800 km long Lesser Antilles volcanic arc, a result of the subduction of the North American plate beneath the Caribbean plate at a convergence rate of around 2 cm/year.

Montserrat is made up of three main volcanic complexes, Silver Hills (c.2.6-1.2 Ma), Centre Hills (950–550 ka), and South Soufrière Hills-Soufrière Hills (c.170 ka – present) (Fig. 2), which get progressively younger from north to south. SHV is the youngest and only currently active volcanic center and comprises of a core of several andesitic domes, surrounded by pyroclastic aprons and other volcanic sedimentary deposits. South Soufrière Hills is the result of a short-lived period of basaltic to basaltic-andesite volcanism that occurred approximately 120 ka.

The current eruption of SHV has consisted of five phases (Fig. 3) of lava extrusion which have erupted a total of more than 1 km³ of andesite in the 18 years since 1995. These extrusive dome-building phases have alternated with distinct pauses, during which no lava was extruded but geophysical monitoring data continued to indicate unrest.

Following a period of 3 years of elevated seismic activity (see the section “[Pre-1995 and Phase 1 VT Seismicity](#)”), the eruption of SHV began on 18 July 1995, with several months of phreatic activity followed by the first dome growth in November 1995 (Young et al. 1998). The first magmatic explosion occurred in September 1996 and activity escalated through 1996 and mid- to late 1997, culminating in the destructive lateral sector collapse event on 26 December (Boxing Day) 1997 with associated blast and debris avalanche. The only known

Volcano-Tectonic Seismicity of Soufriere Hills Volcano, Montserrat, Fig. 2 Map of southern Montserrat showing SHV and other key features. The location of MVO along with two seismic stations, MBGH and MBLG, are shown. The *black star* indicates the explosion crater formed during the 11 February 2010 partial dome collapse, close to the dome summit. The topography shown is pre-collapse, with the approximate location of the 11 February 2010 collapse scar shown in *black* to the

north of the dome. The regions of the four distal clusters of VT seismicity in 1995 are shown by the *shaded ellipses*: north of St. George's Hill (Aspinall et al. 1998; Gardner and White 2002; Miller et al. 2010), beneath Windy Hill (Gardner and White 2002; Miller et al. 2010), to the NE (Gardner and White 2002), and to the WNW (Miller et al. 2010). The approximate location of the Belham Valley fault (Feuillet et al. 2010) is also marked

fatalities of the eruption occurred during this first phase of extrusion following a significant dome collapse event on 25 June 1997, whose associated pyroclastic flows and surges led to 19 deaths. Since Phase 1, several other whole or partial dome collapses have occurred throughout the eruption, notably in March 2000, July 2003 (the largest recorded collapse of $200 \times 10^6 \text{ m}^3$), and May 2006. The fifth, and most recent, phase of lava extrusion ended on 11 February 2010, with a partial collapse of the lava dome that involved $50 \times 10^6 \text{ m}^3$ of material.

The eruption has caused major social and economic disruption to the island. The former capital Plymouth and much of the island's major infrastructure were destroyed, with the southern

two-thirds of the island now a permanent exclusion zone. Many residents were forced to leave the island during the early part of the crisis, although the population has since stabilized. A 2011 census estimated the population at just below 5,000 people, slightly less than half of the preeruption population.

Seismic Crises

Prior to the activity of SHV in July 1995, unpublished evidence from radiocarbon dates of possible volcanic charcoal deposits suggests that the last eruption of SHV occurred during or just before the first European settlement of Montserrat in the early seventeenth century. In later historical times, in the century or so before the onset

Volcano-Tectonic Seismicity of Soufriere Hills Volcano, Montserrat, Fig. 3 Daily numbers of VT earthquakes recorded at SHV, Montserrat, from 1995 to present. Earthquake counts from the analogue network are shown in *black* and those from the MVO digital

broadband network in *blue*. The five extrusive phases are shown in *pink*, with pauses in extrusion in *green*. *Yellow* indicates the initial phreatic phase in 1995, and the *dark-pink* periods are subsequent transitional, precursory, or phreatic phases

of the current eruption, there were several volcanic seismic crises on Montserrat, recurring at approximately 30-year intervals. There is very little record of the first in 1897–1898, but more is known of the second, which occurred between 1933 and 1937. Several thousand felt earthquakes were reported, including a large tectonic (i.e., nonvolcanic) earthquake on 10 November 1935, followed by many aftershocks (Perret 1939). As a result of the Royal Society of London expedition to Montserrat to investigate the activity, Powell (1938) established a seismic network of up to eight stations, which operated until 1951. The locations of around 200 local volcanic earthquakes were reported between May 1937 and May 1938, showing several spatial clusters, notably at shallow depths below Soufrière Hills and St. George's Hill to the northwest (Fig. 2). The seismic crisis in 1966–1967 is also well documented. Following felt earthquake reports in early 1966, four seismic stations were installed by the Seismic Research Unit (SRU), Trinidad, and recorded over 700 local earthquakes between

May 1966 and the end of 1967. Hypocenters of VT-type earthquakes were located across the south of the island and beneath Soufrière Hills at depths of less than 15 km (Shepherd et al. 1971).

Increased hydrothermal or fumarolic activity at soufrières surrounding the volcano was observed in association with each of these seismic crises, which have been interpreted as magmatic intrusions that failed to reach the surface.

Pre-1995 and Phase 1 VT Seismicity

VT Seismicity Prior to the 1995 Eruption

After volcanic seismicity on Montserrat waned in late 1967, seismic monitoring on the island was reduced to a single short-period vertical station until 1980, when a real-time telemetered station was installed at St. George's Hill. Between 1967 and 1980 data were recorded locally, and Shepherd et al. (2002) report an average of 3–4 volcanic earthquakes per month, with occasional bursts of

Volcano-Tectonic Seismicity of Soufriere Hills Volcano, Montserrat, Fig. 4 Daily and cumulative numbers of local volcanic earthquakes recorded on Montserrat between 1992 and July 1995 (Taken from Shepherd et al. 2002)

greater numbers. A $M_{6.2}$ tectonic earthquake occurred on 6 March 1985 approximately 20 km N of Montserrat, near the island of Redonda, followed by a large number of aftershocks in 1985–1986. During this time possible local earthquakes were recorded on Montserrat, and in order to distinguish them from tectonic aftershocks, two new seismic stations were established on Montserrat in 1989 (Shepherd et al. 2002).

Following the pattern of the earlier seismic crises of the twentieth century, seismic activity at SHV increased prior to the 1995 eruption. There is perhaps surprisingly little published literature describing this period, but there is consensus that elevated levels of seismicity on Montserrat were observed from January 1992 (Ambeh and Lynch 1996). However, the earlier seismic network was badly damaged by Hurricane Hugo which impacted the island in 1989, and the network was not restored until 1992 (Shepherd et al. 2002). Therefore, it is difficult to assert with certainty that the period of elevated seismicity began in 1992.

Figure 4 shows the volcanic seismicity on Montserrat from 1992 to the beginning of the eruption in mid-1995, with the average daily rate throughout this period higher than at any time since 1938. Little detail of the waveforms is recorded in the literature, but these events are assumed to be mostly high-frequency VT-type earthquakes, located below southern Montserrat at depths of less than 20 km. A total of 18 steadily increasing episodic swarms, lasting from hours to days, were recorded between January 1992 and 17 July 1995 (Ambeh and Lynch 1996). The sharp increase in mid- to late 1994, including many felt events, prompted the installation of four new seismic stations on the island. The rate began to increase further during 1995, and more than 300 events preceded the first phreatic activity in mid-July. The tenfold increase in the daily rate of seismicity before the first magma extrusion in November 1995 has been attributed to slow-rock fracturing as magma approached the surface (Kilburn and Voight 1998).

Distal VT Swarms

In 1995 seismic monitoring consisted of the short-period (analogue) network, comprising of the existing SRU stations supplemented by a network installed by the USGS Volcano Disaster Assistance Program (VDAP) (Aspinall et al. 1998; Gardner and White 2002). These were mostly 1Hz vertical component instruments, with a total of nine stations, although not all were concurrently active. From October 1996 onwards, a network of telemetered digital seismic stations was installed, eventually superseding the short-period network. This initially comprised of five three-component broadband stations and three short-period vertical stations, but has been incrementally upgraded, evolving into the current MVO seismic network of ten broadband and two short-period stations.

VT earthquakes were the dominant type of volcanic seismicity in both the lead up to the eruption and during the initial phreatic phase (Miller et al. 1998), but were replaced by low-frequency seismicity and rockfalls once dome growth began. They were also more abundant during the early part of the eruption (Fig. 3) and continued in high numbers during the first pause in lava extrusion between 1998 and 2000.

As discussed in the section “**Examples**,” distal clusters of VT earthquakes, away from the main volcanic vent, appear to be a relatively common precursory phenomenon, particularly in silicic systems. This was also the case during the eruption of SHV, Montserrat, in 1995. In terms of hypocentral locations, the vast majority of VT earthquakes at SHV have occurred in a main proximal cluster, occupying a relatively small seismogenic volume beneath the volcanic vent, at depths typically 1–3 km bsl. However, during the early phreatic stages of the eruption in 1995, there is consensus that at least two other short-lived spatial clusters of VT earthquakes occurred (Aspinall et al. 1998; Gardner and White 2002; Roman et al. 2008).

The first cluster occurred approximately 3 km to the northeast of the volcano, over a 2-day period between 5 and 6 August 1995, prior to the onset of lava extrusion. A second distal cluster, 4 km to the northwest of the volcano and

centered almost directly beneath St. George’s Hill (SGH), occurred between 12 and 14 August 1995, although occasional further events continued until early 1996. Earlier studies (Aspinall et al. 1998; Gardner and White 2002) found depth ranges of 1–6 km, but more recent work suggests a narrower depth range of 3–4 km bsl (Roman et al. 2008). Gardner and White (2002) also identify a third cluster of distal earthquakes, to the north of SHV below Windy Hill, and in more recent analysis Miller et al. (2010) identify a fourth, extending WNW from SHV (Fig. 2).

This spatial pattern of hypocenters, particularly the cluster beneath SGH to the NW, is qualitatively similar to that observed in the earlier seismic crises at SHV (Powell 1938; Shepherd et al. 1971). Recent work (Roman et al. 2008; Miller et al. 2010) has interpreted these distal clusters, particularly the cluster below SGH, as resulting from stress changes produced by an ascending magmatic dyke, with an NE or NNE trend. The explanation of the distal VT seismicity is that the intruding dyke altered the stress distribution in a weakened tectonic zone and oriented ESE across Montserrat, promoting localized fault movements and changes in pore fluid pressure. Geological evidence suggests that SGH is a result of tectonic uplift, rather than a parasitic cone, and the stress transfer hypothesis is preferred to a secondary magmatic intrusion below SGH, where the distal VT earthquakes would have been proximal to the secondary intrusion.

VT Earthquakes and Stress

VT Source Characteristics

Since VT earthquakes are produced by brittle failure or shear fracturing along a fault plane in the same way as tectonic earthquakes, analysis of their source characteristics – their focal mechanisms and moment tensors – can be used to infer information about the local stress conditions.

Full moment tensors describing the inelastic deformation in the source region can be obtained by waveform inversion, but data from VT earthquakes are often too sparse for such methods, so

they are often assumed to be a result of a pure double-couple source mechanism. The geometry of the faulting that occurs during an earthquake can be studied by determining the earthquake focal mechanism (or fault-plane solution), since it is the fault geometry that controls the seismic radiation pattern.

Focal mechanisms are usually determined from the polarity of *P*-wave first motions at various distances and azimuths but can also be further constrained by the amplitude ratio between *P*- and *S*-wave arrivals. Sets of focal mechanisms can be combined together in order to invert for a common stress tensor that completely describes the local stress regime. Alternatively, the orientation of the principal axes of the focal mechanism can be used as a proxy for the orientation of the stress field. These are the so-called pressure (*P*) and tension (*T*) axes, which represent the maximum and minimum compressive stress, respectively, and are determined by bisecting the dilatational and compressional quadrants.

Studies at several volcanoes have shown that the orientation of the axes of VT fault-plane solutions can undergo systematic changes in response to volcanic activity (e.g., Umakoshi et al. 2001; Roman et al. 2006) and, in particular, in association with changes in the pressurization of magmatic intrusions.

Regional Stress Conditions on Montserrat

Roman et al. (2008) cite evidence from the fault-plane solutions of nearby regional earthquakes and the orientation of dykes mapped on neighboring islands to suggest that the regional stress field around Montserrat is characterized by maximum compressive stress in an arc-normal, approximately NE-SW direction. Recent studies of the local tectonics, arising from offshore seismic reflection profiles, have suggested that, at a local level, the stress regime may in fact be more complex (Kenedi et al. 2010).

Montserrat is located in the northern part of the Lesser Antilles and is a result of oblique subduction of the North American plate beneath the Caribbean plate, which is accommodated by a combination of large-scale sinistral strike-slip faulting and smaller local normal faults

perpendicular to the arc. The dominant structural feature on the island is the extensional Montserrat-Havers fault system (MHFS) (Feuillet et al. 2010), along which the andesitic domes of the SHV complex and other uplifted features such as SGH and Garibaldi Hill are aligned. The MHFS includes an ESE-trending lineament that passes south of the Centre Hills and is interpreted as the Belham Valley fault (BVF). The MHFS also extends to the southeast towards Guadeloupe, where Montserrat lies at the northern end of the offshore Bouillante-Montserrat graben structure (BMF). This could imply a roughly E-W orientation of minimum compressive stress, approximately normal to the N-S regional extensional trend of the MHFS and BMF structures.

VTs and Stress at SHV

The source mechanisms of VT earthquakes at SHV have been analyzed in several studies in order to improve understanding of the local stress field and the nature and orientation of the magmatic intrusions supplying the eruption.

Roman et al. (2006) analyzed the focal mechanisms from a subset of 551 VT earthquakes at SHV with well-constrained double-couple fault-plane solutions, spanning October 1996 to July 2005, and observed temporal changes in the orientation of the *p*-axes. Several periods of a few months were identified where the dominant orientation of the *p*-axes switched from the predominant NE-SW to a NW-SE trend. This represents a 90° rotation from the assumed arc-normal regional maximum compressive stress. Analysis of seismic anisotropy through study of shear-wave splitting of regional earthquakes recorded on the MVO network has provided further evidence to support the presence of short-term variations in the local stress field at SHV.

Models of the interaction between regional and magma-induced stresses (Vargas-Bracamontes and Neuberg 2012) have shown that VT earthquakes on regionally aligned faults are more easily triggered by lower internal pressures of the intruding magma body. By contrast, pressures much higher than the regional stress field are needed to promote rotated VT

earthquakes, supporting observations of their short-lived episodic nature. The presence of such rotated events could therefore indicate significant pressurization of the volcanic system, and hence, the occurrence of these rotated VT events has been interpreted as evidence of stresses induced by the inflation of a NE-SW-oriented dyke beneath SHV. This is broadly supported by the analysis of distal VT focal mechanisms during the early phase of the eruption (see the section “[Distal VT Swarms](#)”).

This NE to NNE orientation is somewhat in disagreement with the NW- to NNW-oriented dyke proposed for SHV derived from geodetic or borehole strain data. Kenedi et al. (2010) propose an approximately N-S-oriented feeder dyke as a possible way to reconcile these competing models.

Recent VT Seismicity at SHV

Patterns of VT Occurrence at SHV

VT earthquakes were most numerous at SHV in the buildup to the eruption and during the initial phreatic phase before dome growth began. They also continued in relatively high numbers during the first pause in extrusion, occurring at a rate of around 5 per day between March 1998 and November 1999. Since this period the daily rate has been much lower and has remained roughly constant at an average rate of less than one per day from 2000 to present.

However, short-term increases in VT activity have been associated with the restarts in extrusion during the course of the eruption at SHV, often increasing notably during the short transitional or phreatic phases which preceded renewed lava extrusion. Diffuse episodes of VT earthquakes associated with ash venting and minor explosive activity preceded the onset of extrusion of both Phase 3 in mid-2005 and Phase 4 in mid-2008. A more intense swarm of 24 VT earthquakes on 5 October 2009 heralded the onset of several days of ash venting before the start of Phase 5 extrusion.

Since around the end of Phase 3 in 2007, the character of VT seismicity seen at SHV appears

to have changed. Fewer intense swarms have been observed, and instead the dominant feature has been the sporadic occurrence of short bursts of high-frequency VT events termed VT “strings.” A sequence of repeating VT earthquakes with similar waveforms was also observed in late 2008 and early 2009. The timing of this change in behavior roughly coincides with a departure from the longer extrusive periods of Phases 1–3 to the shorter more rapid extrusion of Phases 4 and 5.

Repeating VTs

An unusual quasiperiodic sequence of seven large ($2.6 < M_L < 3.2$) repeating VT earthquakes was observed at SHV between October 2008 and May 2009, straddling the two brief periods of extrusion that comprised Phase 4. Analysis of arrival times, waveforms, and focal mechanisms suggests a common location and source process for six of the seven events, with inter-event cross-correlation coefficients of 0.75 and above. A composite focal mechanism revealed mostly strike-slip-style faulting, with a p -axis orientation of approximately 75° , which does not correspond to either the regional stress aligned or the 90° rotated solutions of Roman et al. (2006).

VT Strings

Description and Characteristics

VT strings, defined as a short, intense swarms of VT earthquakes, a phenomenon occasionally referred to elsewhere as “spasmodic bursts” (e.g., Hill et al. 2002), have become a feature of the eruption of SHV since late 2007. To date, 52 such earthquake sequences have been identified in the 69 months since the first in November 2007, continuing across Phases 4 and 5 of lava extrusion (Fig. 5).

The details of individual strings have varied, but certain common characteristics have been identified. The duration of these sequences has typically been less than an hour, with a mean of roughly 10 events occurring in 30 min, when averaged across all strings. The first event in the swarm is generally not the largest, and thus, VT

Volcano-Tectonic Seismicity of Soufriere Hills Volcano, Montserrat, Fig. 5 Duration of all VT strings recorded at SHV, first seen in November 2007. The white circles represent VT strings that were associated

with observable activity at the surface. Extrusive phases are shown in *pink* and pauses in extrusion in *green*, and *dark-pink* periods represent the transitional, precursory, or phreatic phases

strings do not represent a mainshock-aftershock sequence, instead exhibiting swarm-like behavior, with events tightly clustered in time and space (see, e.g., Fig. 7). In terms of their waveforms, hypocenters, and focal mechanisms, analysis of individual earthquakes has revealed no clear differences between those occurring as part of strings and ordinary or background VT events.

Approximately a quarter of VT strings have been linked to observed surficial activity such as ash venting or visibly increasing degassing and fumarolic activity. This has led to some speculation as to their predictive capability in forecasting such activity or perhaps even renewed lava extrusion. This relationship is supported by SO_2 flux data from SHV, which show some degree of correlation with the seismicity, with often, though not in all cases, a spike in gas output several hours to days after the earthquakes occur (Fig. 6). This has led to tentative proposals that the seismicity is perhaps driven by gas release and/or hydrothermal

processes, although it is clear that this phenomenon is not well understood and that more work is needed to refine the generation mechanism. Similar models have been suggested elsewhere, such as Nishi et al. (1996), who propose a hydrothermal source for spasmodic bursts observed at White Island, New Zealand, based on a mechanism of brittle failure induced by rapid fluid pressure fluctuations in the shallow hydrothermal system.

March 2012

Some of the most significant VT seismicity at SHV occurred on 22 and 23 March 2012, with two swarms of around 50 VT earthquakes each. The second swarm on 23 March was more energetic than the first, with local magnitudes of up to $M_L 3.9$: some of the largest VT earthquakes to have been recorded at SHV. The most intense phase of the VT swarm lasted only 15 min (Fig. 7) and was followed by three large hybrid earthquakes. A very-long-period (VLP) seismic signal (below 0.1 Hz or 10 s period) was also

Volcano-Tectonic Seismicity of Soufriere Hills Volcano, Montserrat, Fig. 6 Correlation between VT strings and SO₂ output at SHV for the period October 2011 to September 2012. The top panel shows daily VT

earthquake counts and the bottom the recorded SO₂ flux in tonnes per day. VT strings are indicated by the red vertical lines

Volcano-Tectonic Seismicity of Soufriere Hills Volcano, Montserrat, Fig. 7 Normalized waveform showing the most intense phase of the VT swarm that occurred

at SHV on 23 March 2012. Shown is a 15-min-long vertical component velocity seismogram recorded at station MBLG. The start time is given in UTC

observed across the MVO seismic network during this swarm, coincident with a large amplitude (≈ 250 nanostrain) strain signal recorded by several borehole strainmeters. The seismicity was followed by mild ash venting several hours later. As with the explosion and accompanying strain signal on 3 March 2004 (Linde et al. 2010), preliminary analysis of the strain data has suggested the involvement of a shallow dyke or fracture, although in this case there was no emission of magmatic material. The events of 22–23 March 2012 have some broad similarities with the VT strings that have occurred since at SHV since 2007, perhaps hinting at a common

driving process. These include the relatively short duration of the VT seismicity and its correlation with ash venting and increased degassing. There was a time lag between the occurrence of the seismicity and the SO₂ output which responded on 24 March (2,400 T) followed by the third highest value ever measured by the spectrometer network of 4,600 T on 26 March. The strong pulse in gas associated with this event is similar to the increase in emissions associated with several other VT strings. However, similar strain signals have not been identified with any other VT strings, although the magnitude of this event was clearly much larger.

Summary

Volcano-tectonic earthquakes are brittle failure events that occur in volcanic environments, sharing many of the properties of tectonic earthquakes. Understanding their characteristics and behavior is of critical importance in monitoring and forecasting efforts, particularly as volcano-tectonic earthquakes are often one of the first signs of volcanic unrest and potential future eruptions. The ongoing eruption of Soufrière Hills volcano, Montserrat, has offered an unparalleled opportunity to observe the evolution of volcano-tectonic seismicity throughout a long-term dome-building eruption.

Several volcano-seismic crises, of presumably mostly VT events, occurred on Montserrat at approximately 30-year intervals throughout the twentieth century, in 1933–1937 and 1966–1967. Volcano-tectonic seismicity was also the most prevalent precursor to the start of the current eruption, with increasing numbers seen in escalating episodic swarms in the 3 years preceding the onset of phreatic activity in 1995. During these initial phreatic stages of the eruption, distal swarms of VT earthquakes several kilometers away from the main summit vent were observed, particularly below St. George's Hill to the northwest of the volcano. This distal cluster is proposed to have resulted from stress transfer through a weakened tectonic zone, rather than a secondary magmatic intrusion. A rapid acceleration in the rate of VT earthquakes, linked to subcritical rock fracturing, also preceded the first magmatic activity and the onset of lava extrusion.

The source mechanisms of VT events can be used to infer the local stress conditions under which they are generated. Analysis of the orientation of the p -axes of focal mechanisms of VT earthquakes at SHV has shown systematic temporal changes in response to volcanically induced stresses, in particular the occurrence of events with a 90° rotation from the dominant trend. The presence of these “rotated” events has been interpreted as the result of pressure changes in an NNE- to NE-oriented shallow dyke beneath SHV overprinting the regional

stress regime and promoting failure on optimally aligned faults.

A different character of VT seismicity was seen at SHV after the end of the third phase of lava extrusion. VT earthquakes were the dominant seismicity during the short transitional phases that preceded restarts in lava extrusion which were associated with minor explosive activity and ash-venting episodes. The emergence of short spasmodic bursts of VT earthquakes termed VT “strings” since 2007 has also been linked to ash venting, increased fumarolic activity, and SO_2 output. An intense VT swarm on 23 March 2012 occurred coincident with a very-long-period (VLP) seismic signal and a large step in strain. This seismicity preceded mild ash venting and a large spike in SO_2 release, suggesting the processes driving this event and VT strings may be similar.

waste management

Introduction

Earthquakes can create large volumes of debris and solid waste. Depending on the severity of the earthquake and the nature of the built environment, waste volumes can be the equivalent of many times the annual waste generated by an affected community. Improved standards for built infrastructure are decreasing the probable impact of earthquakes in many communities. However, increased urbanization and dependence on complex infrastructure networks increase a community's vulnerability to a disaster. This also increases the likely amount of waste produced.

Table 1 shows debris volumes generated from past earthquake (and tsunami) events. Not only can these large waste volumes overwhelm

existing solid waste management facilities and personnel, it can also affect both the response and long-term recovery of an earthquake-affected area. Immediately after an earthquake, debris can block roads, which in turn impedes rescuers and emergency services reaching survivors. In some cases, where hazardous materials are present, waste can pose a public and environmental health risk, for example, where hazardous materials (asbestos, chemicals, radioactive materials, etc.) are present (Brown et al. 2011).

In the longer term, poor management of debris can result in a slow and costly recovery. Rebuilding and repair cannot be carried out before the waste is removed. It is also a public indicator of the speed of recovery. So it is necessary to ensure safe and expedient removal of debris. If managed effectively, debris can become a valuable resource in the recovery and rebuilding process and can have a positive effect on social and economic recovery (Brown et al. 2011).

Historically, disaster waste management has been managed as a logistical exercise. The main focus was removing the material from the affected area with little thought to the longer-term environmental impacts. In L'Aquila, in 1703, a large earthquake severely damaged the town. The debris was deposited in an area behind the Basilica, which now forms the Botanic Gardens. This site has required ongoing remediation to stabilize the poorly compacted fill. In Napier, New Zealand, following the 1931 earthquake, the waste management solution involved dumping

Waste Management Following Earthquake Disaster, Table 1 Reported waste quantities from previous disasters

Year	Event	Estimated waste quantities	Data source
2011	Tohoku earthquake and tsunami	Over 23 million tonnes	(UNEP 2012)
2011	Christchurch earthquakes	8 million tonnes	(Brown 2012)
2010	Haiti earthquake	23–60 million tonnes	(Booth 2010)
2009	L'Aquila earthquake, Italy	1.5–3 million tonnes	(Di.Coma.C accessed 2010)
2008	Sichuan earthquake, China	20 million tonnes	(Taylor 2008)
2004	Indian Ocean earthquake and tsunami	10 million cubic meters (Indonesia alone)	(UNOCHA 2011)
1999	Marmara Earthquake, Turkey	13 million tonnes	(Baycan 2004)
1995	Great Hanshin-Awaji earthquake, Kobe, Japan	15 million tonnes	(Hirayama et al. 2009)

the unsorted debris firstly into a lagoon and secondly onto the beach adjacent to town. With increasing awareness and concern over potential environmental, social, and economic impacts of waste management strategies, as well as the growing size and complexities of disasters, modern disaster waste managers have to take a far more integrated and considered approach.

This chapter will look at the technical and operational aspects of earthquake waste management. The chapter will first consider: waste composition and quantity, waste handling and treatment, waste disposal, hazard management, strategic and operations management, funding, regulations, and planning. The chapter will mainly focus on earthquake-generated waste but will give examples from management of debris resulting from other hazard events.

Waste Composition and Quantity

The composition and quantity of earthquake debris will vary based on the nature of the built environment affected as well as the severity of the earthquake. For example, a community with predominantly timber buildings will have a different waste composition than a community that builds houses from adobe bricks. Or a city with poor building standards affected by a moderate earthquake may generate more debris than a city that has good building standards affected by a much larger earthquake. It is important to understand both the composition and the quantity of

waste generated as this will help authorities determine the most effective strategies for managing the waste.

Waste Composition

In terms of composition, earthquake waste is predominantly construction and demolition waste, that is, waste generated from the demolition of earthquake-affected structures and infrastructure. Waste materials may include metal, concrete, brick, timber, plasterboard, pipes, asphalt, etc. In some cases, where buildings collapse during the earthquake or where buildings are not safe to enter following the earthquake, the waste will include the contents of the building. This could include personal property (e.g., essential documents, money, mobile phones), carpet, furniture, electronic and electrical equipment, plastics, paper, whiteware, putrescible waste, and potentially hazardous materials stored on site (e.g., gas cylinders, oils, pesticides). The exact composition of this waste will depend on the type of building construction and nature of the earthquake impacts.

Earthquakes can also generate other types of waste. Vehicles are often damaged by falling building materials or collapsed buildings. In some earthquake events, liquefaction occurs. Wet silt material is ejected from the ground and accumulates in rivers and on the land surface and can flow onto and into properties. In cases where wastewater pipes have broken during the earthquake, silt can be contaminated. This silt needs to be removed to make buildings habitable and to

ensure stormwater infrastructure can operate properly. Earthquake-generated rockfall is another source of debris that may need to be managed. Solid waste managers may also find themselves dealing with indirect wastes resulting from the earthquake recovery. These wastes could include unwanted donations, health-care wastes, emergency relief food packaging, and rotten food resulting from power outages or damage to food storage facilities.

Earthquakes can also cause secondary hazards that may generate waste. Tsunamis and fires are both possible following an earthquake event. These hazards are unlikely to change the composition of the waste significantly; however, they will affect the nature of the waste. Tsunami debris will be more mixed and will likely be saturated with saline water. Fire debris will also be more mixed and charred. These factors will affect how the debris can be managed. This will be discussed later in the chapter.

On top of earthquake-generated waste, authorities must continue to manage municipal waste. If not collected, municipal waste may pose a public health risk or may become mixed with disaster debris making it more difficult to recycle.

Waste Quantity

Estimating earthquake waste quantities can be challenging. As noted above, both the composition and volume of waste changes significantly depending on the built environment and the severity and effects of the specific earthquake event. Some countries, such as the United States, have developed earthquake debris volume estimation tools for use both before and after an earthquake event. While useful in the United States, these may not be completely transferrable to different countries. One of the main factors restricting the development of estimation tools in other countries is the lack of waste volume data from previous earthquake (and other disaster) events.

There are a number of approaches that can be taken (both pre and post-event) to estimate waste volumes and/or weights. Estimates can be made based on total quantity of waste, or they can be broken down into quantities for different waste

types (timber, concrete, metal, etc.). These methods are briefly explained below.

Unit Estimates

Estimates can be built up based on how much waste is expected from a single type of property and the level of damage it sustained. For example, for residential areas, you could divide the affected properties into the level of damage (say, full demolition, partial repair, and minor repairs). Each level can then be divided further based on the type of construction of the property, its age, and size. For each category you can then estimate, using local information and experience, the quantity and composition of the waste. This strategy is illustrated in Fig. 1. The total waste will be the sum of the number of houses in each category (N) multiplied by the quantity of waste (W , in mass or volume as needed), as shown in Eq. 1. If desired, this technique could be further refined by not only estimating the total quantity of debris but for each subcategory estimating the composition of the waste (20 % concrete, 30 % brick, 10 % timber, etc.). In that case, Eq. 1 would be applied to each type of waste:

$$\text{Total waste} = \sum_{i=0}^n W_n N_n \quad (1)$$

The same technique can be used for commercial properties; however, it is slightly more involved due to the wide range of building sizes and types. If a unit estimation technique is not possible, then a volume estimate may be possible.

Volume Estimates

For variably shaped buildings, a volume estimation technique may be most appropriate. As a very rough rule of thumb, it can be assumed that the weight of debris in a commercial building is one third of the volume of the erect building, as shown in Eq. 2. Note that this varies widely and would be significantly less for lightweight buildings such as steel-framed warehouses:

$$\text{Total waste (in tonnes)} = \frac{1}{3} \text{ Building volume (m}^3\text{)} \quad (2)$$

Waste Management Following Earthquake Disaster, Fig. 1 Schematic for unit estimation technique of residential earthquake waste

This approximation could only be used for buildings being fully demolished and where the volume of the building is known. Building volumes could be obtained using LIDAR images or using local authority held building data (say building height or number of storeys and floor area). As for the above method, this may be further refined by splitting the buildings into construction type and assigning approximate waste compositions for each building type.

Area Estimates

Areal estimates are based on the amount of waste over a particular area, be it floor area of a building or land area.

For buildings, waste quantities per unit floor area (in m²) could be estimated based on damage level and building type. These areal estimates can then be multiplied by the total floor area of that building damage level and building type. This technique is similar to the unit estimates except that instead of estimates per building (N), the estimates are based on floor area (A); see Eq. 3.

As with the previous methods, this technique allows for further refinement and splitting waste quantities into different types:

$$\text{Total waste} = \sum_{i=0}^n W_n A_n \tag{3}$$

Area estimates are especially useful for earthquake damage that is spread over a large area, such as waste resulting from liquefaction and tsunami damage. Aerial images can be used to determine the extent of the damage. If desired, the areas can be split into damage levels. For each area, unit (per m²) waste quantities (and composition, if desired) can be assigned. This technique was used in Japan following the devastating 2011 Tohoku tsunami.

Waste Management System Overview

Depending on the composition and quantity of waste, an appropriate cradle-to-grave waste management system will have to be designed.

Waste Management Following Earthquake Disaster, Fig. 2 Generic waste management system flow diagram

Generally, waste management systems have several stages. Broadly, these are waste collection, waste handling, waste treatment, and final disposal/end use. Figure 2 shows a generic sample waste flow through these stages.

All these stages, as well as transportation and hazard management, will be discussed in the following sections.

Waste Collection

During the emergency phases of an earthquake response, waste may need to be removed or collected to clear roads. Roads may need to be opened to allow emergency service, critical infrastructure, and rescue personnel access. Some emergency debris works may also be required to remove acute hazards such as unstable buildings and hazardous materials. Generally, this work will be done swiftly by first responders, and waste will often be mixed and taken to existing solid waste management facilities.

During the early recovery phase of an earthquake response, provision may need to be made for collection of minor waste from private properties. This would be particularly important if there was liquefaction- or tsunami-related debris that needed clearing. Authorities generally provide for this in one of the following two ways:

1. Curbside collection service

Residents are asked by the local authority to place material cleared from their property to the curbside (either in a pile or in bins or bags provided) for collection. The waste material can be mixed or separated into recyclables. A contractor or contractors are engaged to collect the waste and take it to a designated waste handling facility. Generally, this service is free for residents.

2. Provision of waste depots

Residents are instructed to take material cleared from their properties to a nominated location. These locations could be existing waste transfer stations or may be specifically

established facilities. The waste material can be mixed or separated. This service could be free or charged.

When determining the waste collection system, it is necessary to consider a number of factors, including: (1) the state of roads (a curbside collection may be more suitable if road movements need to be minimized), (2) how easy and safe it is to handle the waste (are there public or environmental health risks that need to be managed?), and (3) how easy it is for residents to separate different types of waste.

The majority of debris following an earthquake will be generated and collected during the repair and demolition stage of the recovery. Demolition and building contractors will generate waste as they demolish or repair building and horizontal infrastructure (roads and pipes). Generally, the contractors will then transport the waste to handling and treatment and/or disposal facilities (see the next section).

Demolition

Demolition works should be carried out by experienced demolition contractors. Demolition methods should follow best practice adjusted as necessary to account for potential building instability. Demolition techniques will not be discussed here, but special considerations around waste management are briefly discussed.

During the demolition process following an earthquake, there are some types of waste that have to be managed carefully. The first is material linked to fatalities. In many cases, authorities will want to retain building material linked to fatalities for cultural and/or investigative purposes. Separate collection and storage for this material may have to be provided. The next is material from heritage buildings. Where heritage buildings have to be demolished, it may be desired that some of the building materials are retained and/or specially documented. Archeological material may also be found and require preservation. Last, personal property salvaged from buildings needs to be considered. People are often forced to leave buildings quickly following an earthquake and sometimes leave valuable

personal items. Where possible, these should be returned to the owner.

Waste Handling and Treatment

Once waste has been collected, it will either go straight to a disposal site (see next section) or it will go to a handling and/or treatment facility to be processed. Waste handling facilities are generally where mixed waste goes to be separated into recyclable and nonrecyclable parts. Following an earthquake these are generally called temporary storage areas. Waste treatment facilities are where waste is physically or chemically changed in form, to make it suitable for recycling or alternative uses such as engineering fill. Waste may also be incinerated. Waste handling and treatment sites are commonly combined.

Temporary Staging Areas

Generally, because of the large volumes of waste, existing handling and treatment facilities cannot take all the waste immediately. Therefore, temporary staging areas are often established to receive mixed waste, separate them, and in some cases carry out treatment. As a result, temporary staging areas slow the rate and quantity of waste going to existing facilities (which otherwise would be overwhelmed). The downside to temporary storage areas is that waste has to be double handled, which has cost implications.

The size and nature of temporary staging areas will vary depending on the composition and quantity of waste; however, there are some general things to consider. As an approximation, the space required for a temporary staging area is 50 ha per 1,000,000 cubic meter of debris (FEMA 2007). Sites should be located to minimize environmental damage. Operational arrangements must consider items such as site layout, plant requirements, traffic management, operations management, recording/invoicing systems, operational costs, public health, and environmental health risk management procedures. It is vital that temporary storage facilities are aware of what waste is entering the site in order to identify and mitigate potential hazards.

Waste Management Following Earthquake Disaster, Fig. 3 Temporary staging area for managing waste following the 2009 L'Aquila earthquake, L'Aquila, Italy (Photo date: September 2010) (Photo credit: Charlotte Brown)

Good monitoring and record keeping is also essential for billing purposes. Where possible, temporary staging site locations should be identified before an earthquake event. Inappropriate location of temporary storage sites has led to environmental and public health effects in past events, for example, following the 2004 Indian Ocean tsunami (Basnayake et al. 2006; Pilapitiya et al. 2006; UNDP 2006) (Fig. 3).

Recycling

Many components of earthquake waste can be recycled. Commonly recycled materials include concrete, metal, untreated timber, vegetation, and plasterboard/gypsum. Recycling is often a desired option because it saves resources, reduces landfill space needed, can (not always) reduce waste management costs (including transportation), and can create job opportunities.

However, there are some disadvantages associated with recycling following an earthquake. First, depending on the value of recyclables and cost of land disposal, it can be more expensive than landfilling, particularly where there is no market available for the large volume of recyclable materials produced. Second, recycling is more time-consuming than landfilling and is resource intensive: both time and resources are often short during an earthquake recovery. Third, specialist equipment may not be available to process the large volumes of waste, and storage of materials for processing can be challenging. Fourth, hazardous material may have contaminated the waste and this will likely make recycling impossible. Last, if there has been liquefaction, tsunami, or fire damage, it is likely that the materials will be difficult to separate and recycle.

For recycling to be carried out, waste needs to be separated. Waste can either be source-separated (by private home owners or contractors) or it can be separated off-site at waste handling facilities such as the temporary staging areas discussed in the previous section. Generally, waste will be source-separated by demolition contractors. This option is more cost-effective as it reduces double handling and there is often a higher yield of recyclables. It also reduces the demand for waste handling facilities. However, source separation will be more time-consuming, meaning demolition work will take longer. If there is urgency in the demolition works (for safety or recovery purposes), then off-site recycling may be more desirable.

Land Reclamation and Engineering Fill

Demolition waste from earthquakes is often used as engineering fill for land reclamation or land remediation. Inert materials such as concrete, brick, and rock can be broken down into small material suitable for filling operations. This has been used following the 1995 Great Hanshin-Awaji earthquake, the 1999 Marmara earthquake in Turkey, and the 2011 Christchurch earthquakes.

In order for construction waste to make good engineering fill, suitable monitoring of the engineering and environmental quality of the material needs to be in place.

Incineration

Incineration (and waste to energy) is a potential treatment option following an earthquake. This technique has been used following the Indian Ocean tsunami and Great Hanshin-Awaji earthquake. However, there is only a small proportion of earthquake waste that is safely and efficiently combustible, particularly in areas where structural timber is treated. Incineration should only be carried out where appropriate environmental controls are in place for both air emissions and ash disposal.

Waste Disposal

All residual earthquake waste (material that cannot be recycled, used as engineering fill or incinerated) has to be disposed of. Most communities will have existing waste disposal facilities (landfills); however, often these disposal facilities will not be big enough to take all earthquake waste. Following some earthquakes, new disposal facilities have been constructed to increase disposal capacity. Often these landfills are constructed to a lesser degree of environmental protection than ordinary municipal waste landfills. If this approach is taken, authorities need to consider the potential for hazardous material and potential environmental contamination. Public and worker health and safety should also be considered.

As for temporary storage facilities, disposal sites must keep clear records of what waste is entering the site and monitoring systems need to be in place to ensure items that are too hazardous are not deposited.

Hazardous material must be appropriately handled and disposed in accordance with local hazardous material disposal standards.

Hazard Management

There are several public health and environmental hazards present in earthquake waste. The main hazards are rotten food, asbestos, fecal-contaminated material (from broken wastewater pipes), treated timber, industrial waste (chemicals, paints, etc.), and household hazardous wastes (oils, pesticides, etc.). It is important that these wastes are identified and appropriate management approaches are put in place to protect public and environmental health. As a minimum, workers should wear correct personal protective equipment (suitable for the hazard), and hazardous wastes should be removed from properties prior to demolition work to reduce the volume of contaminated waste. It is likely that

risks will be heightened during an earthquake recovery due to the speed and volume of work being carried out, likely by those who have not worked in the waste industry.

Management approaches for hazardous materials should be determined in consideration of existing hazardous waste handling and treatment regulations. In some cases, authorities will choose to change environmental regulations to help to speed up the recovery. This must be done with caution, appropriate mitigation measures in place, and with long-term impacts in mind.

Below is a brief description of the main hazards found in earthquake waste.

Rotten food Particularly in cases where there have been prolonged power outages, rotting food waste must be managed. Food waste from residential and commercial properties (supermarket warehouses, cool-stores, hospitality businesses) is possible. Both solid and liquid waste may need to be managed. Following Hurricane Katrina, extended power outages led to significant amounts of rotting food in domestic fridges. Residents were advised to tape their fridges shut and place the entire fridge on the curbside for collection and disposal. Authorities cleaned the fridges, removed the hazardous refrigerant chemicals, and recycled the metal.

Asbestos Asbestos is a fibrous material used in construction. It is highly regulated in many countries now due to its associated health risks. The risk lies in exposure to airborne fibers being inhaled, so the risk is high when asbestos material is being disturbed

during demolition. Asbestos is a serious risk, and typical mitigation measures include: identifying asbestos prior to demolition; removing asbestos where possible; wearing protective gloves, masks, and clothing (which should be disposed of safely); keeping asbestos surfaces damp; carrying out air monitoring; erecting hazard signs; and sealing the worksites where possible.

Asbestos-contaminated material should be separated on site from clean debris as far as possible to reduce the volume of contaminated material. Contaminated material should be disposed of at an appropriate facility and its disposal location marked to prevent further disturbance.

Fecal-contaminated material (from broken wastewater pipes) When there is damage to the wastewater network (pipes or treatment facility), there will likely be sewage-contaminated materials to manage: both during the repair work and from residents immediately after the event who may not have access to a toilet. Public health protection for workers and general public during collection and disposal must be managed appropriately.

Treated timber Treated timber may be present in the waste. Generally, treated timber cannot be recycled or incinerated due to the likely environmental effects; however, this will depend on local environmental regulations. If necessary, efforts should be made to separate

treated and untreated timber during demolition to reduce the quantities of wood that must be safely landfilled.

Household and industrial hazardous wastes (oils, chemicals, paints, pesticides, mercury, etc.) All properties are likely to contain some hazardous materials. The type and quantity of materials are likely to depend on the building use. The occupants are the ones most likely to know about the hazardous materials present and should be included in locating and managing these wastes, separate from general construction and demolition waste. Hazardous materials should be dealt with as they would during normal (non-disaster) times.

Waste Transportation

Throughout most stages of the waste management process, waste needs to be transported. During an earthquake response, it is likely that a variety of different trucks will be used to transport waste as there will not be enough traditional trucks available. Control and monitoring of trucking activities is important to protect public and environmental health. Measures need to be considered such as dust suppression (either by water or dust covers), wheel washes, truck weight limits, dedicated truck routes (e.g., to avoid dangerous roads), and truck travel hour limits.

Authorities sometimes implement a waste tracking system following earthquakes to help monitor waste movement (to prevent illegal dumping) and, where applicable, to help waste managers manage contract costs and billing. Waste tracking systems generally document where waste comes from and goes to, what and how much waste there is, who transports the waste, and when it is picked up and dropped off. Typical systems used are paper-based systems

(e.g., daywork sheets or dockets), barcode/scanner systems, or GPS tracking systems. Paper-based systems tend to be less expensive but can be subject to fraudulent activity and human error. The barcode and GPS systems are generally more expensive to establish but are less susceptible to tampering and errors.

Strategic and Operations Management

As well as the technical details of managing earthquake waste, it is necessary to consider the strategic and operational management aspects.

Strategic Management

There are many organizations that have a stake in earthquake waste. Typical organizations include:

- Disaster response and recovery authorities
- Waste management industry
- Environmental authorities
- Health and safety authorities
- Public health authorities
- Hazardous substance authorities and industry
- Lifeline (critical infrastructure) authorities
- Marine authorities (for tsunami events: debris in marine environment)
- Transportation authorities
- Heritage building and archeological authorities
- Nondomestic agencies (e.g., international governmental and nongovernmental groups)
- Local cultural groups
- Community representatives

When designing a waste management system, ideally all these entities should be consulted. They should also be involved in any pre-event planning. It is beneficial to appoint one organization as the lead organization to oversee the strategic management and operation as a whole.

Operational Management

Operational earthquake waste management programs are managed in many different ways. A common configuration is that community-wide

waste collection is carried out by publically engaged contractors, private property demolition is carried out by privately engaged contractors (either by a home owner or an insurer), and waste treatment sites are managed by public/or private operators, as per usual municipal waste management. For example, this is how the US Federal Emergency Management Agency-funded debris operations are generally carried out (FEMA 2007). However, other arrangements are possible depending on the earthquake event and what funding is available. For example, immediately after the 2011 earthquakes in Christchurch, New Zealand, the national (public) response agency “Civil Defence” carried out scores of emergency demolitions to manage public health and safety hazards and try to get city streets open quickly.

In the United States, there is a growing industry of specialist disaster waste contractors that are ready to respond to disaster events. In particular, they respond to frequent storm events. Contractors can be paid in a number of ways but typically contracts are either a lump sum (for a specific body of work) or time and cost. Generally these costs include for all aspects of waste management from demolition or collection through to final disposal.

For private property demolition contracts, it is important to be clear on who owns the waste collected from the property.

Record Keeping and Monitoring

Another important part of earthquake waste management is record keeping. Information and monitoring are invaluable when planning and operating a waste management system. Information will enable the bottlenecks and potential risks and hazards to be identified and monitoring acts as a deterrent to illegal or improper practices. Record keeping is also important for managing contracts and billing.

Often, information is difficult to track during a disaster response, particularly when there are many different organizations involved in the waste management system. Despite this, an effort, be it paper based or electronic, should be made to monitor waste movement from source to disposal.

Human Resourcing

Following disasters, resources will be stretched. Skilled waste management and emergency management personnel may have lost their lives, and it is likely that unskilled personnel may have to be engaged to assist with waste management. Earthquake waste management offers opportunities for livelihood. Job and business creation is possible during every aspect of the waste management system. It is important to train and adequately manage unskilled workers – particularly when working around hazardous materials and specialized heavy equipment.

Public Communication and Engagement

Public information and communication is essential to all aspects of disaster response and recovery and this includes waste management. Negative public reaction to waste management efforts can lead to delays and disruptions. For example, in 2010, communities in L’Aquila held protests over the slow demolition and waste management of their earthquake-affected town (Brown et al. 2010b). Following Hurricane Andrew in 1992, public protests against incineration of debris led to the abandonment of that treatment technique and authorities were forced to find an alternative management strategy (USEPA 1995).

The public needs to be kept informed of all waste management issues, including health and safety issues (and established mitigation measures), debris handling and disposal procedures, and normal municipal waste collection arrangements (where applicable). Public information can be disseminated in a number of ways including radios, local newspaper, website, television, letter drops, etc. Where possible, information should be prepared pre-disaster for ready dissemination when an earthquake strikes.

There also needs to be good communication between regulatory authorities and the waste management industry. There are many organizations involved in earthquake waste management, and it is important that they work collaboratively following a disaster event.

Funding

Managing earthquake waste can be costly. Funds generally come from both public and private sources. Typically, private property demolition (and subsequent waste management costs) will be funded by the property owner or through their insurance. Debris removed from public spaces (such as on roads and in waterways) will be funded publically – through government or donated funds. There are circumstances where public money will fund private demolition and waste management works. This may be the case where private owners have few financial resources (such as in Haiti in 2010) or where there is a public health and safety risk (e.g., following 2005 Hurricane Katrina) or where there is a public commitment to fund private earthquake recovery works (such as in L'Aquila in 2009). The type, source, and amount of funding will generally dictate what operational strategy will be used.

Regulations

Solid waste management, particularly in developed countries, is governed by diverse legislation and regulation to minimize the potentially harmful effects of waste on humans and the environment. There are public health and environmental regulations around demolition, waste transportation, waste handling and treatment, and waste disposal. In the wake of a disaster, these normal regulations can cause significant delays in the waste management process. Authorities following many earthquake (and other disaster) events have used legal waivers to reduce or circumvent regulatory requirements (Brown et al. 2010a). For example, in 2011 in the wake of the Christchurch, New Zealand, earthquakes, a temporary staging area and recycling facility was approved without going through the normal approval process to enable quick establishment of the facility (and processing of earthquake waste) (Brown 2012). If legal waivers are taken, mitigation measures must be put in place to reduce potential long-term effects.

As well as environmental and public health legislation, earthquake waste managers will also need to be aware of regulations around demolition (and associated rights to the waste) of structures. Where owners are not present or do not consent, more processes may need to be followed before demolition can take place. In some instances, authorities may wish to waive or streamline these regulatory requirements. This was done following the 2005 Hurricane Katrina because many residents were absent but houses had to be removed to enable the recovery.

Planning for Earthquake Waste

Planning for earthquake (and disaster waste generally) has only really started in the last 20 years (Brown et al. 2011). The United States was the first country to have established disaster debris management guidelines (FEMA 2007; USEPA 2008), largely because of the frequency of events in the United States. These guidelines offer technical and operational guidance and are written specific to the United States context and disaster management and funding arrangements. Recently the Joint United Nations Environment Programme/Office for Coordination of Humanitarian Affairs Environment Unit has prepared disaster waste management guidelines specifically for less developed countries (UNOCHA 2011). The guidelines cover many of the technical issues addressed in the USEPA guidelines, and management and implementation strategies are designed for countries with little or no existing infrastructure and/or waste management expertise. Opportunities for livelihood promotion and maximizing value from the resources are also emphasized in this document.

Ideally every community subject to disaster events should develop disaster waste management plans. Plans need to be developed collaboratively with all relevant stakeholders. These plans should be written to align with expected hazards and damage as well as local regulations and waste management practices. Plans should be written generically such that anyone can pick them up and use them and they should be

reviewed regularly. Plans should cover all the aspects discussed in this chapter and are summarized below.

Summary

Earthquakes generate significant volumes of waste. The waste needs to be managed in a coordinated manner to minimize impacts on public health, environmental health, and on the recovery of the community. To prepare for managing earthquake waste, communities should develop waste management plans. Plans should cover the items discussed in this chapter.

Waste composition and quantity	Earthquake waste predominantly consists of construction and demolition waste. The composition and quantity of the waste will depend on the nature of the built environment and the severity of the earthquake. There are three quantity estimation approaches: unit, volume, and area estimates
Waste collection	The majority of earthquake waste is collected by demolition and building contractors carrying out demolitions and repairs. If there is a lot of small debris, curbside collection services or debris drop-off centers can be useful
Waste handling and treatment	Waste handling facilities are often required to separate waste into recyclable and nonrecyclable material and to create a buffer to ease the pressure on existing waste facilities. These are called temporary staging areas. After waste has been sorted, it can be treated in a number of ways including recycling and incineration or used as land reclamation and engineering fill. If the waste is contaminated with hazardous materials or is wet, recycling or reuse may not be feasible
Waste disposal	Ultimately some or all of the waste has to be permanently disposed of in a landfill. Shortage of space in existing landfills may be a problem so alternative disposal sites may need to be considered

(continued)

Hazard management	Earthquake waste generally includes numerous environmental and public health hazards, including rotten food, asbestos, fecal-contaminated material, treated timber, and household and industrial hazardous materials. These hazards need to be assessed and risks mitigated as soon as possible
Waste transportation	Waste needs to be transported throughout the management process. Trucks not usually used for waste management will often be needed. Authorities need to consider and manage any potential risks associated with transportation
Strategic and operational management	There are many different authorities and industries involved in waste management. It is important that they are all included in the planning and implementation of the waste management system. Ideally one organization should be given responsibility to oversee the waste management process In terms of operations, contractors are typically engaged on a lump sum or time and cost basis. Contract templates should be drafted pre-event
Funding	Funding for management of earthquake waste may come from a range of private and public sources. It is important to consider funding when designing the waste management system
Regulations	Regulations govern many parts of earthquake waste management: environmental, public health, building, and waste ownership regulations. Legal waivers have and can be used to expedite disaster responses and recovery, but this must be done with caution

Introduction

Unfortunately, recovering displacements from strong-motion acceleration time histories is not

Wavelet Domain Seismic Correction, Fig. 1 Comparison of estimate displacement time series (for 1999 Chi-Chi event, station TCU068N) using various correction schemes

straightforward. Direct double integration does not yield a stable displacement time history as is shown in Fig. 1. The displacement time histories in Fig. 3 demonstrate the sort of trends obtained from double integrating after filtering with standard low-cut filters with differing cutoff frequencies.

The dashed-line displacement curve is the wavelet-corrected curve which shows a good estimate, as compared with GPS, of the displacement for station TCU068N. The other displacement curves show the difficulties usually encountered in obtaining reasonable estimates of displacement. The reason for this can be due to noise and/or baseline shift, the latter being a DC shift in the acceleration and velocity baseline, which prevents the velocity from reaching zero and therefore gives rise to an upward or downward linear/quadratic trend in the displacement. It is inferred that this is due to the instrument pitching, rolling, and yawing as a result of the turbulent ground motion.

Sophisticated methods exist for correcting baseline errors and obtaining stable double-time integration. Trifunac (1971, 1972), Graizer (1976, 2005) advocated a baseline correction procedure by obtaining and fitting a straight line to a segment of the velocity. Chiu (1997) high-pass filtered before integration. Iwan et al. (1985) removed pulses and steps by locating the time points which exceeded a predefined acceleration, later generalized by Boore (2001) and Boore and Bommer (2005), then added further time points, and made the time points t_1 and t_2 free of any acceleration thresholds, the accumulated effects of these baseline changes being represented by average offsets in the baseline. Wu and Wu (2007) also used a modified method due to Iwan et al. (1985) on the Chi-Chi event and defined t_1 at the beginning of the ground motion and defined t_2 on the basis of a flatness coefficient and defined a further parameter t_3 , the time at which the displacement had reached a final value. Wang et al. (2003) removed pulses and steps fitted

with amplitudes which gave the same areas as the slope of the displacement to achieve stable double integration. Pillet and Virieux (2007), on the other hand, using data from station TCU068 from the 1999 Chi-Chi earthquake, recovered a baseline error as an average acceleration from a linear trend in the velocity and removed it at the time points where the velocity crossed the zero axes. Graizer (2006) proposed a method for identifying the existence of tilts by comparing the sensitivity of the vertical and horizontal components to rotational ground motion by comparing their Fourier spectra, given that the vertical component is insensitive to tilts. It has been shown experimentally that tilt-induced acceleration has to be removed to recover estimates of the true ground motion. The aforementioned methods, however, require some expertise to implement. On the other hand, the algorithm in the wavelet domain Chanerley and Alexander (2010) and Chanerley et al. (2013) presented here is automated, gives immediate results, and is easy to apply. The algorithm uses the undecimated wavelet transform, with a de-noising scheme, which is the key to its success. The advantage of using the undecimated transform with de-noising is that it is, as mentioned, automated; does all the work and recovers the low-frequency “fling” time history; locates an acceleration transient, i.e., the baseline error; and permits stable integration to displacement.

The troublesome baseline error, which for some decades has made direct integration difficult if not impossible, is recovered and found to be embedded in the low-frequency “fling.” It manifests as an acceleration transient (“spike”) in all three translational components, which on integration shifts the DC level of the velocity and causes linear trends in displacement. It has been shown in Graizer (2005) and in Chanerley et al. (2013) that the vertical component is insensitive to tilts; therefore, any “spikes” in the vertical direction in the acceleration time history are usually attributed to instrument noise and indeed are usually small when compared with the “spikes” of the horizontal components, which are attributed to ground rotation. This use of the undecimated wavelet transform recovers the

residual displacement and extracts and then removes the acceleration transients and permits double-time integration to displacement. This shows its usefulness and flexibility in being able to provide not only displacements but in addition locate the baseline error and find information on the rotational acceleration transients hitherto always inferred, but never located. We begin this entry with the section on De-noising.

De-noising Overlapping Spectra Using a Threshold

De-noising is a nonlinear method of removing unwanted signals; it’s advantageous because the spectra of signal and noise can overlap. It works by applying a threshold to outlier amplitudes and has been applied together with the undecimated wavelet transform to seismic events when correcting records. De-noising is superior to filtering, the latter being a function of frequency in the sense that filtering may remove or attenuate those frequencies, which in fact we want to retain. In particular in this case, filtering low-frequency noise will also filter the low-frequency signal (i.e., the fling); therefore, filtering is to be avoided.

The application of a soft-de-noising scheme (Donoho 1995; Lang et al. 1996; Coifman and Donoho 1995) to the low-frequency sub-bands, after applying the wavelet filters, retained the detail without affecting the overall displacement result such that when overlaying the original time history on the corrected time history, it didn’t demonstrate any significant differences.

A soft threshold time series $\tilde{a}_i$, where $i \in \{1, 2, \dots, N\}$, is given by Eq. 1, where τ is a threshold value. Hence, the low-power components of x_i are de-noised (removed):

$$\tilde{a}_i = \begin{cases} (a_i - \tau)\text{sgn}(a_i) & |a_i| > \tau \\ 0 & |a_i| \leq \tau \end{cases} \quad (1)$$

Typically, the threshold τ is estimated from the standard deviation of the data σ , multiplied by Donoho’s “root two log N ” (Donoho 1995):

Wavelet Domain Seismic Correction, Fig. 2 A 4-channel analysis (decomposition) wavelet filter bank showing sub-band

$$\tau = \sigma \sqrt{2 \log N}, \sigma = \frac{MAD}{0.6745} \quad (2)$$

Though there are many other options for the selection of a threshold value, the critical component is the standard deviation σ of the noise in the data, which is unknown in a general case. Ideally, we would have recordings from the accelerographs for in situ cases where there is no earthquake to characterize the background noise levels and its statistics. However, this is not often available in practice. Furthermore, as we have indicated above, the presence of ground tilts introduces noise that is only present during the earthquake. Thus, we have an uncertain estimate of the statistics of the noise. In the case of accelerograms, we use the highest-frequency sub-band as an estimate of the noise for the purposes of computing the threshold. From this, we compute the median absolute deviation (MAD) that is a robust estimator and more resilient to outliers in a data set than the sample standard deviation. In order to use MAD as a consistent estimator for the standard deviation, it is divided by a scale factor that depends on the probability distribution of the noise (which is again unknown). For a normal distribution, this scale factor is $\Phi^{-1}(3/4) = 0.6745$, where Φ^{-1} is the inverse of the cumulative distribution function for the standard normal distribution, hence Eq. 2.

A Note on the Undecimated *à trous* Wavelet Transforms

From an engineering and seismological perspective, the easiest way to envisage the decimated/undecimated wavelet transform is in terms of octave digital filters, which are quite common in digital audio. Octave filters form the basis of the wavelet transform, whether the transform is decimated or undecimated. The wavelet transform (Daubechies 1992) comprises in this case well-designed filter banks. The decimated discrete wavelet transform (DWT) is applied in an octave-band filter bank, implementing successive low-pass and high-pass filtering and down-sampling by a factor of 2, so that every second sample is discarded. As an example, a four-channel filter bank scheme is shown in Fig. 2. The filters used in wavelet filter banks are digital finite impulse response (FIR) filters, also called non-recursive filters because the outputs depend only on the inputs and not on previous outputs.

The discrete convolution expression for a FIR filter is given by

$$y(n) = \sum_{k=0}^{N-1} h(k)x(n-k) \quad (3)$$

where $h(k)$ are the filter coefficients and $x(n-k)$ are the time-shifted samples of data. Equation 3 lends itself to the multiply-accumulate data shift

Wavelet Domain Seismic Correction, Fig. 3 The undecimated or stationary wavelet transform (SWT) filter banks, showing the dyadic up-sampling of the filter coefficients, i.e., the pushing of zeros in between the coefficients

Wavelet Domain Seismic Correction, Fig. 4 The *à trous* frequency responses for the Haar wavelet at three levels of decomposition

architecture (MACD) of most modern processing engines.

Therefore, we proceed in octave sub-bands as per Fig. 2, where the filters H and G operate on the data vector x , as follows:

First octave low-frequency sub-band = Hx
Second octave low-frequency sub-band = $H(Hx)$
Third octave low-frequency sub-band = $H(H(Hx))$
First octave higher-frequency sub-band = Gx

Wavelet Domain Seismic Correction, Fig. 5 TCU052NS LFS fling, which shows results before (*red, green*) and after (*blue*) baseline correction; wavelet used is the *bior1.3*

Second octave higher-frequency sub-band = $G(Hx)$

Third octave higher-frequency sub-band = $G(H(Hx))$

The behavior of the filters is to operate on a column vector of data by convoluting the data with the filter coefficients and to down-sample by 2, i.e., discard half the values.

However, there is a problem with the DWT in that due to down-sampling the DWT, it is not shift invariant. Aliasing can occur between the sub-bands, which is undesirable if the application needs de-noising as in this case. Therefore, the easiest way to overcome this is not to down-sample so that the length of the signal remains constant and not as in the decimated DWT, and so we use a generalization of the DWT, which is the undecimated wavelet transform or stationary wavelet transform (SWT), which is shift invariant.

Since we don't decimate, then instead we have to interpolate by pushing zeros into each level of the transform (i.e., between the filter coefficients), i.e., dyadically "up-sampling"; this is the *à trous* algorithm (Shensa 1992) (*trous* = holes). It was also shown that the SWT de-noises with a lower root-mean-square error than that with the standard DWT and de-noising rather than filtering are a key requirement for this application. The *à trous* algorithm imitates the subsampling (decimation) of the filtered signal as shown in Fig. 3, by up-sampling the low-pass and high-pass filters. Their impulse responses (i.e., filter coefficients) are up-sampled versions of the filter coefficients from the previous level. Figure 3 shows the undecimated case for both the analysis and synthesis of filter banks; it should be noted that data remains at the same length, but the filter coefficients are dyadically interpolated. The *à trous* transform is applied as circular convolutions and multiplications with zero elements,

Wavelet Domain Seismic Correction, Fig. 6 TCU052EW low-frequency sub-band fling, which shows results before (red) and after baseline correction (blue). The wavelet used is the *bior1.3*

which can be omitted. The frequency response for the Haar wavelet in Fig. 4 shows how the frequency band is divided by two (50Hz, 25Hz, etc.) after each up-sampling by adding zeros in powers of two. In this particular case, the low-pass filter coefficients are given by:

L1 = [0.7071 0.7071]; j = 1 (Haar/dB1)
L2 = [0 0.7071 0 0.7071 0]; j = 2
L3 = [0 0 0 0.7071 0 0 0 0.7071 0 0 0]; j = 3 etc.

The original Haar coefficients are given in L, and then the zeros are increased as $(2^{J-1} - 1)$, where J is the next level of decomposition.

In the synthesis case, the inverse *à trous* transform averages the estimates at each level again minimizing the noise, so overall the SWT is a better transform to apply.

Time domain filter banks in Fig. 11 show the SWT; there are also the iSWT synthesis filter banks for reconstruction. In the analysis filter

banks, the easiest thing to do is to push zeros (*à trous*) in between the filter coefficients and keep filtering even and odd samples from every band. In the synthesis filter banks, they are averaged at each level. The data of course is also de-noised between the analysis phase and the synthesis phase using the iSWT.

Results

Some Results from the Chi-Chi (1999) Event in Taiwan: Stations TCU052, TCU068, and TCU129

The TCU052NS station from the 1999 Chi-Chi event shows the low-frequency, fling profile time history of Fig. 5, which hides an acceleration tilt transient of 3.015 cm/s/s peak, at 48.45 s. The acceleration transient is recovered by subtracting the corrected and uncorrected “fling” time history. The recovered tilt acceleration transient

Wavelet Domain Seismic Correction, Fig. 7 Recovered tilt $g\theta$ acceleration, velocity, and displacement response of instrument A900 for the TCU052 component

leads to a velocity offset and displacement trend after double-time integration of the transient. These are precisely the error offsets observed in the velocity and displacement time histories after double-time integrating the (almost) sinusoidal acceleration time history of Fig. 5. It is inferred that acceleration transient of 3.015 cm/s/s is in fact a $g\theta$ tilt transient. The area of the acceleration tilt profile is 7.21 cm/s, which is the velocity offset. Similarly, the area under the velocity step is 294.7 cm, the maximum displacement offset as shown in Fig. 5. The corrected displacement is 641 cm, which compares with those of other researchers; the GPS reading is 845 cm. The point to note is that the area of the acceleration transient is exactly equal to the constant velocity offset after integrating the acceleration transient and observed in the velocity sub-band. Then, after integrating the constant velocity offset, then the result matches exactly the linear trend in the displacement before correction. The

TCU052EW low-frequency, fling time histories are shown in Fig. 6. In this case, the acceleration tilt transient occurs at 40.06 s, approximately 8 s earlier than the NS component. The displacement is -352 cm (GPS -342 cm); the instantaneous tilt acceleration $g\theta$, shown in Fig. 7, is 12.96 cm/s/s; and θ , the instantaneous tilt angle, is 13.2 mrad. The area of the acceleration tilt profile is 2.98 cm/s, the velocity offset.

Similarly, the area of the velocity step is 180.7 cm, which is also the maximum displacement offset as shown in Fig. 7, and Fig. 8 shows the resulting, corrected time histories. Moreover, as for the NS component, then on integrating the extracted acceleration transient, it yields the velocity DC shift and displacement offset of the velocity and displacement profile after integrating the acceleration time history as shown in Fig. 8.

Similar results are obtained for TCU068NS in Figs. 9 and 10; using the undecimated wavelet

Wavelet Domain Seismic Correction, Fig. 8 The resultant plots for TCU052EW after the corrected low-frequency sub-bands (LFS) are added to the high-frequency sub-band (HFS)

transform method, the peak instantaneous tilt angles calculated from the peak acceleration transient are calculated as -6.9mrad (-6.75 cm/s^2) (EW) and 9.8mrad (9.57 cm/s^2) (NS), and the resulting dynamic tilt amplitude obtained is 12.09mrad (11.86 cm/s^2). It is these peak acceleration transients, which are inferred as due to instantaneous tilt/rotation angles, that cause the DC shift in velocity in the latter portion of the time history and prevent stable double-time integration. These results are similar to those in (Pillet and Virieux, 2007) using a different method, with which to estimate the tilt angles. The estimates of displacement are shown in Table 1.

Station TCU129, Chi-Chi Event (1999)

Figure 11 shows the low-frequency fling for record TCU129EW after the application of the undecimated wavelet transform, before and after baseline correction. There is clear post-fling

distortion in the acceleration. At 30s (Fig. 12), there is a δ pulse-like jump in the acceleration of $g\theta = -4.8\text{ cm/s/s}$ and so an instantaneous tilt angle $\theta = 4.9\text{mrad}$ s, similar to that discussed for stations TCU052 and TCU068.

However, in addition, there is another set of distortions at 40 s to 55 s. This has led to a series of downward steps in velocity giving rise to a velocity shift of -7.5 cm/s/s from zero. The profile of these changes in the acceleration, in particular at $t > 30\text{ s}$, with a spike at 30s shown in Fig. 12 giving a step in velocity, followed by further velocity steps at $t \geq 40\text{ s}$. Of course there isn't any certitude that these distortions are due to tilts/rotations; there are other effects that could have caused these. However, there is some justification for proposing that these distortions may be due to tilts/rotation. The net permanent displacement is shown in Figs. 11 and 13 as 78.48 cm . The GPS station AF11 at 2.3 km away measured a permanent displacement of

Wavelet Domain Seismic Correction, Fig. 9 TCU068NS low-frequency sub-band fling, which shows results before (*red*) and after (*blue*) baseline correction. The triangular area in the acceleration is the

results of an acceleration transient $g\theta$ at 45.65 s. The resulting constant velocity DC shift of 11.61 cm/s is shown in light gray as a post-shaking, flat velocity time history

Wavelet Domain Seismic Correction, Table 1 Lists of the component acceleration transients and displacements and the time at which the transients occurred at which baseline corrections were applied

Greendale Station			
Component	Tilt acceleration cm/s/s	Time/s	Displacement (cm)
N55W	2.33	26.55	−177.8 (level 10)
S35W	3.44	28.56	−47.85 (level 9)
UP	0.49	27.2	−66.5 (level 10)

approximately 100 cm. The time history profiles for TCU129NS are shown in Fig. 21, and in this case the *bior2.6* wavelet was used at a level 9 of decomposition. At 28.1 s, the low-frequency fling showed an acceleration transient of magnitude $g\theta = 9.93$ cm/s/s, giving a DC shift to the latter part of the velocity time history of 7.65 cm/s. The velocity offset after integration then gave a linear trend with a DC offset of 435 cm at 90s. These sorts of baseline errors make double-time integration impossible without removing the error.

Therefore, the undecimated wavelet algorithm then zeroes out the acceleration from 28.1 s and reintegrates to give the corrected time histories shown in Fig. 14. The GPS displacement for the NS component was −32.1 cm and that obtained using the presented wavelet transform method is −26.8 cm. The TCU129V component is interesting because it suggests either at least 9 more tilts or just a very noisy instrument. However, in Chanerley et al. (2013), there is a suggestion that the location of the instrument (A900) on a

Wavelet Domain Seismic Correction, Fig. 10 Acceleration tilt transient for TCU068NS at 45.65 s. The resulting constant velocity DC shift of 11.61 cm/s is a clear example of a post-shaking, flat velocity time history

concrete pier may have been the cause of the oscillatory ringing. Certainly, there are significant oscillatory effects as can be seen from the time history in Fig. 15.

Nevertheless, the fling pulse in TCU129V is clearly visible both in the acceleration and velocity time history, and we take the zero-velocity cross-over point at 33.97 s immediately after the fling pulse in velocity zeroes the acceleration from that point and reintegrates. The first acceleration transient occurs at 33.97 s, with a magnitude of 2.12 cm/s/s. The displacement shown in Fig. 15 and Fig. 16 is -18.34 cm and that given by GPS is -17.7 cm.

At the time point where the velocity fling pulse crosses the zero axis, the acceleration is zeroed to the end of the record and reintegrated, giving a displacement of -18.34 cm; the GPS reading for that component is -17.7 cm. The acceleration transient, though not explicitly shown, is small

in magnitude (2.12 cm/s/s) compared with that of other components, suggesting its origin may be from instrument noise.

New Zealand M_w 7.1 Darfield Event, 4 September 2010

The Canterbury region on the South Island of New Zealand experienced a magnitude M_w 7.1 earthquake on the 4 September 2010. The epicenter was located about 10 km SE of the town of Darfield and about 40 km west of the city of Christchurch. The seismic event produced a right-lateral, strike-slip surface rupture ≥ 28 km long, approximately west-east. Much damage occurred to residential buildings as well as a lot of liquefaction and lateral spreading. The situation however deteriorated further after a second earthquake of M_w 6.3 hit, damaging the Christchurch city center with considerable loss of life.

Wavelet Domain Seismic Correction, Fig. 11 TCU129EW, low-frequency sub-band fling before (*red*) and after (*blue*) baseline correction showing tilt/rotation in acceleration and baseline DC shift in velocity

The fling pulse for N55W is presented in Fig. 17, and the acceleration transient and displacement results are given in Table 1 for all components from the Darfield earthquake as recorded on a 14-bit CUSP-3B Avery et al. (2004) at the Greendale station, using the wavelet transform method. More displacement results obtained using the wavelet transform method are in Chanerley and Alexander (2010), Chanerley et al. (2013), and Berrill et al. (2011). The horizontal displacements give a resultant of 183.6 cm, which compares well with GPS at 189.79 cm (Berrill et al. 2011), 1.6 km away. Table 1 also gives estimates of the tilt acceleration transients taken at the fling zero-velocity time point, at which the correction is applied.

Figure 17 shows the low-frequency, sub-band fling for the N55W component, at level 10 decomposition, and Fig. 18 shows the net acceleration, velocity, and displacement after correction, as well as the individual higher-frequency components. Table 1 also demonstrates that the vertical acceleration transient is small compared to the two horizontal components, as would be expected (Chanerley and Alexander 2010), and may be a measure of the noise floor. It should be noted that as for the Chi-Chi station TCU068, level 10 decomposition has removed any post-fling perturbations in the fling acceleration and produced an almost sinusoidal time history. The zero-velocity, cross-over time point is taken at time $T_i = 26.55$ s at the end of the fling, at which the correction is applied. The acceleration

Wavelet Domain Seismic Correction, Fig. 12 Recovered tilt $g\theta$ acceleration, velocity, and displacement response of instrument (A900) for TCU129EW component

transient at that zero-velocity, cross-over point is 2.33 cm/s^2 .

Acceleration Transients for the ICEARRAY After the M_w 6.3 Ölfus Earthquake (29th of May 2008) in the South Iceland Seismic Zone (SISZ)

The ICEARRAY is the first small-aperture strong-motion array in Iceland, which has yielded some really interesting results. The ICEARRAY has been in operation since October 2007 and was installed in the village of Hveragerdi on the western edge of the SISZ (Halldorsson and Sigbjornsson 2009). The final layout of the array comprises 14 ICEARRAY stations with an aperture of approximately 1.9 km and an inter-

element distance of 50 m (Halldorsson et al. 2009; Halldorsson and Avery 2009).

The recording system at each ICEARRAY station consists of a CUSP-3C1p strong-motion accelerograph unit manufactured by Canterbury University Seismic Project in New Zealand, for the Canterbury Network in New Zealand. The units are equipped with 24-bit, triaxial, low-noise ($\sim 70 \mu\text{g rms}$) microelectromechanical (MEM) accelerometers with a high maximum range ($\pm 2.5 \text{ g}$) and a wide-frequency passband (0-80Hz at 200 Hz sampling frequency).

The ICEARRAY yielded a useful set of data from the 11 CUSP stations, and the 33 component results for the displacements using the wavelet transform were compiled in May 2009

Wavelet Domain Seismic Correction, Fig. 13 Low-frequency sub-bands (*red*), high-frequency sub-bands (*black*), corrected (*blue*) using *bior1.3* for TCU129EW component obtained at level 9

(Rupakhety et al. 2010). We present some time series plots for the purpose of demonstrating the wavelet transform method for obtaining displacement estimates as well as the inferred tilt acceleration transients. Also included are the horizontal displacements obtained using the wavelet transform method in Table 2, which lists the NS and EW permanent displacements obtained for the 11 CUSP stations. A comparison of the displacement is given in Table 3 for station IS609, showing a resultant of 16.81 cm NW using the wavelet transform method, which gives reasonable correlation with a GPS station 1.6 km away at 17 cm NW, operated by the Icelandic Meteorological Office.

Figure 19 shows the corrected acceleration, velocity, and displacement for station IS604 EW as an example. The decomposition level is 7 with

only one threshold iteration and in this case using *bior1.3*. This is a somewhat lower decomposition level than the previous, probably due to a lower-magnitude earthquake compared, for example, to that of the Chi-Chi event. Level 7 produced a clear fling from which the zero-velocity, cross-over time point, $T_i = 20.21$ s, is used to remove the acceleration transient at $t \geq T_i$ and reintegrate the fling, sub-band acceleration to give a sub-band velocity without a DC shift and a displacement without any linear/quadratic errors as shown in Fig. 20. The acceleration transient is taken at the fling at $T_i = 20.21$ s and has a value of 18.6 cm/s^2 . As for the Chi-Chi events above, the higher-frequency sub-bands didn't require baseline correction and double-time integrated normally. Level 7 includes a band of frequencies up to 0.78 Hz, higher than for Chi-Chi TCU068, for

Wavelet Domain Seismic Correction, Fig. 14 Low-frequency sub-bands (*red*), high-frequency sub-bands (*black*), corrected (*blue*) using *bior2.6* for TCU129NS component obtained at level 9

example, but then the displacements are much smaller.

Other stations for the EW component give similar results all at level 7 decomposition, and all time points, T_i , were measured at the optimal fling, and all acceleration transients were removed at that point. This gave some consistency in analysis. The focus here is on the acceleration transient at the low-frequency fling, since it is from there that the correction for baseline shift is applied and the permanent displacement obtained. Table 2 gives the complete list of acceleration transients obtained from each of the ICEARRAY stations. Table 2 shows that the EW components have the largest initial acceleration transients, though most stations had several velocity zero-crossings.

The EW component of most stations had several zero-crossing points at level 7 with smaller acceleration transients further along the time

history in much the same way as station IS604. Therefore, any one of those could have been used by the algorithm which also gave sensible displacement values. However, following Graizer (2005), a clear-cut fling profile of the velocity pulse is used by the algorithm at which time point the acceleration transient removed. The results also show that the acceleration transients and their T_i times correlate well for each component for each station, but that the NS transients are much lower in magnitude and similar to those of the vertical component and so can be attributed to noise. The much larger acceleration transients for the EW component may be indicative of tilts/rotations.

The results are consistent with the fact that the aperture of the ICEARRAY is, as mentioned, small at 1.9 km; therefore, perhaps it is right to expect some degree of correlation from such a close-knit array of sensors. This consistency in

Wavelet Domain Seismic Correction, Fig. 15 Low-frequency sub-band (red, before correction), LFS (blue, after correction) of the vertical component TCU129V

results does lend some weight to the fact that certainly in the EW component, these transient accelerations may be due to tilts/rotations.

Some Permanent Displacement and Tilt Estimate Summaries

The results show some consistency in the occurrence of the acceleration transients in TCU129 and the other events displayed in Table 4. Generally, the horizontal component “tilt” acceleration transients are larger than that of the vertical component; in particular, that for TCU129NS, TCU068NS, and TCU102N are very much larger suggesting strong ground rotation.

However, it could also be argued that the component TCU129EW is too close in magnitude to that of the vertical and therefore could be attributed to noise. The results for TCU052 exhibit a large acceleration transient or “spike” for the

TCU052EW component (suggesting ground rotation), but demonstrate small acceleration transients for the TCU052NS and TCU052V, suggesting these are just noise. The disparity in the times of occurrence of the acceleration transients, for each component, also suggests that instrument noise plays a part. The results in Table 4 for TCU068 and TCU102 are consistent with predicted behavior, where the vertical components are either not responding to tilts or responding to small amounts of noise, while the horizontal components are responding to ground rotations, given their large magnitudes. In all cases for the above events, the estimates of residual displacements show good correlation with those from GPS.

The collated results in Tables 5, 6, and 7 show that the wavelet transform method (Boore and Bommer 2005; Boore 2001) produces a good

Wavelet Domain Seismic Correction, Fig. 16 LFS (red), HFS (black), corrected (blue) for TCU129V

estimate of residual ground displacements and estimates of the baseline error in the form of δ -like acceleration transients (“spikes”) caused by ground rotations. There are many more results from events in New Zealand (Berrill et al. 2011), Iceland, and Taiwan in the literature published by the author and listed in the references.

Results from the Nepal 2015 event recorded at Lamjung Station 2015 06:11:26 UTC

The recent 25 April 2015 event in Nepal occurred at a depth of approximately 15 km, with the Indian plate pushing under the Eurasian plate, the result of thrust faulting on or near the main thrust interface between the subduction of the Indian plate and the Eurasian plate to the north. The earthquake activity in Nepal is caused by the

ongoing continental collision between India and Asia, which formed the Himalayan Mountains and the Tibetan Plateau. At the location of this earthquake, the Indian plate is converging with Eurasia at a rate of 45 mm/year, toward the north-northeast, driving the uplift of the Himalayas and the Tibetan Plateau. The earthquake was damaging in this case because the capital Kathmandu is located in a basin filled with soft sediment. These basins of sediment exert a large effect on the ground motion above, because they amplify the amplitude of the earthquake wave above as the wave slows down at the rock–sediment interface.

The results presented are from the Lamjung Station in Lamjung, Nepal, which lies about 180 km from Kathmandu and approximately 31 km ESE from the epicenter. The results show some consistency with radar measurements (Fig. 21) from NASA/USGS and from the results obtained by Professor Roger Bilham from the University of Boulder, Colorado, who predicted such an

Wavelet Domain Seismic Correction, Fig. 17 N55W component time series, *bior1.3* wavelet, at decomposition level 10, showing low-frequency fling with an (*tilt*)

acceleration transient of 2.33 cm/s/s at 26.55 s giving a velocity DC shift of -0.5 cm/s and a displacement offset of 25.8 cm. Instrument is CUSP 3B

event in the 1990s (Bilham 1994; Bilham et al. 1995).

The results of using the wavelet transform method are shown in Figs. 22, 23, and 24.

Professor Roger Bilham describes from Kathmandu that “the rupture front travelled 90 km from the epicentre at 2.5 km/s towards Kathmandu, arriving at the western outskirts of the valley 35 s after the mainshock. There it slowed to 1 km/s as it ruptured 10 km beneath Kathmandu eastwards. Strong motion data and GPS high rate sampled data (5 Hz) in the Kathmandu Valley indicate that in less than 5 s the city was heaved upwards by 60 cm, and to the SSW by 1.5 m, at velocities of up to 50 cm/s.” The Lamjung station results, using the wavelet transform

method (Chanerley and Alexander 2010; Chanerley et al. 2013), are largely vindicated by Professor Bilham’s findings. The Lamjung station vertical results from the USGS raw data are as Professor Bilham describes; the graphs below show that indeed for the Lamjung station UP profiles, from the start of the fling step at 40 s, the displacement upward is 60.07 cm at 45.5 s and continues to then leave a residual displacement of 1.44 m up at the end of the fling step, which is consistent with information from NASA/USGS that radar shows an uplift of 1.5 cm. The maximum velocity of 55.36 cm/s for Lamjung station UP is consistent with the velocity as stated of 50 cm/s, and the maximum fling velocity is 23.16 cm/s, the latter giving rise to the

Wavelet Domain Seismic Correction, Fig. 18 GDLC (N55W) results for first and second integration of superimposed “fling” component (red), higher-frequency component (black), and resultant sum of low-frequency fling and higher-frequency component (blue). Permanent displacement shows -177.8 cm

Wavelet Domain Seismic Correction, Fig. 21 Radar shows Kathmandu area uplifted 5 ft by the Gorkha, Nepal, Earthquake (Courtesy of NASA/USGS)

Wavelet Domain Seismic Correction,
Fig. 22 LAMJUNG STATION 90: (a) *Top trace*: acceleration fling pulse (red), max 50.44 cm/s/s, overlaid with the high-frequency signal (b) *Middle trace*: velocity fling pulse, max velocity -72.86 cm/s, overlaid with the high-

frequency signal (c) *Bottom trace*: fling step with a residual displacement of -1.61 m, overlaid with the high-frequency signal. The analyzing wavelet is the *bior1.3* at level 9

fling step. The horizontal displacement shows a shift south by approximately 1.6 m.

This recent event in Nepal demonstrates the utility of the wavelet transform method as published by Chanerley and Alexander (2010) and Chanerley et al. (2013). The method recovers the residual displacements with a good degree of accuracy, but moreover, the method recovers the fling pulse(s) and the fling step.

Summary

In this entry, some of the state-of-the-art techniques for mitigating noise/error in accelerogram time series have been reviewed. Older analogue accelerographs clearly present a greater challenge due to their design. Nevertheless, this legacy

recording is still an important source for structural and geotechnical earthquake engineering designers/analysts. Modern, digital accelerographs are a great improvement in many ways as they correct design problems of earlier instruments such as higher dynamic range, higher sampling rate, automatic digitization and triggering, flat instrument response down to DC, etc. However, the problem of ground rotation (tilt) noise corruption of low-frequency components of accelerograms is still present, because all strong-motion instruments are 3 (translational)-axis instruments rather than full 6-axis instruments. This may be partially due to the cost of designing and building a 6-axis instrument, but it is also the case that rotation accelerometers (such as gyroscopic transducers) currently may have lower performance specifications than translational ones.

Wavelet Domain Seismic Correction, Fig. 23 LAMJUNG STATION 360°: (a) *Top trace*: acceleration fling pulse (red), max 7.768 cm/s/s, overlaid with the high-frequency signal (b) *Middle trace*: velocity fling pulse, max value 28.15 cm/s, overlaid with the

high-frequency signal (c) *Bottom trace*: displacement fling step, with max displacement -227 cm, residual displacement -163 cm, overlaid with the high-frequency signal. The analyzing wavelet is *bior1.3* at level 10

One solution may be to use multiple 3-axis instruments spaced on a rigid structure such that differences in translational accelerometers (in different instruments) can be used to obtain rotational acceleration estimates. This is often done on bridges for evaluating torsional (rotation) deck modes and could also be applied to ground motion. In this case, the classical 3-axis instrument is not redesigned; however, it would have to be strategically positioned in situ very close to other 3-axis instruments. Another solution may be to have 2 sets of 3-axis sensors in one instrument, with one set fixed and the other on a 6DOF platform with the difference in the time series

giving an estimate of the rotational ground motion.

Nevertheless, it is clear that modern, state-of-the-art signal processing techniques such as the undecimated wavelet transform and de-noising algorithm presented have been applied to a range of seismic events and facilitate meaningful double-time integration and recover the fling pulse, the displacement fling step, and to some extent the rotational (tilt) acceleration transients that are generated by ground rotations. This goes some way toward the recovery of credible ground motion velocity and displacement time series and therefore better-quality boundary conditions in the design of structural artifacts.

Wavelet Domain Seismic Correction, Fig. 24 LAMJUNG STATION-UP: (a) Top trace: acceleration fling pulse (red), max 5.64 cm/s/s, overlaid with the high-frequency signal (b) Middle trace: velocity fling pulse, max value 23.16 cm/s, overlaid with the

high-frequency signal whose max value is 55.36 cm/s (c) Bottom trace: displacement fling step, with residual displacement 144.4 cm, overlaid with the high-frequency signal. The analyzing wavelet is *bior1.3* at level 10
